Drag marks are caused when a tumbler is under so much tension that it cannot smoothly glide out of its depression as the blank is withdrawn. Consequently, it ploughs a deep pathway from its cut to the tip of the blank. Drag marks are the chief cause of impressioning failure because they lower the overall level of the bitting surface. Tumblers that were already at shear line will become too low and start digging again.

30_12.2.1.8 Duplication of Original Lead Key

Duplicate the key on a regular blank, taking care not to exert excessive pressure with the key guide. Rough cut the key first and then slide the guide gently over the lead a second time. The guide should now leave a steady unbroken "shine line" across the lead.

30_12.2.2 Elastic Tape Impressioning System

Bates and others have developed impressioning systems utilizing plastic tape with special blanks to open dimple-style locks. The keys will not work in damaged or non-functioning mechanisms.

Plastic tape is another form of pressure-sensitive material and will deform based upon tumbler pressure. Unlike metal foil, plastic tape will not **retain** depressions for more than a few minutes once the key is produced. It does not have the same resolution as metal. It is also difficult to decode the depth of impressions with this material.

In practice, a specially milled blank selected for a particular

keyway is covered with a thin layer of tape prior to insertion. Milling of the bitting area is required in order that the tape might clear the keyway wards. Holes have been predrilled in each of the tumbler positions that slightly exceed the maximum depth-cut.

This form of impressioning follows the same procedure as used with metal foil: apply torque, lift in each of four planes, release torque, and repeat the cycle until the plug turns. No filing is required. Generally, the procedure will result in an opening in about five minutes.

30_12.2.3 Foil Impressioning Systems

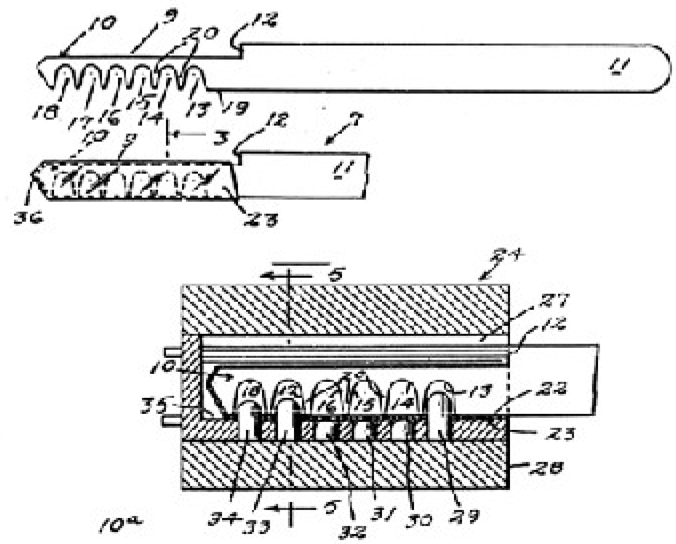
Falle and others have introduced impressioning systems based upon the use of thin metal foil rather than blank keys. Whereas in conventional impressioning metal bitting is removed with a file, in these systems the foil is depressed or altered in each tumbler position. The depth of the depression will be in direct correlation to the action of those tumblers that are not at shear line. No filing is necessary.

These systems can produce keys for five or six-pin standard mechanisms, and up to sixteen-pin dimple locks within one minute, without the necessity of filing a blank key. The use of foil is silent and generally defies detection. Often, the resulting foil impressions can be decoded and reproduced on a metal blank. Foil systems graphically demonstrate the fundamental theory of impressioning described throughout this chapter. **The forced interaction of active locking components** (pins, levers, wafers) **and a bitting surface** (key blank or similar device) **will displace material equal to the vertical movement of that bitting surface**.

30_12.2.3.1 Falle Impressioning Systems

Falle has refined the use of foil to impression dimple and conventional pin tumbler locks using a process originally patented by Martin (**4400956(299)** and **4817406(300)**). John Falle has introduced two pressure-responsive impressioning systems. These are designed to replace conventional brass key blanks to open specific dimple and standard pin tumbler locks. In addition, a plasticine system is available for lever locks.

For pin tumbler locks, special **comb carriers** and tension tools are available for each keyway. The Comb Carrier system utilizes a series of .4 mm stainless steel combs designed for specific



profiles. The carrier is covered with 30-micron self-adhesive foil and is inserted into the lock. Tension is applied to the plug, using a specially designed torque wrench. The comb is moved up and down, causing the foil to depress corresponding to the individual pin depths, until all tumblers reach shear line. The lock can then be opened and the comb decoded so that a key can be produced. See **LSS+/^{x} CD/ROM** for a demonstration of this technique.

The **lever lock system** utilizes plasticine in combination with a specially prepared blank. Keys cut for individual lever positions used in combination with a variable key generation system allow the production of a key based upon the information derived from the plasticine imprint. This system is described both in this chapter and in Chapter 31.

In the original Falle system, a **die** exactly the shape of a blank key, was precisely drilled to match the positions of the pins within a dimple lock. Because many manufacturers alter the placement of pin chambers to increase the number of differs, use of this tool requires information about the lock and its configuration prior to impressioning. Because of the uniqueness and utility of each of these systems and their use by the law enforcement, intelligence, and professional locksmith communities, they are described in detail here. They are the most effective way of opening pin tumbler cylinders and producing keys for them. If the fundamentals of impressioning described in this chapter are mastered, proficiency in the use of these tools can be quickly achieved.

30_12.2.3.2 Profile Comb Carrier System

The comb and foil system was first patented and introduced by Martin in 1981. It was never commercially feasible. Falle perfected the system in 1996, using etched stainless steel to create an impressioning tool fashioned in the shape of a multipronged comb. Each segment of the comb corresponds to the position of a chamber and its pin-stack within the plug of a pin tumbler lock.

30_12.2.3.2.1 Components of the System and Design Characteristics

The comb system is provided with all of the necessary equipment to open one particular type of lock. The components include:

- **Quantity of aluminum foil (30 or 40 micron thickness);**
- **Hobby knife to trim the foil;**
- **Foil combs for five and six-pin tumbler locks;**
- **Different tension bars and spacers;**
- **Insertion and extraction tools.**

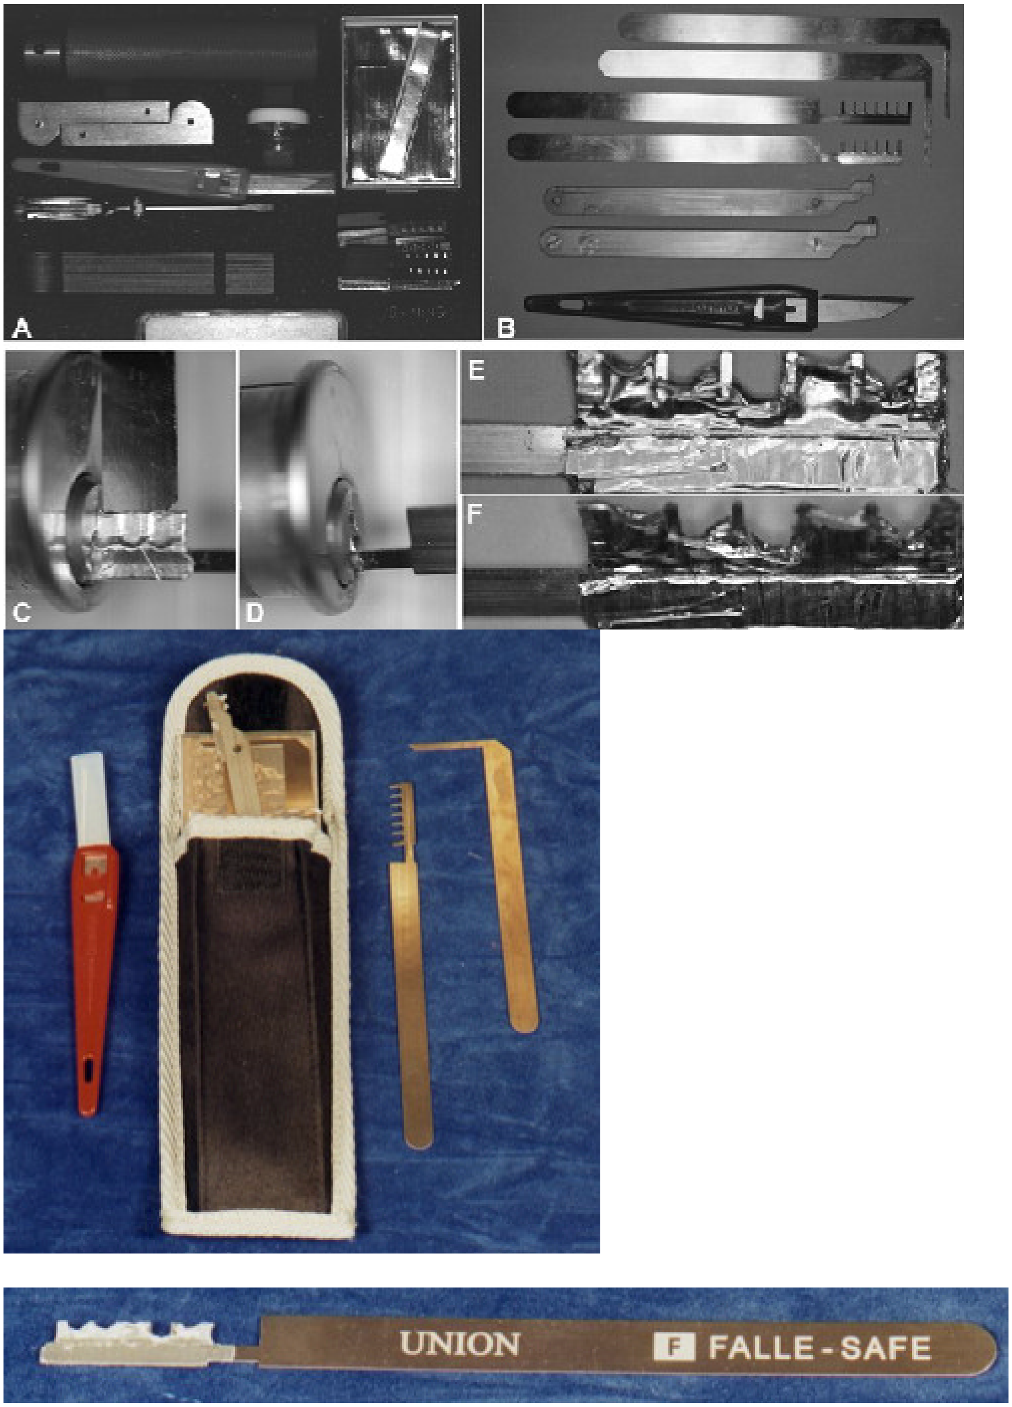


Figure LSS+3004 The Falle foil system for pin locks. Courtesy of John Falle. The completed key is a foil impression of the tumblers and simulates the original.

Profile Comb Carrier: Each foil comb is fabricated from .4 mm

chemically etched stainless steel and is created to fit a particular keyway. Depending upon the cylinder profile, two foil combs may be supplied that accommodate different ward patterns for five and six-pin configurations.

The design of the carrier provides for the creation of a channel between two vertical members (teeth) for each chamber. When these channels are covered with foil, a solid surface is presented to each pin-stack. This replicates a blank key. During impressioning, the foil is actually depressed within each of these channels, corresponding to the position of each pin.

A **tension channel** to allow for vertical movement of the carrier has been created in the same location as the shoulder on a traditional key. This channel provides clearance to elevate the tool when it is used in conjunction with the special tension wrench. It is the mechanism by which the foil is displaced during the impressioning process.

Tension Tool: Most systems are supplied with one assembled tension wrench and one extra tension bar. These allow the assembly of the tool to provide for the application of torque from either side of the keyway. This design provides flexibility as to the orientation and position of the tool and is critical when there is no clearance to one side of a door.

The tension wrench is actually comprised of two metal bars held into place by spacers. The tips have different widths; one is narrow and one is wide. The narrow portion is inserted at the top of the keyway, while the wider end is indexed to the base of the plug. This design allows the tool to be firmly anchored while impressioning. The extra bar will have a different tip width.

In each case, the lower bar will be identical in design but the width of the upper tip may need to vary depending upon the lock profile. Before attempting an opening, the user should examine the lock and its surroundings and assemble the tension tool accordingly.

Insertion/Extraction Tools: The comb as constructed presents an impassable barrier to each tumbler. It looks much like a key that has been back cut in all pin positions and in both directions. The comb cannot be removed, once the impressioning material has been exposed to the tumblers, and thus the need for the extractor.

The insertion/extraction tool allows the tumblers to be lifted to the top of the keyway in order to clear the comb prongs while the foil carrier is inserted or removed. Two different designs of the tool are supplied: one is angled and one is straight. Each is provided in two lengths for five and six-pin locks. The tool must enter the keyway to one side of the foil carrier.

30_12.2.3.2.2 Producing a Simulated Key

There are four fundamental differences between the Falle foil system and conventional impressioning:

- **A simulated key is produced automatically;**
- **Torque is not applied directly through the blank key but indirectly through a separate torque wrench;**
- **The foil carrier can be reused;**
- **The skill level required to impression is minimal.**

There are four steps to successful impressioning utilizing this system: **carrier preparation**, **insertion**, **movement**, and **extraction**.

30_12.2.3.2.2.1 Carrier Preparation

The carrier must be prepared for insertion into the keyway by covering all of the individual teeth with self-adhesive foil. A strip measuring approximately two square inches (2-2.5 cm) is cut. The backing is removed and the comb is placed onto the lower half of the foil. Then the remainder is folded over itself in order to fully enclose the teeth.

Verify that the foil is pressed firmly against the comb so that each side bonds with the other. It is very important to ensure that a solid mass of foil is created and presented to the base of the tumblers during impressioning. The foil should be trimmed as shown and depressed into each area between the teeth. Be certain that the material is removed from around the tension channel to allow for unrestricted movement. Avoid creases and bubbles that may cause tearing during insertion of the tool and result in a failed procedure.

30_12.2.3.2.2.2 Tool Insertion

Insertion of the carrier must be accomplished carefully so as not to damage the fragile foil covering. A normal key presents a 45°

angle that allows the pins to smoothly traverse the ramps. In contrast, the teeth of the comb present a **perpendicular** angle to the face of the tumblers. Thus, they must be lifted out of the way in order for the tool to enter and leave the keyway.

The procedure to insert the carrier requires the following operations:

- **Place the correct insertion tool into the lock underneath the pins. The angled point should engage the bottoms of the tumblers;**
- **Lift the insertion tool to the top of the keyway, thereby forcing the pins upwards and clearing a path for the carrier. Once this is accomplished, no pins will protrude into the plug, thus providing a clear path for insertion of the carrier;**
- **While maintaining the pins in a fully lifted position, carefully insert the prepared foil comb into the lock alongside the insertion tool. Although generally it is easier to locate the comb to the right of the tool, its placement is dependent upon the position of wards. Never force the carrier into the keyway as this will cause the foil to tear;**
- **Continue to insert the foil comb into the lock until it is about 5 mm short of the rear stop, or at the front edge of the tension channel;**
- **Remove the insertion tool;**
- **Insert the tension tool into the keyway, so that it is secure against the face of the cylinder;**
- **Push the carrier into the lock until the rear stop contacts the back of the tension tool. This is the impressioning position that aligns the channels of the carrier directly beneath the pins.**

30_12.2.3.2.2.3 Movement of the Carrier

Movement of the carrier closely resembles the actions required of

a key blank in conventional impressioning; the foil carrier is moved in four vertical planes. Unlike a key blank, however, a separate tension tool is utilized to create torque. The following operations must be performed to obtain proper contact between the foil and tumblers:

- **Press the tension tool against the face of the lock, and the foil carrier against the back of the tension tool;**
- **Apply and maintain clockwise torque to the plug;**
- **Lift the rear of the carrier upwards towards the top of the cylinder so that contact is made between the foil and those pins closer to the front of the plug;**
- **Lower the foil comb back to its original position;**
- **Release the applied torque;**
- **Execute five repetitions of the above procedure, being certain to release the torque after each vertical movement, and return the foil carrier to its home position;**
- **Repeat the above procedure, changing the direction of lift away from the pins (downward) and forcing the tip of the carrier to lift upward, thus insuring that all pins are contacted;**
- **Repeat the above procedure, applying torque in a counterclockwise direction for both upward and downward movement of the carrier;**
- **Continue to repeat this entire sequence until the lock opens;**
- **Remove the tension tool by bending the foil comb away from it until there is sufficient clearance to disengage it from the keyway.**

Twenty different movements of the carrier will have been accomplished:

- **Clockwise and upward movements**
- **Clockwise and downward movements**
- **Counterclockwise and upward movements**
- **Counterclockwise and downward movements**

30_12.2.3.2.2.4 Mushroom Tumblers

Mushroom tumblers can cause excessive depressions in the foil, resulting in the failure to produce an opening. The presence of security pins requires a different technique for the application of vertical lift of the carrier, as well as placement of the foil.

When a mushroom driver crosses the shear line, the plug will turn to a substantially greater angle than from a standard driver. This is because of the smaller diameter head or gap at the tip of the pin. The problem can generally be traced to excessive vertical travel of the comb. If after three minutes of repeated movement of the foil carrier the lock still fails to open, it is very likely that one or more of the pins has over impressed the foil. Generally, this results from the presence of spool or mushroom pins, or from new pins.

There are two methods to prevent over-impressioning:

- **Technique I**

Attempt to impression the lock again, insuring that the carrier is **not** lifted to the maximum distance permitted by the keyway. Most foil carriers are produced to a width that is approximately .4 mm shorter than the height of the keyway, thus allowing a corresponding .4 mm vertical movement. Based upon the tolerance of some locks, this distance may be too great and will exceed the plug-shell gap. In such a case, depressions will be created in the foil for each sample that is too deep. They will result in a tumbler setting above or below shear line, but never precisely **at** shear line.

Move the foil carrier less than the maximum distance. This will cause a shallower depression to be produced for each pin and will provide a greater opportunity to match the depression depth with the precise position at shear line. The problem of over-impressioning is complicated by the fact that the center pins will always receive less movement than the pins in the tip and bow positions. Thus, it is more likely that pins at either end of the carrier will over-impress.

- **Technique II**

This procedure involves a different method of applying the foil to the carrier in order to reduce vertical movement by increasing its overall width. Place the comb at the top of the strip of foil so that the excess material rests at the base of the

channels. The foil is wrapped around the underside of the comb, over the top and around the bottom for a second time. This effectively places one layer of foil over the teeth, and two additional layers around the underside (which is usually free of foil). The result of this action will elevate the "home position" of the comb. It will rest slightly higher within the keyway and thus reduce its vertical travel. This will create smaller depressions for each sample.

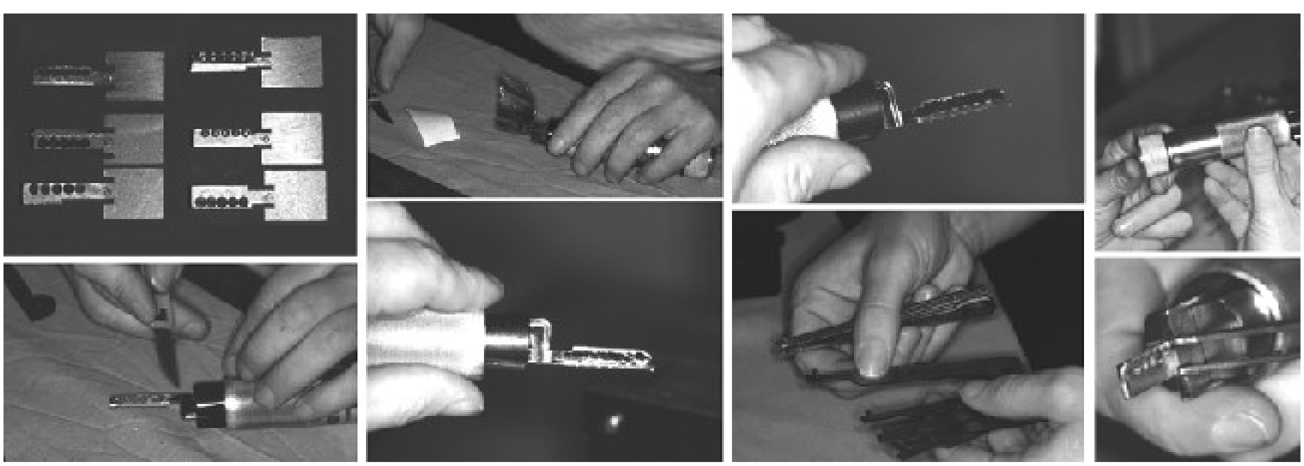
30_12.2.3.2.2.5 Extraction

Once the lock has been impressioned, the tool must be removed. Because the pins are trapped within the channels of the carrier, the extraction tool must be utilized to lift the tumblers above the teeth of the comb. This is achieved by the reintroduction of the insertion/extraction tool to the same position at the top of the keyway that was required when the carrier was first placed in the lock. With caution, minimal damage will occur to the shape that the foil had assumed in simulating the correct key. This will enable the user to identify an approximate pin-stack combination and code. Careless movement of the insertion/extraction tool will result in distortion and tearing of the foil, making decoding of the key impossible.

The use of a particular extraction tool and whether it is inserted to the right or left of the carrier is dependent upon the design of the keyway. Some keyways, such as the Yale 8, require a straight tool first be inserted into the keyway to the right of the foil carrier, just above the lower ward. This will partially lift the pins so that the angled extraction tool can be inserted on the left. The use of two extraction tools is only necessary with complex profiles. It occurs where the pins can fall beyond the wards where the normal tool would set, effectively preventing reintroduction. Grease or Vaseline may be rubbed onto the foil to facilitate smoother insertion and extraction from the lock.

30_12.2.3.2.2.6 Difficulties and Precautions

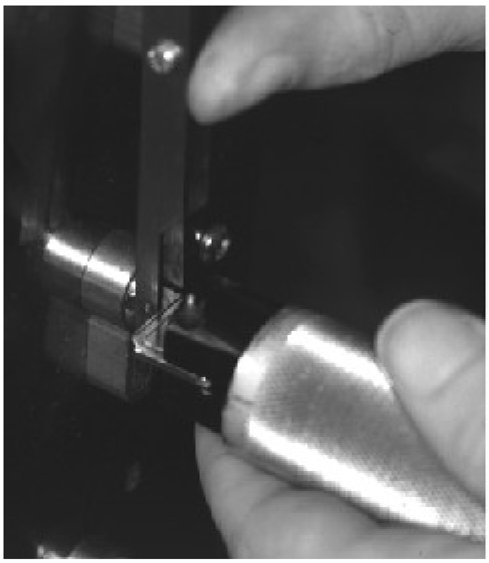
Certain locks may present unique difficulties when impressioning with foil. Others may not respond to the procedure at all. For example, locks that have high cuts at the tip and bow position, with low cuts in the center, are unfavorable to this technique. Difficulty may be experienced with older locks that tend to have vertically elongated keyways at the front of the cylinder. They will over-impress the foil due to excessive movement of the



carrier. When this problem is suspected, limit the vertical travel of the comb.

Never apply excessive torque to the plug. Remember that soft metal foil rather than a hard key blank is being utilized. Only the slightest amount of tension is necessary. Too much torque will result in damage to the tension tool or the face of the lock. Never force the tool or apply excessive tension directly to the carrier. Failure to release torque between each movement and to return the foil carrier to its home position will delay or prevent success. The repetition of movements **without releasing torque** will not allow the pins to seat into the newly created depression within each foil chamber, thus preventing further impressioning.

30_12.2.3.3 Falle Precision-Die Foil Impressioning Systems

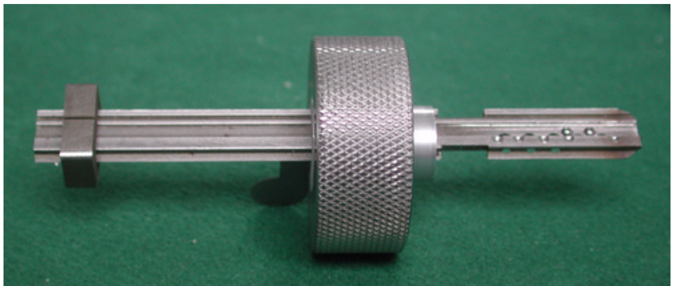


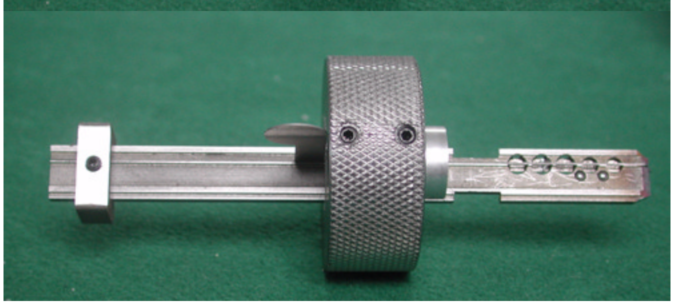
LSS301: Foil impressioning system, by John Falle

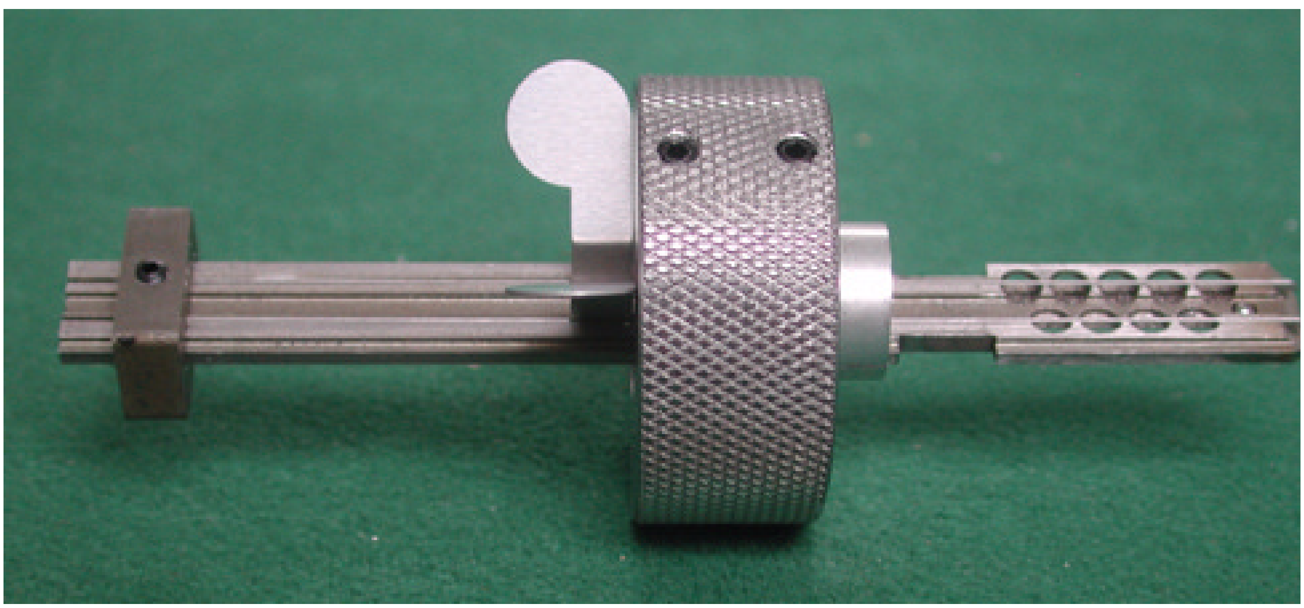
The original foil impressioning system that was developed by Falle was designed for specific dimple pin tumbler locks. It functions in almost identical fashion to the profile carrier system described above. The difference is that a specific steel **foil carrier** die must be prepared for each type of lock. The die has holes drilled to maximum depth in all tumbler positions. Falle offers **foil impressioning systems** and **variable key generation systems** for many dimple locks including Keso, **DOM, UCEM, MCM, and Azbe**. The reuseable key generation systems allow the decoding of the lock and the production of a simulated key using etched stainless steel. This process is described elsewhere in this text.

Exploded view 1, 2, 3, 4, 5, 6.

The design of the die, once covered with foil, allows each tumbler to displace the metal until the pin reaches shear line. A special tension tool must be utilized for this technique. Proper use of the tool allows the required vertical movement of the die.



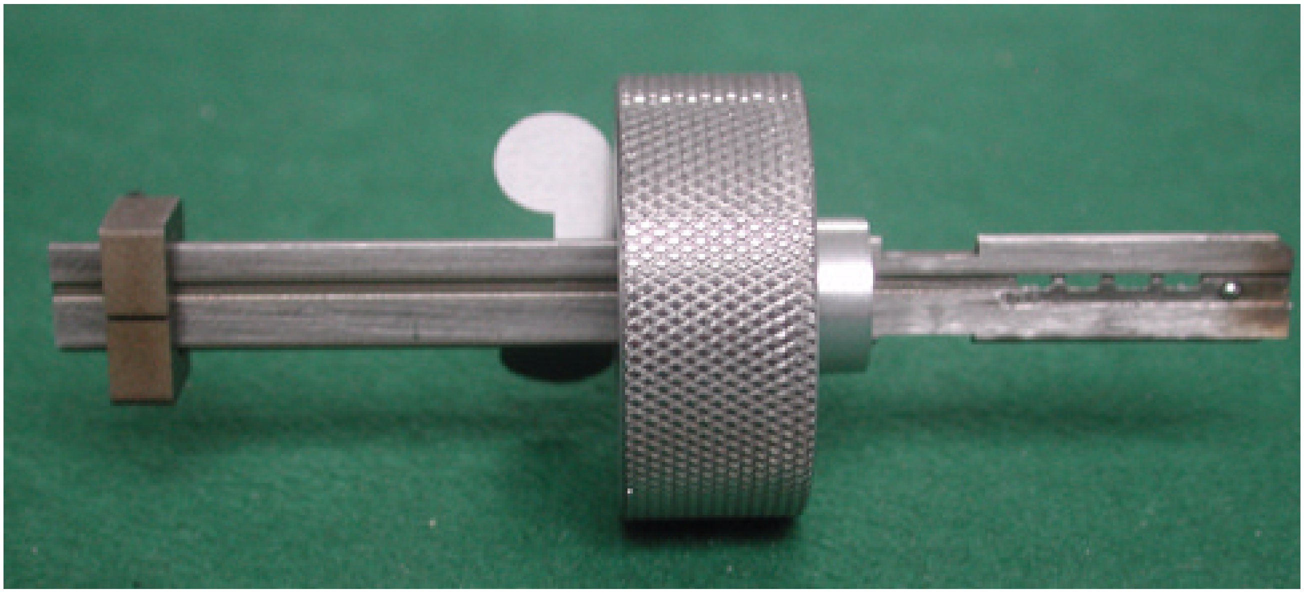


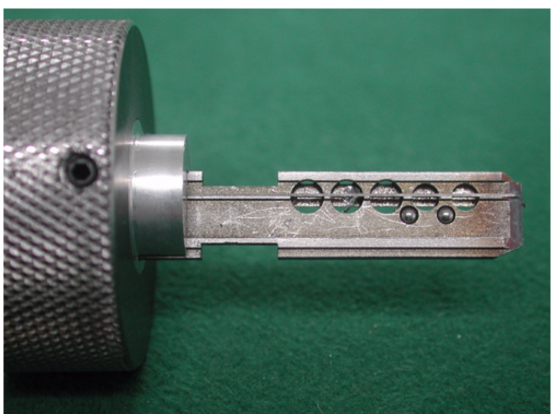


Since the second edition of ***Locks, Safes, and Security*** was published, John Falle has introduced a significantly improved foil impressioning system, shown below. The Dimple Foil Key technology contains many sub-separate systems that are designed

for use on a wide range of dimple key locks. The system allows entry rapidly, often within sixty seconds, with minimum skill level. The lock can be opened, and decoded to within a close proximity of the key, to allow generation off-site. There are certain locks that cannot be bypassed with this system.

LSS304: DOM Dimple foil impressioning system, by John Falle





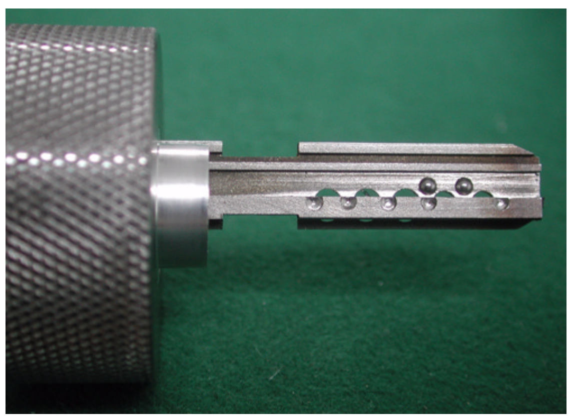


Figure LSS+3005 The carrier for the foil impressioning system, by John Falle.

Although the basic system is quite easy to learn, it is suggested that training from John Falle be required for any agency utilizing this system. In certain cases, locks can have lock-out or detector systems. Once triggered, the covert operation can be compromised by preventing the tool from being removed.

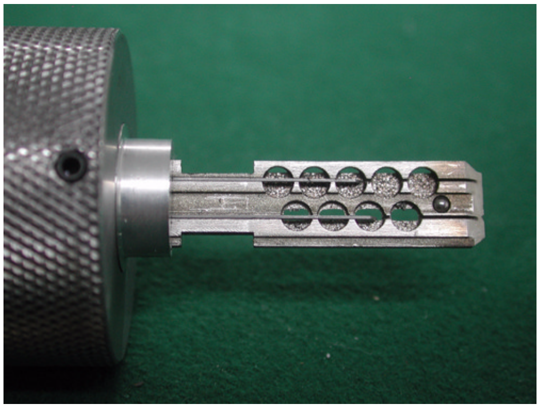

Figure LSS+3006 Specific dies are available for each lock. Note the fine wires extending through each tumbler position.

The system presently is available for use on the following locks:

STS / DOM IX (10 pin staggered);
DOM (10 Pin staggered) with ball;
DOM IX (5 pin) with ball;
MCM 10;
MCM 4SS;
AZBE HS3;
UCEM 5D;
UCEM 8D;
KESO 2000;
KESO 1000;
TESA T10 & T12;
LINCE 19D;
EZCURRA DS10 & DS15 (10 pin).

30_12.2.3.4 Falle Plasticine System

Falle has developed a plasticine impressioning and decoding system for lever locks. A collection of several different keys is provided within a kit, each of which is cut to lift one lever within the lever pack. In this manner, the lock may be decoded (see Chapter 31). A specially cut blank is also provided and upon which plasticine is overlaid. Once coated with the material, the blank is inserted into the lock and turned against the levers. The depth of each belly is defined as an impression, allowing a key to be generated.

30_12.2.3.5 Conductive Material Impressioning System

The author received a patent in 1994 for a conductive resistor impressioning system for use with Ving pin tumbler card locks (5355701(301)). This system relies upon the use of etched conductive ink, superimposed upon a thin mylar plastic base. Claims in the patent also provided for the use of carbon paper in conjunction with a fine wire rake (.020” diameter) to determine the position and pressure of each tumbler. The carbon paper enters the lock between two protective thin metal layers to prevent marking of the paper upon insertion and removal.

The top protective layer is then withdrawn and a thin wire rake moved across each row of tumblers. Those pins that present hard pressure will mark the carbon paper. The protective layer is then reinserted and the carbon paper removed. When held up to the light, the exact outline of the key is displayed.

30_13.0 Practice Locks

Virtually any lock can be used to learn impressioning, even high-security mechanisms with security tumblers (pin tumbler locks) or false gates (lever locks). In the case of pin tumbler locks, the author suggests good quality, consumer five-pin cylinders or four-pin Master padlocks. The Schlage 923 series is ideal for impressioning.

Be certain to obtain a sufficient number of brass key blanks, and have available the depth and space coding data for the lock that is to be used. Have the key that actually opens the lock visible during impressioning in order to provide feedback as to where the marks should be located and the depth of each cut.

It is recommended that impressioning be practiced in the same fashion as picking, which is described in **Chapter 29**. A lock should be initially impressioned with only two pins. Once the ability to discern marking on the key blade is mastered with only two pin stacks, then another is added, until the entire complement can be decoded.

31_1.1 Introduction

There are three primary means to open a lock covertly: picking, impressioning and decoding. The main reason to decode a lock is to enable the production of a change or master key for immediate or subsequent use. If a forensic examination is being conducted, then the components may be decoded in order to determine, for example, cross-keying combinations, the actual code or codes of the tumblers, and whether additional components have been added. This chapter will detail the various techniques for deriving code information from the basic types of locking mechanisms discussed throughout this text.

Decoding may involve several disciplines and is often done in conjunction with picking and impressioning. There are many systems, tools, and procedures available. Their selection and use will depend upon the kind of locking mechanism and how the active locking components interact. Decoding generally does not require disassembly of the target lock, although in some cases the lock may be picked then taken apart in order to derive the needed information. In certain instances, viewing active locking elements using an otoscope or borescope can produce keys. Depending upon the lock, impressioning may first be required, then the impressioned key is decoded.

As will be described subsequently, there are many ways to decode a lock in order to produce useable information. Various systems

have been devised to sense the position of each component, and determine its length, distance from shear line, relationship between belly and gate (lever lock), depth, and other factors. The reasons for choosing decoding as the method of entry rather than picking or impressioning are contingent upon many factors. Our discussion begins with an analysis of the motivation to decode a lock and the primary sources from which code data can be derived. The material in this chapter is presented and organized based upon tools, procedures, techniques, and applications involving specific locking mechanisms.

31_1.1.1 Purpose for Decoding

Decoding provides the means to produce a key when the original is not available. The process can take many forms. Often, picking or impressioning must first be accomplished before code information can be derived. In some cases, traditional forms of bypass are not an option, thus making decoding necessary. In certain instances, disassembly of the lock may be required. There are four primary reasons to decode a lock or its key:

- **Production or simulation of a key for immediate use;**
- **Derivation of code information for later production or simulation of a key;**
- **Derivation of information that will allow the determination of code patterns for a given lock system;**
- **Derivation of information that will allow for the production of keys for other than the target lock.**

There are usually two sources for gathering data: **the lock or the key may be decoded.** In essence, decoding involves a process wherein the key may be analyzed or the internal components of the lock can be examined for position and measurement. Many locks are subject to the decoding process, which can often be accomplished within a very short period. The decision as to which technique to use for producing a key will be dependent, in part, upon the following conditions:

- **Can keys can be copied by physical duplication using a key machine;**
- **Is it possible to derive code data using the various techniques that are detailed in this text;**
- **Are key blanks readily available, or will molds,**

milling, or other techniques be required to simulate restricted keyways;
- **Is key code information readily available from internal lists, manufacturers, or locksmiths.**

31_1.1.2 Information from Decoding

The information that is derived from the decoding process generally provides data about keys and active locking components, relating to a number of critical items:

For Keys

- **Position of each active locking component on the bitting surface;**
- **Number of active locking components;**
- **Depth of each bitting position;**
- **Design or shape of each active locking component;**
- **Presence of security enhancements such as mushroom tumblers, false gates, or serrations.**

For Active Locking Components

- **Position or distance from or with respect to shear line;**
- **Number of active locking components;**
- **Position, angle, polarity, or other feature that provides the security for the locking mechanism;**
- **Length of each component;**
- **Shape or angle of each component;**
- **Interrelationships between segments of the active locking element that vary based upon the depth coding of the component;**
- **Exact dimensions of the component;**
- **Indirect information that will allow the extrapolation of a direct code.**

31_1.1.3 Use of the Results of Decoding

There are several instances where a lock must be decoded. Usually, the principal reason is to produce a working key or the capability to do so in the future. It is one thing to

successfully decode a lock; it is quite another to translate the information into a key. Once **direct code** data has been obtained, there are several methods of using the information. These include:

- **Cutting a key by hand;**
  - **Using depth keys as a reference;**
  - **Using a micrometer or other device for measurement;**
- **Producing a key with a code cutter;**
  - **Manual code machine;**
  - **Automatic code machine;**
- **Use of variable key generation systems.**

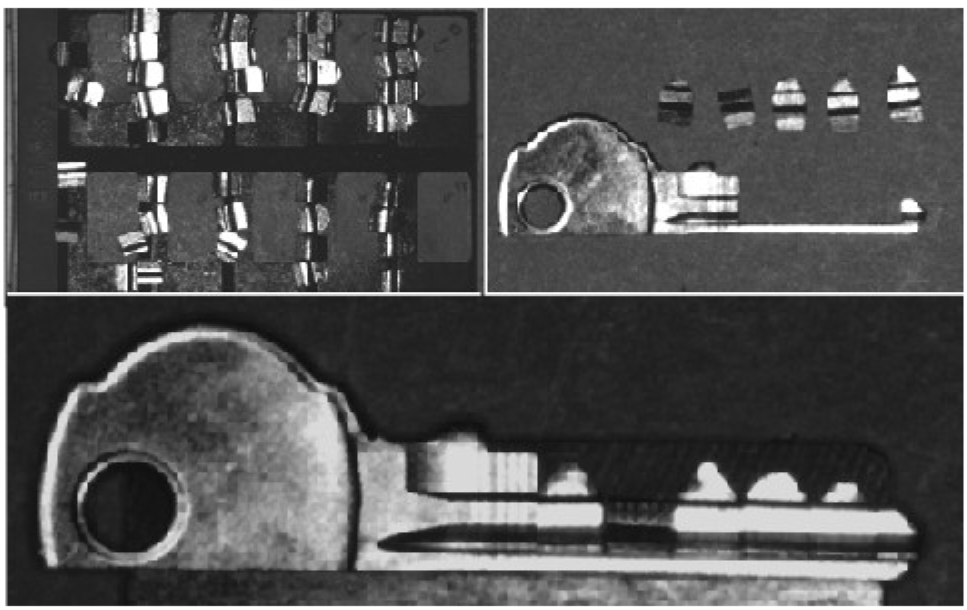
Direct codes or precise measurements can be translated into a working key using the techniques discussed below.

31_1.1.3.1   Cutting Keys by Hand

Keys can cut by hand, using a file, punch, or variable key generation system. Cutting by hand requires a Pippin and warding file for best results. A set of depth keys that provide a reference for each cut can be used if no precise measuring instrument is available. Handheld code punches are available for many keyways and are especially popular for automobile and axial pin tumbler locks. They allow for the instant production of keys based upon direct codes. Variable key generation systems, discussed below, allow keys to be produced from predefined segments, or they can be cut using scissors.

31_1.1.3.2   Producing Keys with a Code Cutter

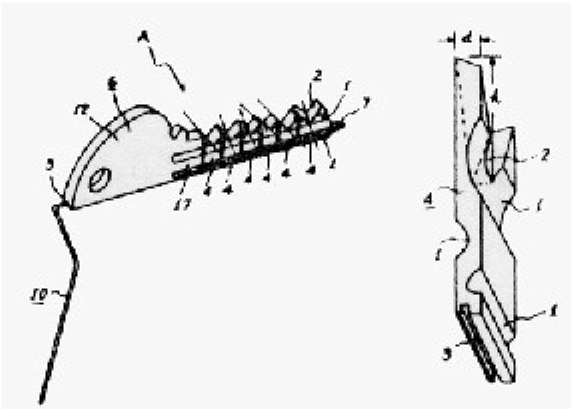
A more thorough discussion of code cutters is presented in **Chapter 8**. HPC, Silca, and other manufacturers produce an extensive line of cutting tools for use both in the shop and on location. Code-cutting machines are either manual or electric and can utilize dies or cutting wheels. These are calibrated by hand or computer control to precisely reproduce depth and spacing for a specific manufacturer and keyway.



31_1.1.3.3   Use of Variable Key Generation Systems

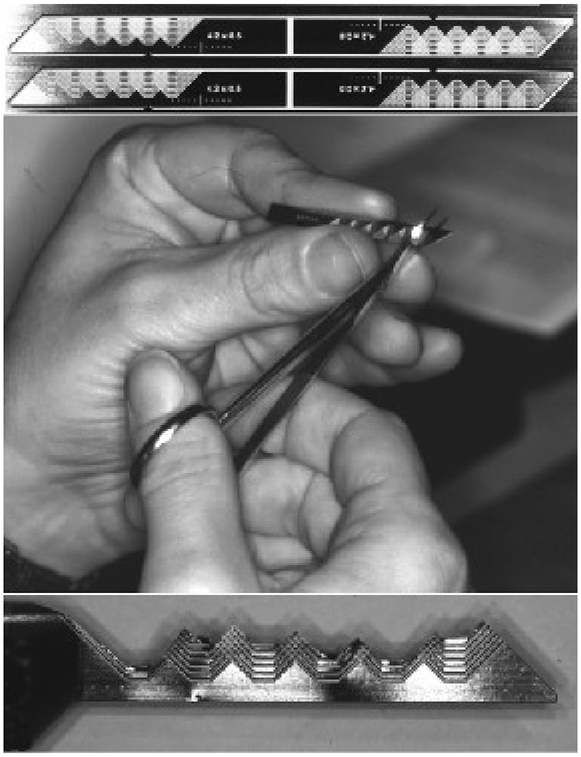
Falle has developed two unique key generation systems for

translating information from a lock decoder to produce a composite key. One system employs magnetic keyway segments; the other uses etched stainless steel "blanks" that can be trimmed with a scissors to simulate depth and spacing for most pin tumbler and wafer locks.



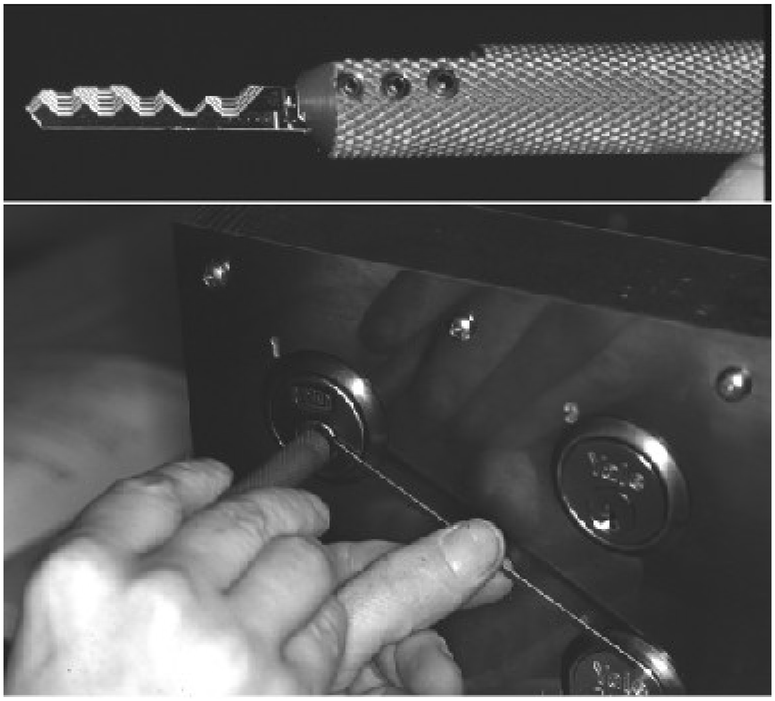
31_1.1.3.3.1 Magnetic System

The Falle magnetic system is actually a combination of keyway segments cut for each depth for an individual keyway. Once the lock has been decoded, the information for each tumbler is known. The proper magnetic segment is then placed on a key carrier and the completed key is inserted into the lock.



Exploded view 1, 2.

The composite resembles a key that has been vertically sliced into segments; one for each chamber. A selection of all possible depths is provided in the kit, and a key is "built" by abutting all the proper segments. This system has the advantage of providing a precisely fitting key that does not have to be manipulated to operate the lock. A Japanese patent was issued in 1975 (Kokai No. **52-51298(302)**) for a magnetic segmented key system for opening Medeco Locks.



31_1.1.3.3.2 Falle Adjustable Depth and Spacing (Variable) Systems

This technique provides a rapid means for fabricating a key to a specific code. The system will work with many pin tumbler locks and can bypass most keyways, thus reducing the problems created by restricted profiles. The Falle reusable systems are available for **Mul-T-Lock**, **Euro dimple** designs, STS DOM IX, **Chubb AVA**, **Abloy Disc Pro**, and the 14 Lever Lips. Other designs may be available. The **system** may also be used when a lock has been decoded incorrectly. It will frequently open a mechanism where the extrapolated codes are off by one or two depths on several cuts, by utilizing the variable key generation system as a rake pick.

This kit utilizes etched stainless steel blanks that have been marked and scored for eight different depth and spacing parameters. Once code information is derived, a blank is cut with a scissors to form the depth and position for each tumbler. The resulting key is manipulated horizontally and vertically until the correct level is achieved, bringing all tumblers to shear line. The blanks do not have any warding; thus, there is no precise point of reference within the keyway.

In some respects, the blank is moved like a rake or rocker pick until the correct position of all tumblers is achieved. The difference between rake picking and the use of this system lies in the fact that the depth and spacing relationship has already been defined, so it is only a question of the proper vertical alignment.

31_2.0 Overview: Tools, Techniques, and Procedures for Decoding

There are several disciplines for developing coding information as well as a variety of devices, technologies, and procedures for decoding locks. Some are extremely simple; others quite complex. The primary tools and their application to locking mechanism are described here.

The reader will note that some of the information presented in this chapter has been previously discussed, with slightly different emphasis in **Chapters 29** (Picking) and **30** (Impressioning). That is because some procedures involve more than one discipline. For example, certain picking tools actually perform the tasks of picking, impressioning, and decoding. Each section integrates information regarding the various tools utilized for decoding, with applicable techniques and procedures

for their use on different types of locks. In some cases, detailed information about a particular locking mechanism is presented.

31_2.1 Primary Sources for Code Data and the Production of keys

Code information is available from many sources. The following discussion is organized according to source and will provide the structure for the subsequent materials relating to tools, technologies, and techniques.

Code data can be derived through many disciplines involving the use of a combination of tools, procedures, and knowledge. Codes for a given manufacturer and lock can identify depth and spacing parameters that will provide the means to generate keys for a specific lock. They can be obtained through impressioning, discussed in **Chapter 30**, or by physically observing numbers on keys, the bitting depths from keys or active locking components, or through disassembly of the lock. Key codes may also be obtained from the manufacturer. As will be explained subsequently, codes may also be determined through the use of special pick and decoding tools and by the utilization of simple to sophisticated optical instruments.

31_2.1.1 Summary of Code Data Sources

The following is a summary of code data sources and provides an outline of the materials that follow. Codes may be obtained from the following sources:

- **By impressioning the lock;**
- **By obtaining code numbers from:**
  - **Keys;**
  - **Locks;**
  - **Other records;**
  - **Warranty data;**
  - **Code lists;**
- **Derivation of direct code from indirect code stamped on lock or key, by using reference sources;**
- **By visual inspection of a key;**
- **Lock data from manufacturer;**
- **Information from special pick/decoding tools;**

- **Original combination from lock manufacturer wherein the settings have not been altered;**
- **From lock specifications that provide a correlation between code depths and measurement of bitting surface of the key;**
- **By shimming the lock without disassembly, through the use of a shim and depth keys.**

31_2.2 Impressioning the Lock

When a lock is impressioned successfully, a working key is produced that may be duplicated and decoded. Impressioning is actually a **combination** of picking and decoding. It is a procedure wherein the position and depth of each active locking component is determined by reading a blank or partially cut key that has been inserted into the lock and manipulated. For a detailed discussion of impressioning, see **Chapter 30**.

31_2.3 Obtaining Code Numbers

Keys for most locks can be produced by code. Direct and indirect code numbers may be obtained from many sources including the key, lock, other records, warranty data, or from internal code lists. Most padlocks and motor vehicle locks have indirect codes stamped on them.

Direct codes are often imprinted on the key, and correlate to the depth of each tumbler, wafer, or lever. They are specific to each manufacturer. Standard depth and spacing information will allow a key to be produced from a direct code number. **Indirect codes** must be correlated to direct codes with code books or other references. A key cannot be reproduced from an indirect code until it is translated to the direct code measurements (see **Chapter 8)**.

Many manufacturers, especially for high-security locks, will maintain a customer registry of code numbers for a project or facility. This information may often be obtained through unauthorized channels. Likewise, internal lists of key codes are usually stored on premises or by the locksmith responsible for installation and maintenance. In any investigation of possible entry through the use of code information, a determination should be made as to where code lists, especially of master key systems, are maintained.

Master key records. Courtesy of Hans Mejlshede.

Often, locks are set to factory default codes that must then be changed in the field after installation. When attempting to open a lock, factory codes should always be tested, especially for combination locks.

There are many references for manufacturer's codes, including HPC, Silca, and Reed. These and other sources provide comprehensive data on most locks. Much of the information is now available on **CD/ROM**, and the Internet (see **www.security.org)**.

31_2.3.1 Codes on Lock Bodies and Equipment

Direct or indirect code numbers can often be found imprinted on lock bodies, padlocks, glove compartment cylinders, file cabinets, computers, and other equipment enclosures. Once these codes have been acquired, keys can be produced. Many locks used in commercial applications have very few different keys. For example, file cabinets may use ten codes for 100,000 locks. The Yale S99 and S100 locks, used in office equipment, have very limited numbers of keys.

31_2.3.2 Automobile Locks

Codes for automobile locks may be obtained from a number of different sources, including keys, the lock itself, the manufacturer, and through the vehicle identification number (VIN). The author obtains codes directly from the automotive makers in cases involving criminal investigations by supplying the VIN. If the lock has not been altered, a key can be quickly generated in the field based upon the code provided by the manufacturer.

The procedures for obtaining vehicle lock data can become more complicated in the newer electronic keying systems, where VATS or transduced bit codes are employed. From 1935 until 1966, all Briggs and Stratton keys had an indirect code that read from 8000-9499; there were 2500 useable permutations. In 1969, the code sequence changed to three digits and a letter. The letter designation was altered yearly.

Until 1966, sidebar wafers had four depths that were denoted by different colors: Copper, Nickel, Black, and Yellow. Wafers may also have their depth code imprinted on their face; these can be

read with a borescope or ophthalmoscope. Numbers have always been stamped on lock bodies.

31_2.3.2.1 Numbers Stamped on GM Keys for Automobiles

There are special standards for automotive keys which are mandated in federal statutes. Regulations require that codes be placed on a knockout to make the theft of cars using key codes more difficult. Numbers on GM keys are indirect codes and must be translated through a reference source. The shape of the key head was changed in 1969 to signify the addition of depths. Originally shaped like an octagon, it was changed to a rectangular and oval in that year in order to denote the difference in locks.

31_2.3.2.2 Numbers on GM Automotive Lock Bodies

Until 1978, code numbers were stamped on all car locks, including glove compartment and right-hand door cylinders. Within all General Motors vehicles since 1974, the ignition cylinder is keyed by itself; doors, trunk, and glove compartments are keyed alike. After 1974, the direct reading number stamped on the glove compartment lock would only provide information regarding the last four tumblers (because these locks only had four wafers). Consequently, several keys might have to be produced in order to determine the first and second positions.

31_2.4 Visual Derivation of Codes

In many cases, codes may be derived by looking at a target key. Depending upon the bitting design, this can be a fairly simple task, especially if there is a discernible difference between cuts. The process may be aided by use of a micrometer, depth gauge, and other tools described elsewhere in this chapter.

In order to decode a key by simple observation, a familiarity with the range of differs is helpful but often not mandatory. To the trained technician, the **relationship** between cuts can be determined quite accurately. Trial keys can then be made that have that same pattern, but with different depths. For example, a source key is observed and is thought to have the code of **23467.** However, when a key is cut to this code, it does not work. The operative may then produce keys with the codes **34578**, **45689**, and

12356. In this example, the important issue is the accuracy of the reading as to the number of depths between each cut, and their **relative position.**

31_2.5 Special Pick/Decode Tools

Special picking and decoding tools will provide direct reading codes for many types of locks and are described throughout this chapter. Depending upon design, they will allow the direct duplication of a key, or the interpolation of data to derive codes. As detailed subsequently, tools have been engineered for many medium and high-security locks, including Chicago axial pin tumbler, Medeco, Abloy, Keso, Abus, Briggs and Stratton, Ford, and others.

31_2.6 Wax or Clay Impression Copies of Keys

Imprints of keys can be made quickly with clay, wax, silicone, and other materials. Precise measurements, as well as visual decoding of such impressions, can then be obtained. Often, direct copies of the target key can be produced from molds using low melting temperature metals or epoxy. Procedures for obtaining impression copies are detailed in Chapter 8.

31_2.7 Disassembly of the Target Lock

A lock can be disassembled and decoded using a variety of techniques, including measurement of active components, fitting a key to the lock, and analysis of each active locking element. Taking a lock apart is a simple procedure and requires that each lever, wafer, disc, or pin be individually examined to determine its size and position. Once disassembled, it is also a simple matter to fit a key to the individual tumblers. The color, marking, or size may also identify tumblers. In the case of wafer, disc, and lever locks, some manufacturers imprint a code on each component for identification.

The proper procedures for disassembly are detailed in the Forensics Section of this text. It is critical that these procedures be followed so as not to disturb the configuration of active locking components and the various key combinations that will open the lock. The process of disassembly becomes more complicated for a master key system. In such cases, a pin-stack containing more than one master pin gives no clue as to which pin must be at shear line for a given key. It may be necessary to

generate many permutations in order to derive the proper code.

31_2.7.1 Derivation of Master Key Codes

It is not possible to disassemble one lock in a **positional** master keying system and derive the master key coding for the entire facility. It is possible, although often difficult, to decode one lock and successfully produce a master key in a **conventional** pin tumbler lock. This is because there may be more than one chamber containing master pins, or more than one master pin for each chamber. In a lock that is keyed using total position progression or rotating constant schemes, there will be a maximum of two pins in addition to the top pin in each chamber. Thus, in a six pin lock, there will be a total of 64 possible combinations (2^6). Conventional locks can be decoded through disassembly, by extrapolation of the top level master key through the use of a change key, or by shimming the lock through the use of depth keys, without the need to disassemble the cylinder. These techniques are discussed in later sections.

Depending upon the construction of the lock and the requirements of the keying system, a lock may have several physical or virtual shear lines. Some locks, such as Corbin, may have a master ring that create two physical shear lines. The ICore lock also has two shear lines: one for operating and one for control. In order to service a cylinder that has been master keyed, both the change key and master key are usually required. A detailed discussion of master keying can be found in **Chapter 11**.

31_2.8 Electronic Signatures as Codes

Locking systems utilizing special technologies including magnetic stripe, barium ferrite cards, magnetic pins and discs, infrared, radio frequency, and proximity sensing will all have electronic signatures that can often be decoded. This subject is covered later in the chapter.

31_2.9 Common Characteristics as a Partial Code

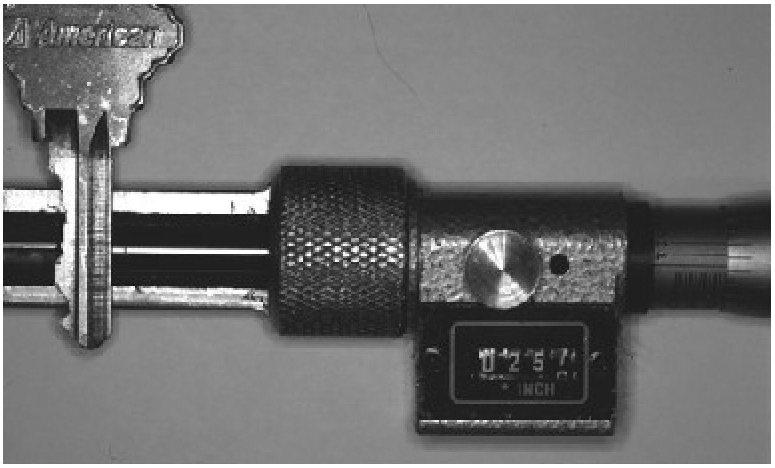
Some manufacturers utilize a common sidebar or similar code scheme as part of the overall coding system for a lock or group of locks. Once obtained, all locks in the series will have the same characteristic. Assa, for example, will assign a common sidebar pattern to all locks located within one geographic area, or installed by one dealer. All keys for locks having a common

characteristic (dealer, geographic area, and facility) can be compromised if that sidebar code becomes known.

31_3.0 Specific Methods for Obtaining Code Data

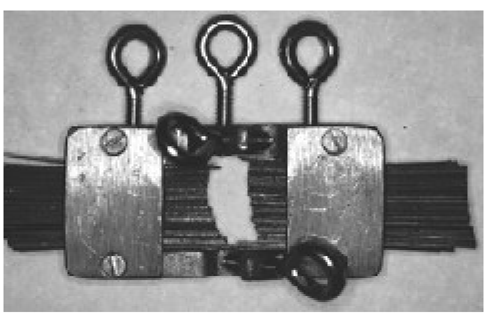
Code information can be derived from the direct physical measurement of keys or the active locking components within the mechanism. Several methods will yield the desired data:

- **From another key;**
  - **Visually determining the bitting depths;**
  - **Micrometer measurement of the key;**
  - **Using depth gauge to measure the target key;**
  - **Making an impression copy of the key, then decoding it;**
- **By shimming the lock:**
  - **Use of a shim in combination with depth keys to decode each pin stack;**
- **Disassembly of the lock;**
  - **Fitting a key to the tumblers;**
  - **Decoding tumbler depths visually by inspection of pins;**
  - **Observing individual tumbler marking, thereby identifying depths;**



- **By fitting a key to the tumblers (impressioning);**
- **Examining the lock using external viewing means;**
- **Observation of active locking components;**
- **Measurement of active locking components;**
- **By utilizing a decoding device, such as the John Falle Pin Lock Decoder, or the MSC Sputnik for reading the length of pins, wafers, or levers.**

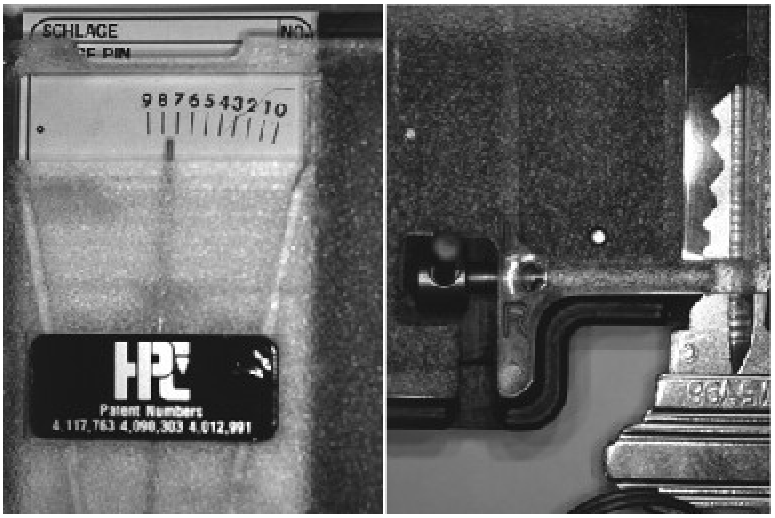
31_3.1 Direct Measurement of a Source Key



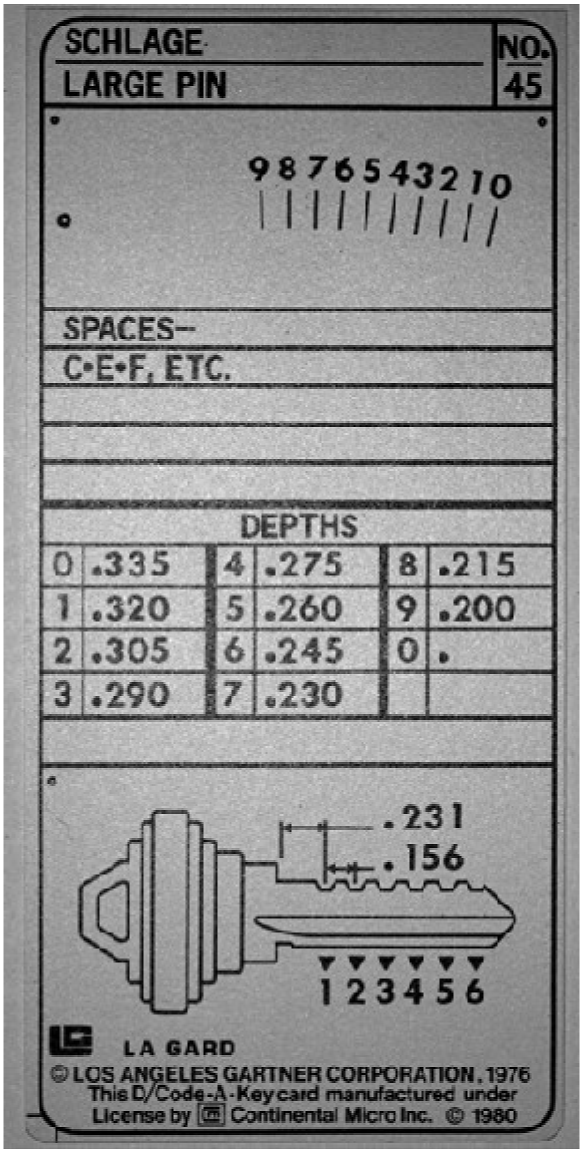
Decoding of keys, courtesy of Harry Sher.

Many instruments are relatively simple in design that can be utilized to measure both internal components and keys. They

provide dimensions, calculated in inches, or direct code correlation based upon manufacturer. The HPC SKM-20 key micrometer and the HPC HKD-75 have been specially designed for precise determination of depths for each bitting position of a key.



The micrometer is accurate to .01”, and may be used to measure any key with ramps and valleys. When determining the depth of a cut, be certain that the micrometer or other measuring instrument is capable of seating at the root without being affected by the ramps.



The HPC HKD-75 is an extremely versatile tool; it is a necessity for any craftsman involved in field operations. It is furnished with comprehensive manufacturing depth and spacing data for over sixty keyways. In cases where the original key is available, this tool will allow exact decoding of the depths for later duplication. The device is also capable of measuring keys with different cut angles, such as Medeco. The stylus can be set to Right (R), center (C), or Left (L) positions.

The code card for the HKD-75 is shown below. Each card has an

identifier that denotes the kind of lock or key classification is being measured. Thus, (H) refers to standard keys, (HF) foreign, (HMC) for motorcycles, (HPKS) for KABA PEAKS, and (HX) for special. Three shims are also included for measuring double-bitted keys.

Depth gauges and keys are also used for making measurements. Gauges are marked for each depth and may be utilized with keys as well as for decoding locks. Each depth may be compared to the cuts on a source key to determine precise coding for each tumbler position.

Gauges may also be inserted into a wafer lock, once picked, to determine individual wafer coding.

31_3.2 Decoding Wafer Locks by Direct Observation

This section presents material describing the decoding of wafer locks by observing the wafers through the keyway. In **Section 4.5.2,** the decoding of wafer mechanisms by **indirect** methods is presented. The two techniques differ in the type of data collected and the way in which it is derived.

31_3.2.1 Introduction

Wafer locks are probably the predominant mechanism in the world for use in access control and for low to medium-security containers. They are relatively easy to decode.

31_3.2.2 Information Required

In order to successfully decode a wafer mechanism, several critical items of information must be known before the procedure is initiated. Data can often be derived from the type of lock, where it is installed, and identification of the blank. It is essential that the following characteristics be obtained prior to decoding:

- **The number of depths or differs. It is suggested that the data sheets from the HPC 1200, the HPC HKD-75 handheld decoder, or other reference source be utilized;**
- **The number of tumblers;**
- **The proper key blank;**
- **The position of the highest and lowest depth;**
- **How the depths appear in relation to each other;**
- **How to differentiate each depth;**
- **Relationship of each depth with the keyway wards;**
- **If for a motor vehicle, determine which cylinder contains all wafers in order to enable cutting a key to fit all locks.**

31_3.2.3 Theory of Decoding Wafer Locks

Specific depths for particular locks can be found in "depth and spacing" manuals or by taking measurements on keys from other locks of the same type. Generally, all wafers rest at the same vertical position when not at shear line. Their bitting surfaces will be in perfect alignment and will mirror the depth coding of the key. If the entire wafer pack could somehow be lifted to shear line without disturbing the relationship between each component, the lock would open. It is this interrelationship between active locking elements that must be decoded and will yield depth information, which can be translated to a cut key. The relative depth of each bitting position on the key corresponds to the internal area of the wafer that forms the

keyway and thereby allows the lock to be visually decoded.

It will be remembered that the design of a wafer is such that the key passes through its center, allowing the vertical surface (which is spring biased) to reside on the key bitting area. There is in essence a programmable slot in the center of every wafer tumbler. The vertical position of this slot will be adjusted either upward or downward, depending upon the corresponding depth of each cut on the key. If the cut for a particular wafer position on the key is deep for example, then there will be more material at the top of the wafer slot and less on the bottom. The slot will appear to be lower in its overall position.

A comparison of each wafer with respect to the others, and their position relative to a side ward in the keyway (used as a constant value), allows an estimate of the depth of each wafer. Usually, the bitting difference between differs ranges between .015" and .025", with .020" being common. For example, a lock may have the following five depths:

Cut	***Depth***
1	***.240"***
2	***.220"***
3	***.200"***
3	***.180″***
4	***.160″***

The depth coding for each individual wafer can thus be extrapolated by assessing the relative position of each slot, in comparison to a known standard such as a keyway ward or other wafers. Once the slot position of the highest and lowest differ is ascertained, the intermediate depths can be determined.

31_3.2.4 Tools for Decoding Wafer Locks

Several tools can be employed in the decoding process for viewing, moving, and measuring wafer positions. These include a borescope or magnifying otoscope, wafer depressor (reading tool), spring door tool, code cutter, slip coder, and depth and spacing keys. Patents have also been granted for specialized tools, such as that developed by Hansen in 1935 (**1991151(303)**).

A **wafer depressor or reading tool** is utilized to move all but the selected wafer out of the field of view.

A **slip coder** provides a means to read individual differs on a key and translate them to direct codes and measurements.

A **borescope** or **otoscope** allows the magnified viewing of wafers.

A **straight pick** can be used to lift all wafers.

31_3.2.5 Guidelines for Decoding Wafer Locks

- **Wafer design is standardized for conventional mechanisms: they are either square cut or under cut (rounded edges);**

Motor vehicle wafer locks can feature different wafer configurations. For example, Datsun introduced a wafer with a notch in the top to prevent removal when rotated 180°. The design was not popular due to wear, jamming, and collapse. A half or split wafer is used in Mercedes cars to provide twice the number of permutations. Each side of one tumbler can operate at a different depth while using the same space in the lock. Thus, an eight-wafer lock will have sixteen permutations;

- **A lock will generally have only one shear line;**
- **Locks that have been master keyed will have two shear lines;**
- **Master pins have two contact surfaces for left and right bitting. The key blade is either oriented right or left in order to raise the appropriate portion of the wafer. A two-digit code will indicate which side of the wafer is acted upon by the key.**

It is important to know which side of the key to use when a lock has master pins and which side of the wafer is being decoded. Decoding is particularly applicable to these locks and is preferable to impressioning because of the likelihood that the wafer will slip when torque is applied;

- **A lock that has been master keyed will have two keyway profiles;**
- **All wafers within a single-bitted lock will extend in one direction;**
- **There is always an area above and below each wafer**

within the shell;
- **Depths are determined from a measurement of the internal dimensions of the open space within the wafer;**
- **The overall length of the wafer will be equivalent to the diameter of the plug;**
- **An uncut key that exceeds the dimensions of the free space within one or more wafers will be blocked from entry into the keyway;**
- **An undercut wafer will not prevent reading the lock;**
- **Half and split wafers (utilized in Mercedes, BMW, and other cars) can be visually decoded;**
- **Do not apply turning pressure to the lock while decoding. To do so will "hang" the wafers and cause false readings.**

31_3.2.6 Difficulties and Cautions

A number of conditions can cause difficulties in decoding certain locks or producing properly operating keys for them. The following problems should be identified and analyzed prior to attempting to open a wafer lock:

- **Worn wards within the keyway;**
- **Worn wafers;**
- **Keyway wear;**
- **Bent wafers (from excessive torque during picking);**
- **Small difference between differs;**
- **Many differs;**
- **Inability to observe a specific wafer;**
- **Inaccurate extrapolation, causing too deep or shallow cuts to be made, resulting in binding or the necessity to "wiggle" the key to make it work;**
- **If cutting a key for a vehicle ignition, try using it in the door lock first. If the key has been cut improperly, the ignition may turn due to wear but the key may not be able to be withdrawn (resulting from depths which are too low or too high).**

31_3.2.7 Procedures for Decoding Single-Bitted Wafer Mechanisms

The following decoding procedures apply to single-bitted wafer locks. Decoding may be accomplished in either direction (front to back or back to front) without the necessity of disassembling the lock. Knowledge as to the appearance of wafers prior to viewing them will facilitate accurate estimates as to their depth.

31_3.2.7.1 Decoding with a Reader Tool

- **Lubricate, then run a blank key through the keyway, insuring that wafers do not "hang" in the shell or at shear line;**
- **Insert blank key and cause marks to be made by each wafer, denoting their position. The blank may be "smoked" with carbon for this purpose. File each wafer to the first depth-cut;**
- **Move the keyway cover out of the way (if applicable);**
- **Illuminate the keyway so that the bitting material above the wafers is visible;**
- **View the keyway directly dead center, without creating any angles or perspective. If viewed at an angle, wafers closest to the front will appear higher;**
- **Insert a reader tool and raise all tumblers to shear line. A straight pick may be employed to lift each tumbler;**
- **Read each wafer in succession, and estimate depth. Remember, there are generally 5 depths, with "1" being a "no cut", and "5" being the deepest cut. Also, there may not be 5 differs, but only 3 or 4, causing the improper interpolation of each differ;**
- **If unsure of a particular depth, make the cut more shallow than deep;**
- **Use a gauge or micrometer when cutting the key after each depth has been determined.**

Reading a Chrysler lock with an EZ Reader tool, by Harry Sher

31_3.2.7.2 Decoding by Observation of Bitting

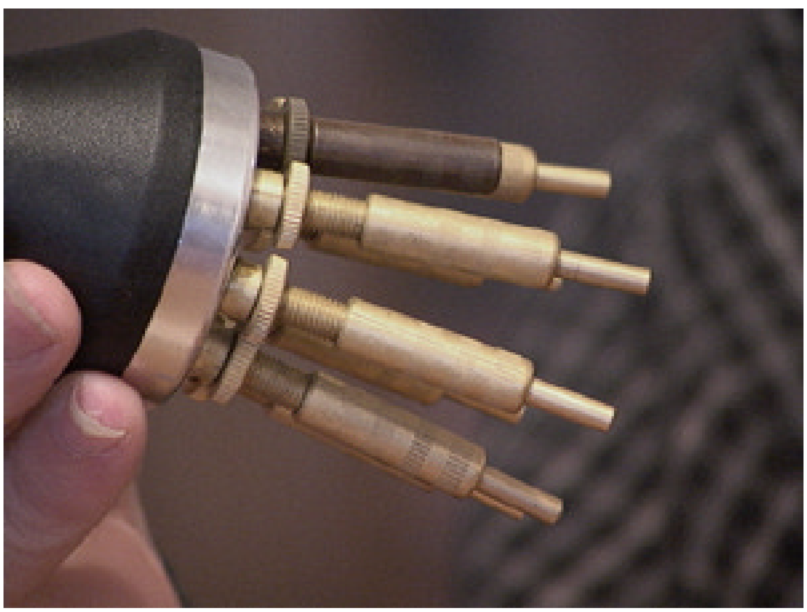
Decoding may be easier with a borescope or ophthalmoscope. In

such case, a depressor is utilized to move all but the active wafer from view. Once a landmark is determined from which to estimate each depth, the tumblers are viewed in sequence and a notation made of the information. A key is then produced to the direct code.

31_3.2.8 Decoding Double-Sided, Double-Bitted Locks

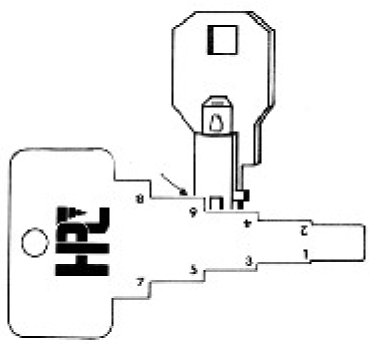
There is a difference in the decoding procedure for single and double-bitted locks. The following guidelines apply for wafers having bitting surfaces on two sides.

- **If the lock is used in a motor vehicle, the following information should be known:**
    - **Make, model, body, and year of the vehicle;**
    - **Code data and code location on the lock body;**
    - **Key blank types;**
    - **Root depths and spacing;**
    - **How keys will operate;**
    - **Which bitting is active on both sides of the key;**
- **Be certain that the lock is double-bitted, with active wafers oriented in opposite directions. A key with bitting on both surfaces may merely be mirrored for convenience;**
- **Locks for motor vehicles may contain up to eleven tumblers. On certain models, there may be an added cut at the tip of the key that does not correspond to a wafer position. In such cases, cut both sides of the key to allow entry through the keyway;**
- **Some locks will have active wafers in all positions on both sides; others in only certain positions. For example, a key may be coded 13545 on one side and 35 on the other;**
- **If there are active wafers on both sides of the plug, then alternating cuts must be made on either side of the key;**
- **The order of reading must be determined, beginning with the first wafer. It may be on the top or bottom of the plug;**
- **If producing a key for a motor vehicle, it must be determined if there is a valet function. Knowledge of the lock is required;**



- **It is preferable to read all bottom cuts or all top cuts in sequence;**
- **When illuminating the keyway, shine the light at the bottom to read top wafers, and at the top to read the lower set.**

31_3.3 Decoding Axial Pin Tumbler Locks



When a tubular lock is picked, it must also be decoded. Code depths may be read from a decoder tool or from the key that opens the lock. Keys that have been produced during the impressioning process may be damaged or chipped. The HPC TKPD-1 can be utilized to determine the depth of each cut, measured in 1/64" segments. In order to use the tool, the key is rotated in a clockwise direction with the blank facing the technician. These locks may also be disassembled using the HPC APF tool. The **Peterson PRO-1 tool** may also be used to pick and decode an axial pin tumbler lock.

The Peterson PRO-1 tool, courtesy of Harry Sher.

LSS204: Harry Sher on picking axial pin tumbler locks

31_3.4 Decoding G.M. Sidebar Locks by Direct Measurement

Sidebar locks can be directly read using the HPC GMTD-5 decoder gauge. This process requires that pressure be applied directly to the sidebar by drilling a very small hole through the lock cover. A stiff wire or pick is then used to depress the sidebar while the wafers are raked to alignment. Each of the five depth gauges is then inserted to read the height of each tumbler.

31_3.4.1 Sidebar Code Reader

A patent (**2070228(304)**) was granted in 1937 to FitzGerald and assigned to Briggs and Stratton for a simple code-reading device

for their lock. The tool allowed the direct measurement of the four depths associated with each of six wafer positions.

31_4.0 Indirect Measurement of Internal Components

Active components may be measured indirectly, using various procedures involving observation, touch, and special tools. Decoding devices produced by HPC, Falle, and others are available to provide precise extrapolation of depth and spacing data during the decoding process. **Indirect** measurement refers to a process whereby components are evaluated and decoded through other than direct means. The analysis is generally accomplished by comparison of data from a known standard, without actually being able to physically examine the component. Dimensions are either estimated or precisely determined through extrapolation. The primary means for deriving code data by indirect measurement include:

- **Visually reading the lock;**
- **Set of tryout keys;**
- **Impressioning the lock;**
- **Examining tumblers or levers through a viewing hole or keyway;**
- **Silicone impression of the inside of the lock after picking;**
- **Use of pressure-responsive materials;**
- **Utilizing a special pick/decode tool;**
- **Utilizing a shim decoding device;**
- **Tactually decoding the tumbler positions;**
- **Picking, then decoding the picked lock;**
- **Other means of reading tumbler combination.**

31_4.1 Tryout Keys

Tryout keys are designed to exploit the tolerance errors of active locking components. They utilize a matrix of specially cut blanks that encompass all possible permutations that will open the lock, based upon depths that are between standard levels. Once a tryout key has been found to open a target lock, a matrix of codes can be determined that will produce a properly working key. In a simple example, let us assume that a three-

wafer lock has been opened using a **tryout key** with the code of 2.5 4.5 1.5. In our example, a 1.5 cut will simulate a 1 or 2 code; a 2.5 will simulate a 2 or 3 code; and a 4.5 will simulate a 4 or 5 code. The matrix of combinations must include:

CUT #1	CUT #2	CUT #3
2	4	1
3	5	2

Based upon this knowledge, all of the keys that theoretically must be cut in order to find the correct one would be: **252, 251, 241, 242, 352, 351, 341, 342.**

31_4.2 Examining Active Locking Components Using a Viewing Hole or Keyway

Active locking components can be observed and measured externally. They can be viewed by using optical instruments and their measurements derived through the use of decoders. Ophthalmoscopes, otoscopes, and magnifying loops may be utilized to peer into the lock and calculate the depth of each wafer, disc, lever, or tumbler. Depth gauges and feelers can likewise be employed to extrapolate individual bitting.

Lever locks generally have a viewing hole that allows observation of the lever pack, gates and fence. Calculations can also be based upon the appearance of the bellies. Certain locks, such as wafer and disc tumbler, are particularly well suited to visual decoding techniques because of the design of the active locking components. The procedure for decoding a standard wafer mechanism by **indirect measurement** is detailed in **Section 4.4.2.**

31_4.3 Impression of the Inside of the Lock

It is possible to obtain an impression of the position of the active locking components after they have been picked or manipulated to the open position. Impressioning material such as silicone can be injected through the keyway, then removed once it sets up. An imprint of the various tumbler depths will be reproduced. Another method, patented by the author (**5355701(305)**), utilizes carbon paper in conjunction with a fine rake wire combined with a protective covering during entry and removal. A precise image of the VingCard key can be produced in seconds using this process. Impression marks, caused by a difference in pressure upon the tumblers, will be indicated on

the surface of the carbon. This can be directly translated for the production of a key. A more sophisticated electronic method for decoding this lock and others was also patented by the author. It is described elsewhere in this text.

31_4.4 Utilizing a Special Pick/Decode Tool

There are many instruments that are designed for picking and decoding lever and pin tumbler locks. Most of these utilize some form of moveable shim to sense the position of each active locking component. The more sophisticated devices use fine wire and are detailed later in this section. The best engineered, most accurate, and versatile of these tools are examined in the following discussion. Detailed instructions, including video presentations, may be found in **LSS+/x CD/ROM**, and at **www.security.org**.

31_4.4.1 Lever Lock Decoders

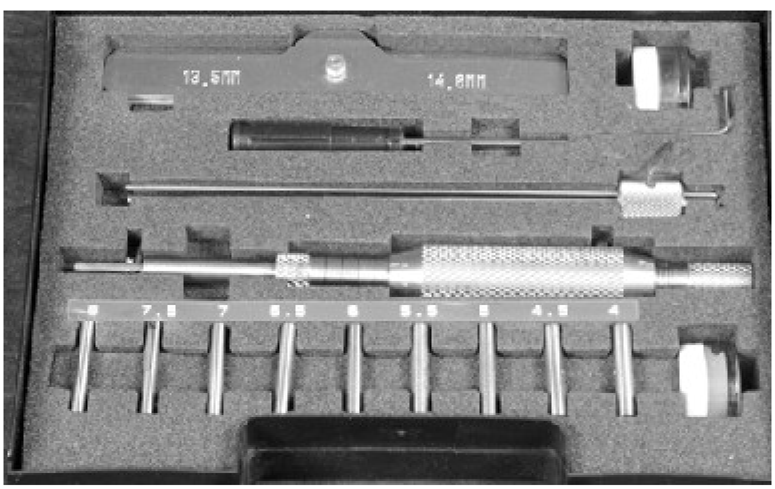
Because of the popularity of lever locks throughout the world, many decoders have been devised that range from simple to very complex. The first lever lock decoder could be said to have been a fine wire with a mirror attached to it. A lighted taper was placed in the lock in order to smoke the levers. Then, a blank was inserted and rotated until it made contact with each belly. The bellies were then examined to determine points of contact.

The crude decoding device was used to read the marks left in the carbon. A finely focused lamp was employed to see where the key bit had touched each lever. This information told the lock picker where the key would make contact with the levers and where it began the lifting action for each belly. With patience, he could figure out a key that would not trip the internal detectors that had been developed to frustrate this practice. Ultimately, Chubb solved the problem: they implemented the curtain as a shroud. Since the use of this primitive procedure, many decoders have been developed as a response to the introduction of improvements in lever mechanisms. See Lee (**3735496(306)**) for a method of decoding certain high-security lever locks by measuring the distance between the lever and other components within the lock by utilizing a special set of keys with predetermined bitting depths.

Based upon a study of the famous Bramah lock that was successfully bypassed by Hobbs, the author has concluded that a form of decoder was developed by him to measure the length of

each slider. It is possible that this was the first rudimentary pin and cam system, perfected two hundred years later by John Falle.

There are various forensic implications that will often result from the bypass of lever locks. In other cases, essentially no trace will be found. Each lock must be studied, and a thorough knowledge is required of the latest bypass techniques, in order to assess whether in fact a lock has been compromised.



Forensic implications of the bypass of lever locks. Courtesy of Hans Mejlshede.

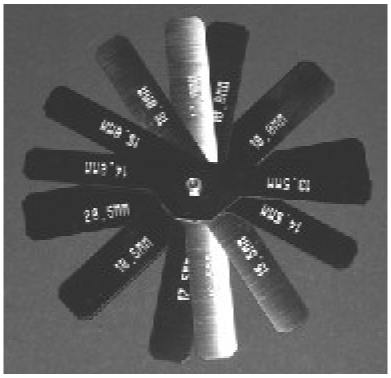
31_4.4.1.1 Universal Lever Lock Belly Reader

A discussion of reading the belly of a lever. Courtesy of Hans Mejlshede.

LSS304: Universal belly reader system, by John Falle

This decoder, manufactured by Falle, is sold exclusively to government agencies. It is designed for use with medium security five and six-lever locks with barrel and curtain, such as the Chubb 114, the Union five-lever Red, and many other models.

The system is an improvement over the use of plasticine, discussed in **Chapter 30**. It will be remembered that such a system relies upon the insertion of a plasticine key that is turned under the levers, so that they make an impression mark in direct correlation to the height of each belly. There are three disadvantages to using plasticine:



- **In many instances, the skirt rotates counterclockwise, which may result in breaking or fracturing the metal in order to take readings;**
- **Markings that are left on the plasticine can be very difficult to interpret;**
- **Often, the plasticine can be deposited onto the belly of the levers and then onto the users key, thus providing an alert to the process.**

The Falle kit is supplied with a series of data sheets for each lock for which the tool is designed. Information includes lever spacing to properly position the plunger pin under any specific lever. Belly height for each type of lever is also provided. The tool is calibrated in 1-mm increments.

31_4.4.1.2 Basic Lever Lock Decoder

This Falle kit is supplied with tools that are designed to identify the make of a target lock to be opened. The system utilizes a set of feeler gauges to measure the length of the keyway. The operator inserts the gauges (from end to end) to find the largest size that will fit.

There is also a pinhole-measuring tool to ascertain the diameter of the pin or post size of the key. This gauge is inserted into the keyway; the bow is then slid down to hit the face of the lock. The user can then read from the gauge to determine the required dimensions.

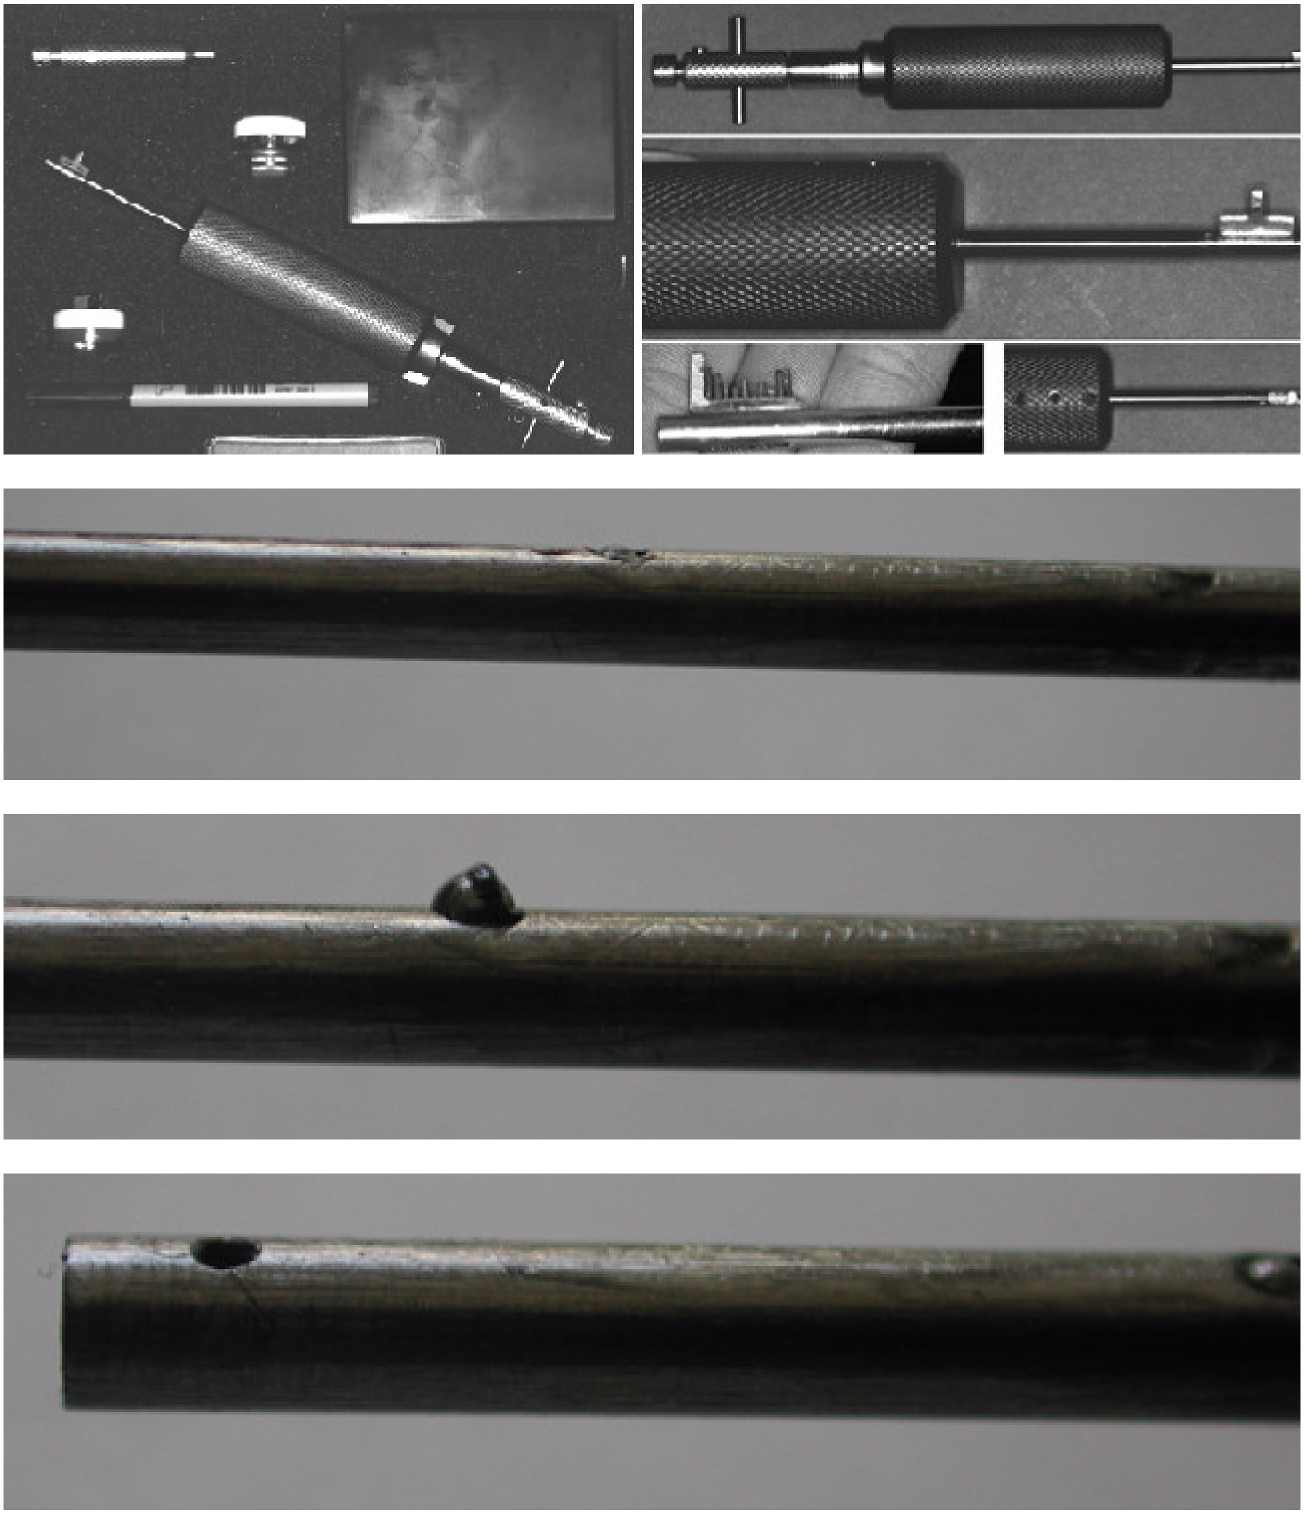
The decoder consists of two separate gauges; the one at the front of the tool controls the depth for which the plunger pin is inserted into the lock. The decoder gauge at the rear adjusts the height to which the plunger pin is inserted underneath the levers.

31_4.4.1.3 Pin and Cam System (Universal Lever Lock Decoder)

The John Falle lever decoder system. Courtesy of Hans Mejlshede.

LSS303: Universal pin and cam system, by John Falle

The term “**Pin and Cam**” refers to the original design which used a small cam to apply lift to the pins in the key tip. The basic design has since been modified and updated, but the underlying theory remains constant. There are several different versions of the Pin and Cam system, customized for specific lever locks. The **European** lever Pin and Cam will open certain of the locks that are found in Europe. The **Universal Pin and Cam** system can be utilized for many different **lever locks.** One example (shown in the linked photograph) is the Mottura lock. Shown in the hyperlinked photograph are different versions of these systems produced by John Falle.



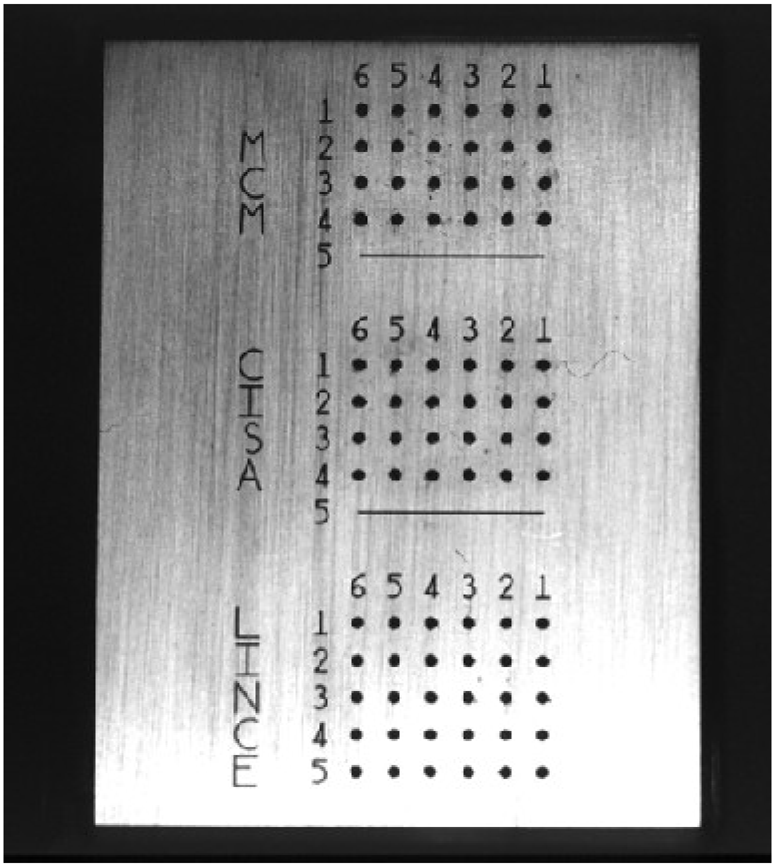


Figure LSS+3101 The John Falle Pin and Cam system relies upon the movement of a bearing under each moving pin that is inserted into the die corresponding to

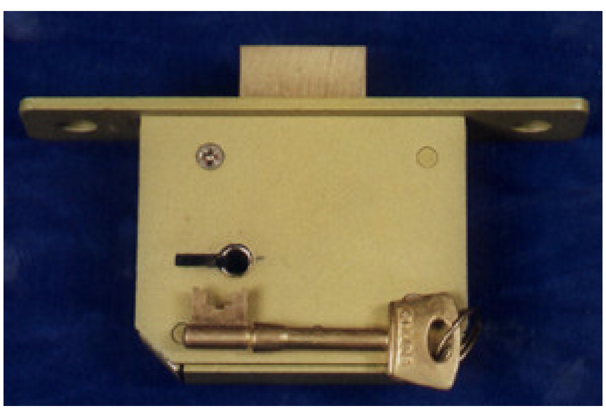
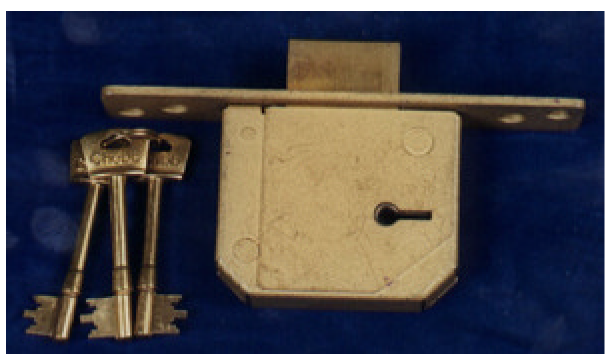


the location of each lever. Extremely precise sensing of movement in each individual pin is achieved by forcing the bearing to move vertically against each lever. The tolerance error is determined for each of the levers through the movement of the individually adjustable pins within the tool.



This system was initially designed to defeat the Chubb 110 lever lock. The original process required the insertion of a probe into the keyway so that it would rest to the left side of each lever in order to take readings. The space that was vacated enabled the operator to probe for the gate in the adjacent lever, thus allowing the decoding of all levers. A modified system has been introduced for **British** lever locks.

In response, Chubb introduced a spring steel clip that was placed underneath the bellies of the levers at exactly the point that the probe was trying to reach, thus preventing the system from working. As a result, Falle introduced a modified and upgraded approach. The system consists of a simulated key-bitting surface that allows the placement of different length pins into each lever position. These pins are precisely controlled through a plunger located at the end of the tool and can be individually lifted to calibrated positions.

The **pin and cam system** is supplied for use on any one of five high-security locks. Currently, this includes the Chubb 110 (seven lever heights), 3G 114 (eight lever heights), and seven-lever safe lock, the Leg five-lever black insurance lock, and the CR European double-bitted lever locks.

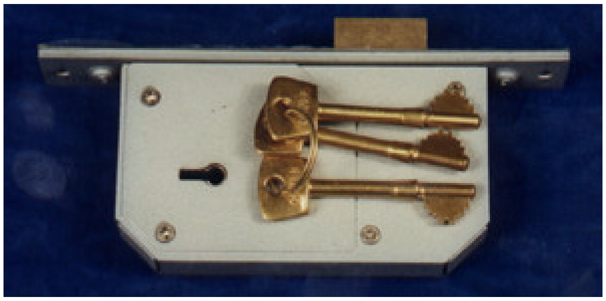


Figure LSS+3102 examples of different British locks that can be opened with the specialized pin and cam system. Courtesy of John Falle.

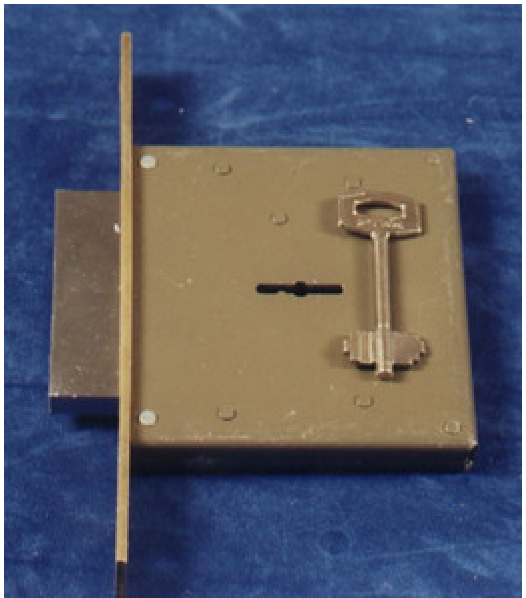
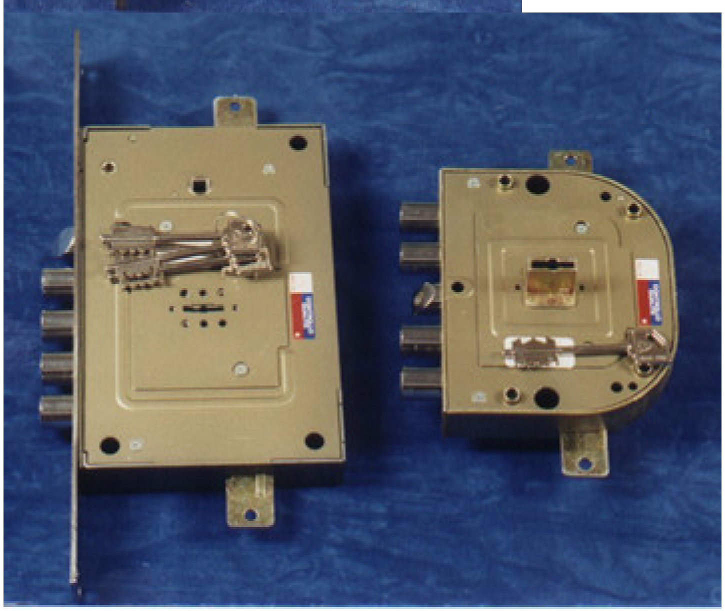
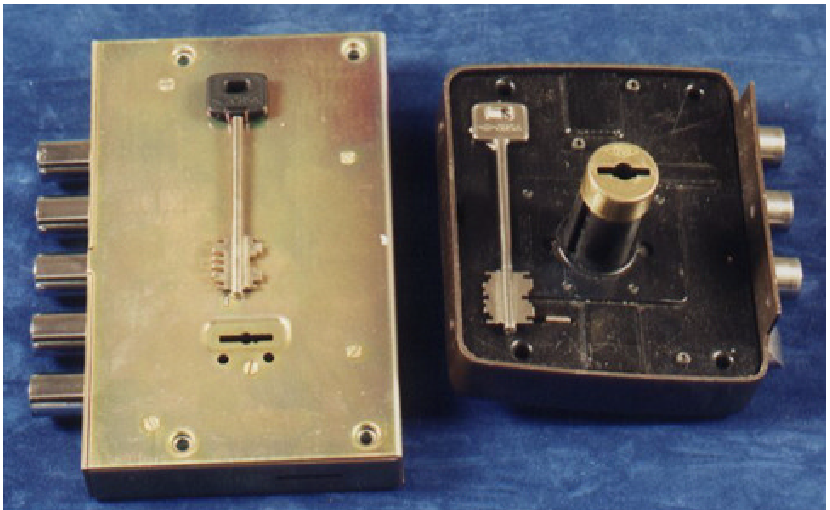


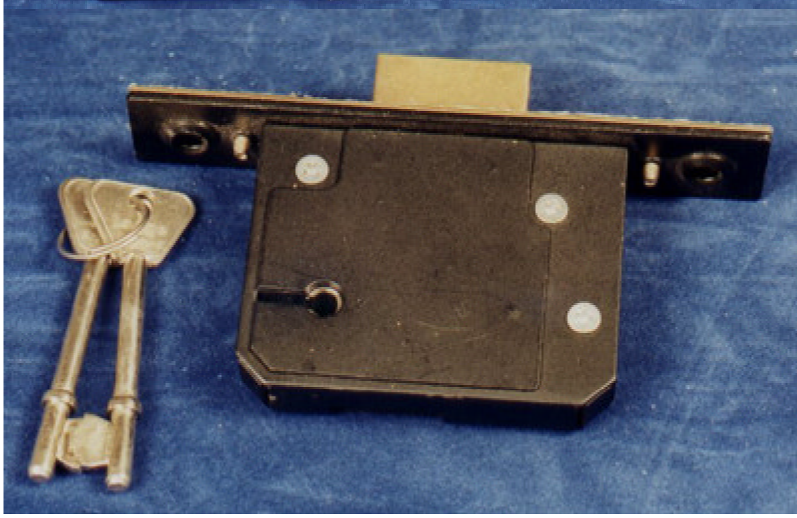
All of these high-security locks have one of the following design features in common for which the Pin and Cam system is primarily designed:



- **They may have very large belly groupings as in the case of the Chubb 114. Thus, even if the groupings are known, a large number of keys would have to be tested in order to determine the correct combination;**
- **They may have (as in the case of the Leg five-lever black insurance lock), belly groupings that are very difficult to distinguish, even with the universal belly reader tool;**
- **The locks may have no belly groupings whatsoever. This is the case with the Chubb 110, seven-lever safe lock, and the CR lock.**



The system is effective against most high-security locks, regardless of:



- **The number of levers;**
- **Barrel and curtain or pick-protection mechanisms;**
- **False notching on the levers that are designed to frustrate picking.**

Different versions of the **Pin and Cam system** are effective on many locks listed below, including those shown in the photographs:

- **Antonioli**
- **Beta**
- **Boda 428, 2925, 2926 (unlocked) (locked)**
- **Cerutti**
- **Chubb 6K174 (locked) (unlocked) (Bankers Safe)**
- **Chubb 6K75 (Leamington and Conqueror Safe, 7 and 8 lever)**
- **Chubb 3G110, 3G114, 3G117**
- **Cisa**
- **Esety**
- **FAS 309, 389 (S&G 68/80) (locked) (unlocked)**

- **FAS 6880 (locked) (unlocked)**
- **Ferr**
- **Fiam**
- **ISM**
- **Jewel**
- **Kassel**
- **Legge Black**
- **Moia**
- **Mottura Serrablocca**
- **Potent (7-lever lock)**
- **Potent**
- **Power Titan**
- **Preffer**
- **Ross 600 (6-lever lock)**
- **S&G 68-80 (Fas)**
- **Sab**
- **Securemme**
- **SLS (multistump lock)**
- **SMP (dual-stump lock)**
- **Teseo**
- **Viro**
- **Yale**

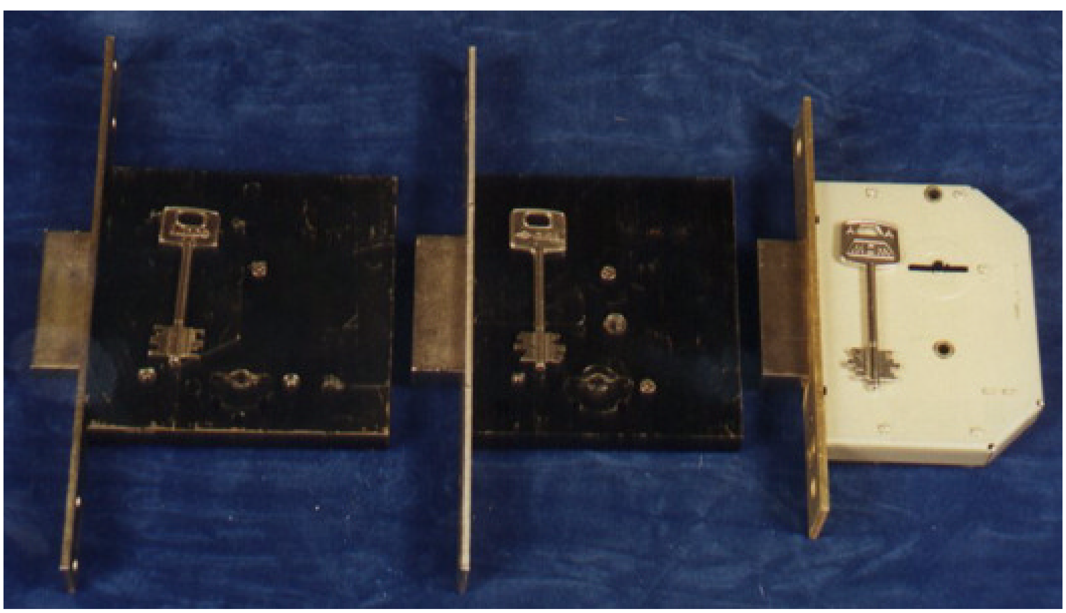


Figure LSS+3103 A variety of European lever locks can be opened by

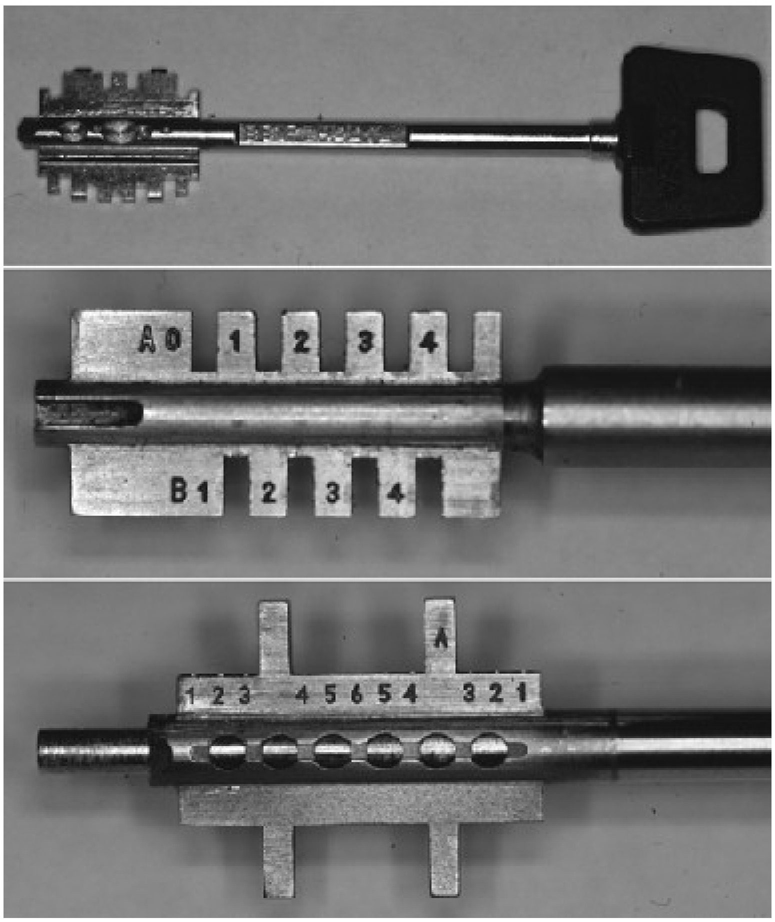
the John Falle Pin and Cam systems. Some examples are shown within section 31_4.4.1.3. Courtesy of John Falle.

31_4.4.1.3.1 Pin and Cam System Operation

The system is a high-tech improvement over traditional impressioning techniques. It will be recalled that to impression a lever lock, a blank is inserted, torque applied, and the bitting surface is moved against the levers. This will cause marking, correlating to the position of each lever with respect to its gate and the fence. In the Pin and Cam system, the tip of the decoder tool simulates the function of the blank, as a series of interchangeable steel pins are inserted to reproduce bitting positions within a key. In the case of the 110, for example, there are nine possible cut depths, and the decoder tip itself measures a #9 height.

Positioned within the tip and directly below the pin is a hardened steel cam. It is free to slide forwards and backwards in relation to the pins. When the cam is rotated, the pin that is positioned directly above it would be raised exactly .5 mm. With practice, the user would place five pins of equal length into the holes directly below the levers. The decoder is inserted into the lock and rotated to the unlocking direction, and torque is applied. The cam is positioned below each pin and then turned and twisted to see how easily it will rotate. Each lever is tested to determine whether there is movement (when the gate and fence are properly aligned) or whether there is no movement (when the lever is blocked against the racking stump). This procedure is repeated with all the pins in the decoder. Eventually, the shape of the key will be formed with the combination of pins within the cam and the lock will open.



Actually, the system is quite simple in concept and operation. If the cam is stiff and unable to rotate, the pin should be changed to the next shorter length. When the cam becomes loose and is free to move, the pin should remain because the lever either is in the correct position or is not binding at that time. This system will work on any tensionable lever lock without regard to the number of levers. False notches are not relevant.

31_4.4.1.3.2 CISA Lever and Pin, Pin and Cam System

LSS303: Pin and cam system for CISA and other European locks, by John

Falle

This highly specialized decoder is for use on the latest development by CISA. The cylinder lock is designed for attachment to an existing CISA six-lever mechanism. The new lock has eleven pins which seat within cuts on the shaft of a normal lever lock blank (six pins on one side and five pins on other).

The user then has his original key duplicated onto the new blank; the result is a key which contains both lever cuts and pin cuts. To open the door, the user must first insert his key into the outer pin lock and turn it 90°. Once this has been accomplished, the key is free to enter the original lock and operate it in the normal manner. This is a clever improvement and is designed to protect the lock against picking, impressioning and many other forms of attack.

The modified Falle system defeats this lock with considerable

ease and consists of two decoders. The first will identify the code of the pins in the external pin lock. This information is then transferred to the tip of the modified Pin and Cam System, then used to defeat the internal lever lock.

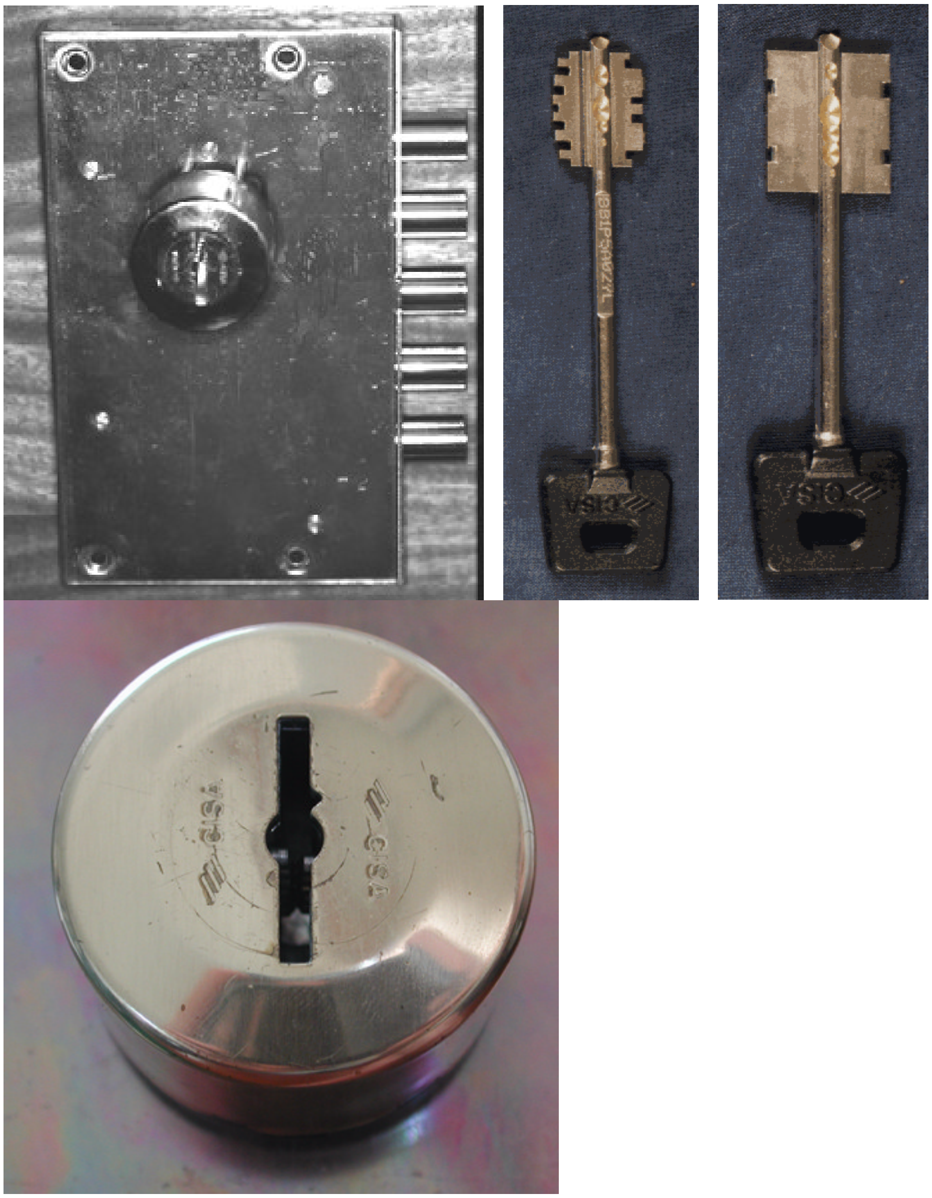


Figure LSS+3104 The secondary locking system introduced by Cisa. Note the bitting for a pin tumbler lock on the middle of the lever keys.

31_4.4.1.3.3 Chubb Battleship Pin and Cam

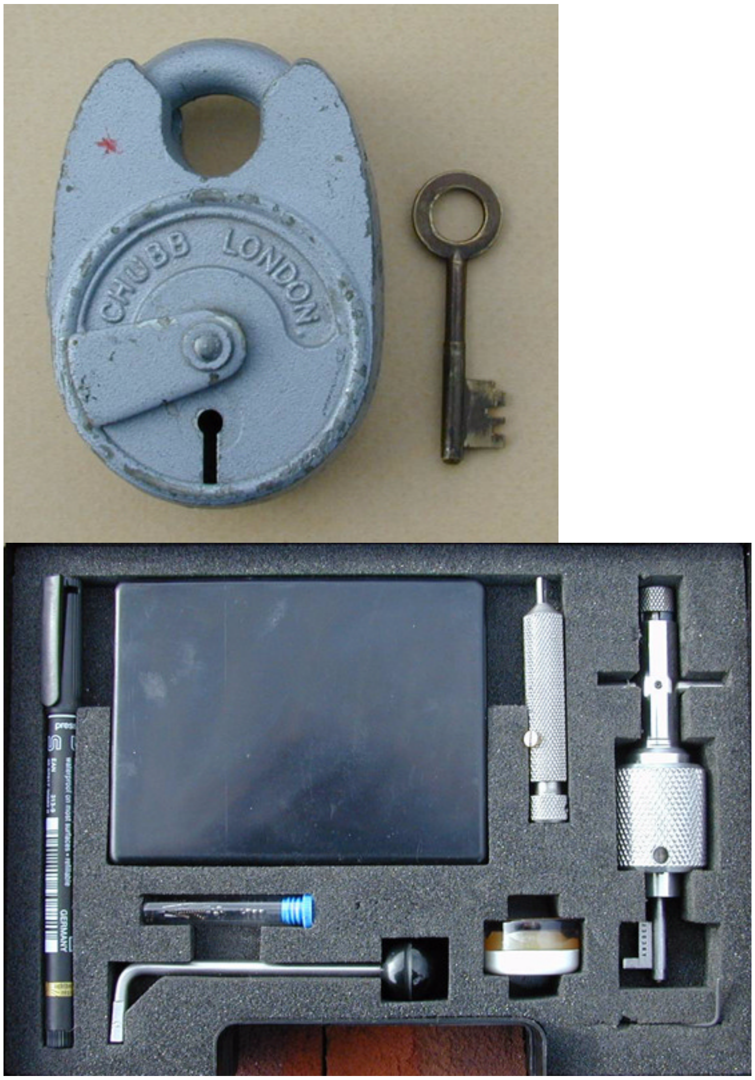

Figure LSS+3132 Chubb Battleship Pin and Cam system by John Falle.

This Pin and Cam System is for use on the Chubb Battleship six Lever padlock. The system is slightly modified and is much smaller than other systems for normal lever locks. The decoder will both open the lock and also allow the code to be derived. The system is easy to learn and use within a relatively short period of time. A lock can usually be bypassed within a period of three minutes of less. No additional training is required if the operative is familiar with other pin and cam systems.

31_4.4.1.4 European Lever Lock Decoder

This device, also produced by Falle, is only sold to law enforcement and government agencies. In order to function

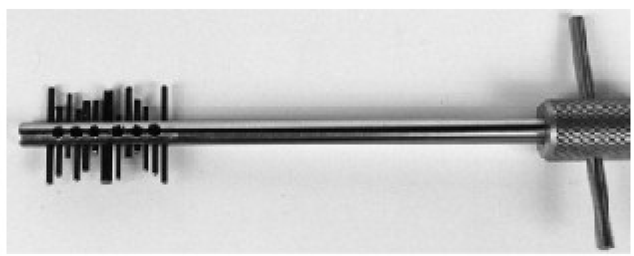
properly, the lever lock first must be picked before decoding. It is effective on all **double-bitted lever mechanisms** that require the key to be turned at least two complete revolutions to open. Cisa has also introduced a secondary locking system that must be bypassed before the lever pack can be accessed. Note the **triple bitting** on the keys shown above. The **new Euro Lever Lock decoder** is also shown. See **LSS+/x** for detailed operating instructions.

LSS301: European lever lock decoder, by John Falle

LSS302: European lever lock pick, by John Falle

This tool is designed to open **lever locks** with certain characteristics. Specifically:

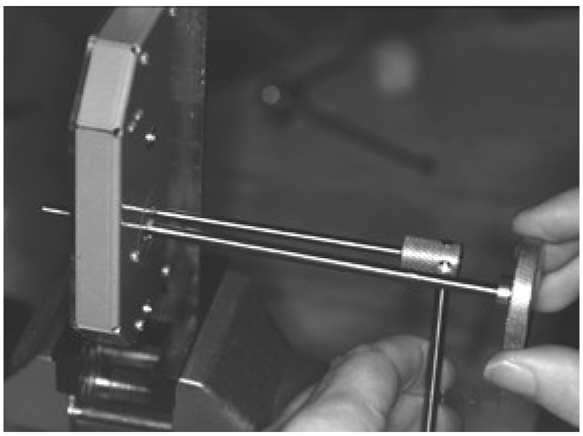
- **The levers have several gate areas; the first and the third, and the second and the fourth always have the same coding;**



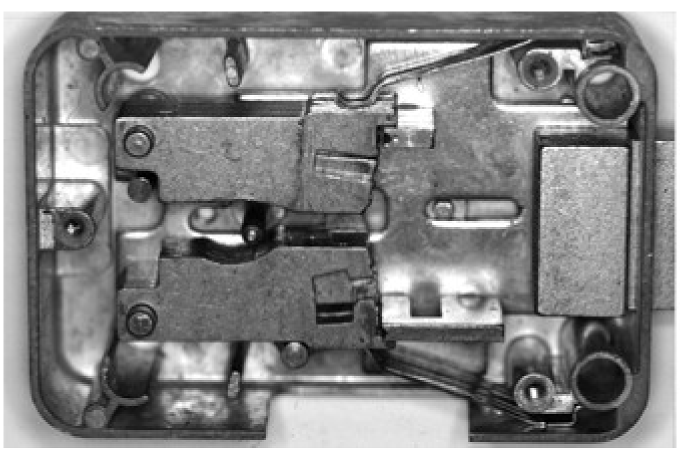
- **In most cases the opposite sides of the bitting are symmetrical and reversed, allowing the key to work when inserted from either side of the door;**
- **There are two packs of three levers each, one on either side of the bow. This effectively prevents the design of a two-in-one pick (wheel pick) for this mechanism; a three-in-one pick would be too weak to manipulate the levers.**

Figure LSS+3105 The MCM lock is one that can be decoded and opened with the Euro Lever Lock system. Courtesy of John Falle.

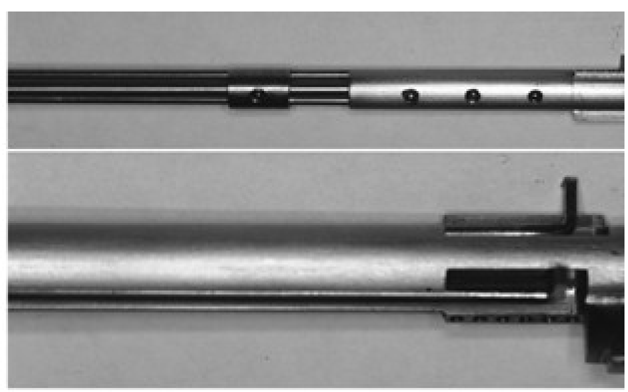
Consequently, Falle has designed a **two-in-two** system, incorporating a series of three tension tools and two different picks. Each of the tension tools and picks have adjustable and interchangeable lever lifters. The tool allows the picking and decoding of a multiple-turn device. This requires the resetting of tension to different bolt sections and repicking the lever pack.



In practice, the lock is picked to a partially rotated position (bolt not entirely thrown) so that decoding may proceed. On the pick body, there are a series of 1 mm markings as well as fractional indicators. A separate depth gauge is also provided.



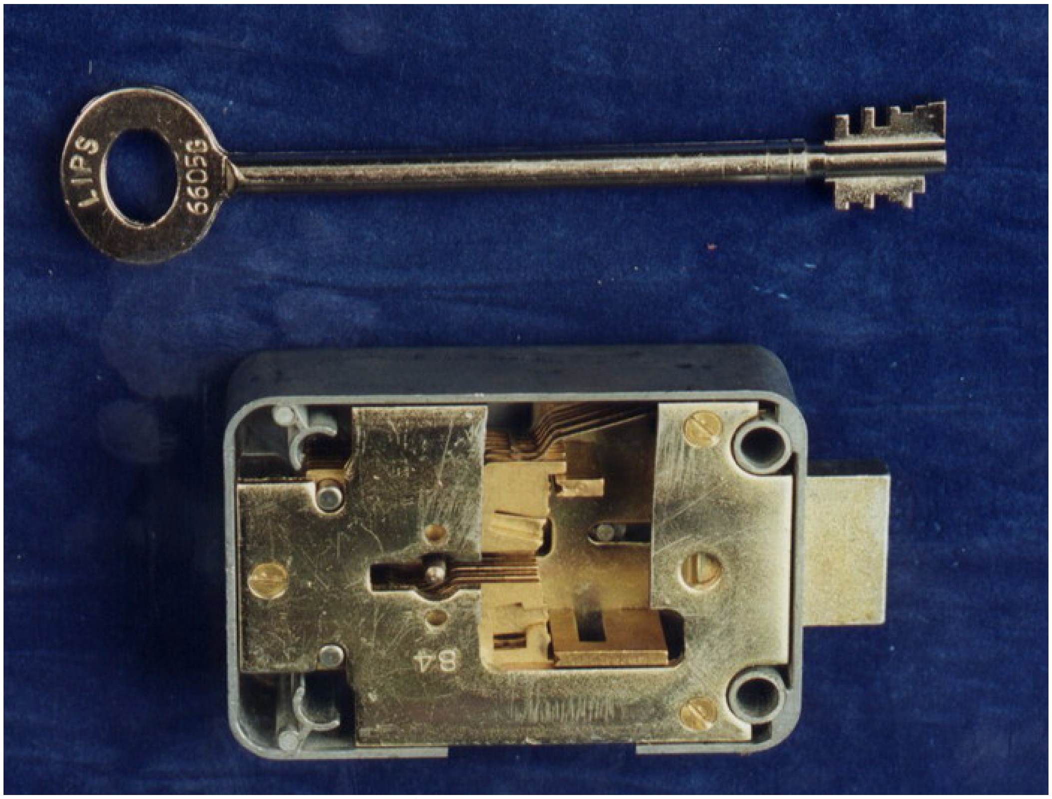
The tool is placed under each lever and moved into position to lift that lever to the correct height. Once all levers are decoded, a key is produced.

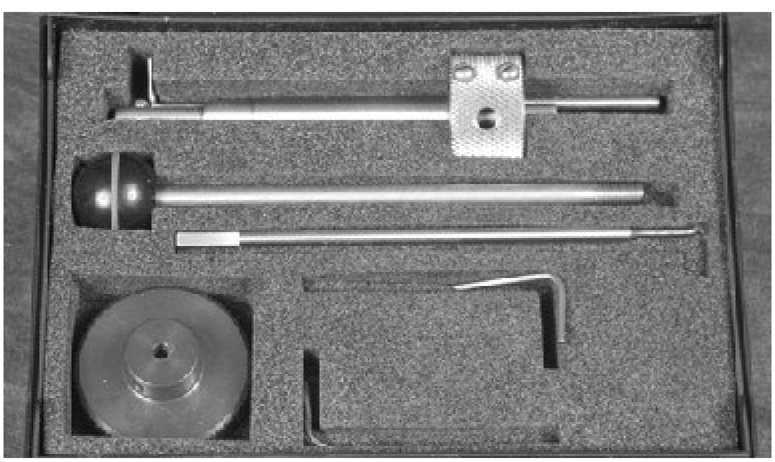


A recent innovation has been developed for many of the double-sided lever locks in Europe. The decoder will effectively identify the codes of one half of the key very quickly and silently. This enables the user to construct a variable key and rotate the lock into its second position before using the Pin and Cam system to identify the second side of the key.

The system has been designed for several popular locks in Europe, including Cisa, Lince, MCM, CR, Esety, Fiam, Mottura, S.I.A.S, and Cerutti.

31_4.4.1.4.1 Chubb/Lips Decoder





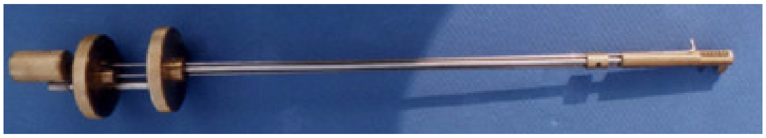


Figure LSS+3106 The Chubb/Lips lever lock can be opened with the John Falle system. Courtesy of John Falle.

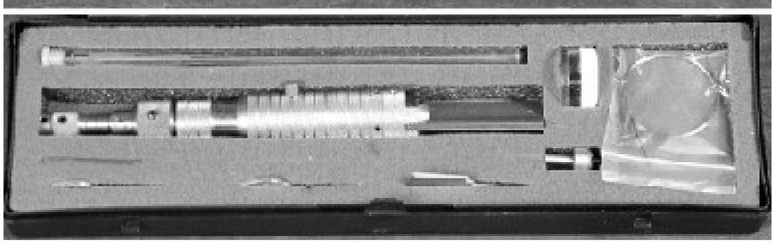
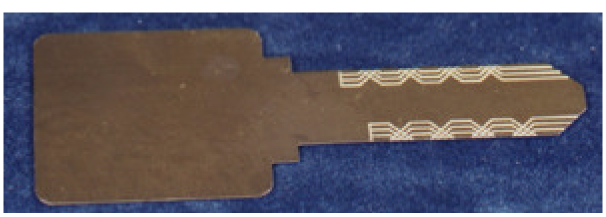
The Chubb/Lips lock decoder system is designed for use on the fourteen-lever Lips Lock which is now being fitted to top-grade Chubb Safes and various other European safes. The system is a modified three-in-one wheel pick combined with a variable key in one tool. It is relatively simple to use and will allow the lock to be opened and a code generated for the key.



31_4.4.1.5 Ingersoll Decoder

The **Ingersoll Impregnable** lock is produced in a ten-lever high-security padlock or cylinder and six standard lever systems. Although Ingersoll is a relatively small company, their locks are extremely difficult to covertly bypass. They are available in several countries, and the tool is thus briefly mentioned here.



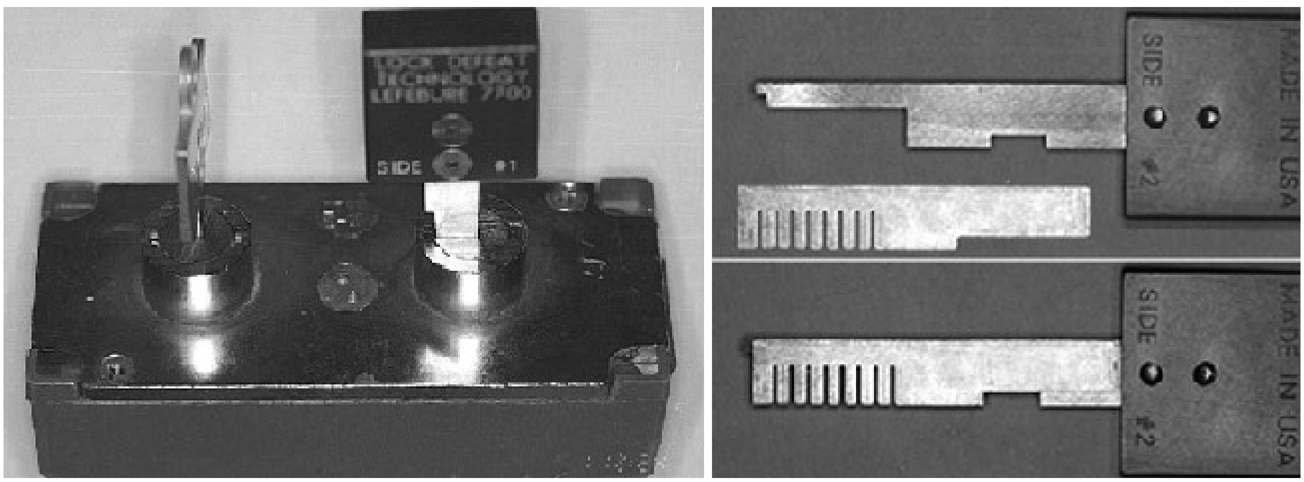


Figure LSS+3107 A key is produced as the result of decoding the Ingersoll, using the variable key generation systems. Courtesy of John Falle.

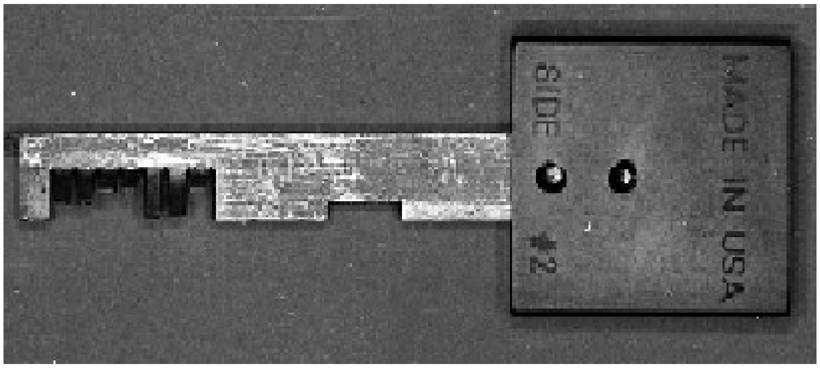
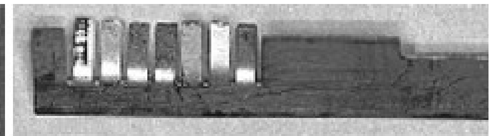
The decoder is a modified **pin lock decoder** as described above. It incorporates a specially engineered key tip, and a custom gauge on the body that controls the position and angle of the

needle and shim delivery system.

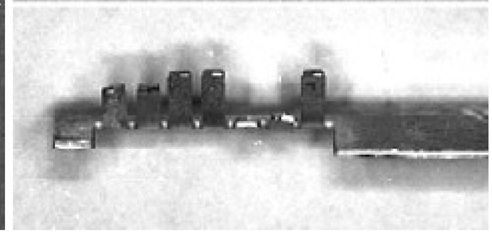
31_4.4.1.6 LeFebure Lever Lock Decoder

The LeFebure seven-lever dual-control lock is utilized in safe-deposit vaults throughout the United States. The bitting combination for both the renter's key and guard key can be changed without disassembling the mechanism. See **Chapter 22** for a detailed description. A decoding/impressioning tool for the 7700 series was introduced in 1997 by **Lock Defeat Technology.** The system allows almost instant bypass of the renter's lever pack and will produce an impression on a brass blank that can be decoded through extrapolation.

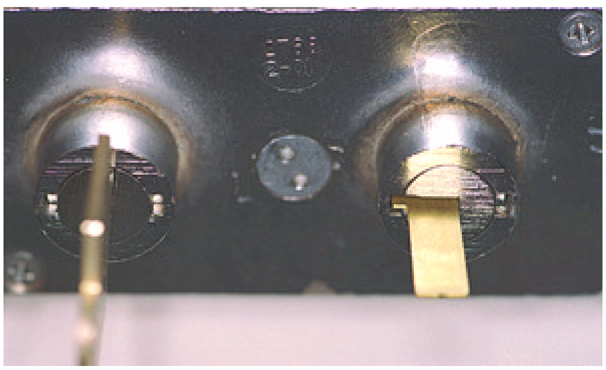




Exploded view 1, 2, 3, 4, 5.



Individual levers in each lever pack are identical in design with regard to the spatial relationship between gate and belly. Differs are created by physically placing a lever in a different position within the lock.



Decoding and impressioning this lock is extremely simple because the location of each gate directly correlates with the position of the lever and its belly. In many respects, the design of this lock is identical to a conventional wafer mechanism. In both instances, the active locking components are offset by the precise distance to the gate or shear line. The impressioning and decoding process resembles the use of plasticine and yields almost identical results. In practice, a special brass strip is inserted into the lock alongside a key guide that is used to actuate the bolt. The strip is then forced against the lever pack until stopped, resulting in a precise impression of the

relative position of each lever.

The guide key, in concert with the impressioned brass strip, is then turned until the levers are raised to the position of the fence. Because the strip mirrors the relative height of each lever at the drop in point, all that is required is that the strip be rotated to the correct position. The impression strip can then be decoded if the amount of rotation required to bring all gates to the fence can be ascertained.

31_4.4.1.7 Falle Floating Pin Decoder

Falle developed what can be described as a floating pin decoder for determining the position of the bellies in a lever lock. This device consisted of a nylon cam that had holes drilled to correspond with the spacing of each lever. Steel pins were inserted into the cam, and the lock was in effect impressioned. As each tumbler was biased, the position of each pin would change, until all of the pins corresponded to the height of each lever.

31_4.4.1.8 Fichet Decoder Systems

There are now at least three different safe locks produced by Fichet in France. The oldest of these locks is now very rare and was produced for safes prior to 1966. Several tools have been introduced that are capable of opening the original mechanism. Consequently, the lock was upgraded and modified to prevent bypass.

31_4.4.1.8.1 Fichet Monopole Decoder

Falle initially designed a tool to decode the original lock. Fichet introduced another modification to increase security. The present decoder will defeat this lock, but it is much more difficult to do. The Monopole system is shown below.

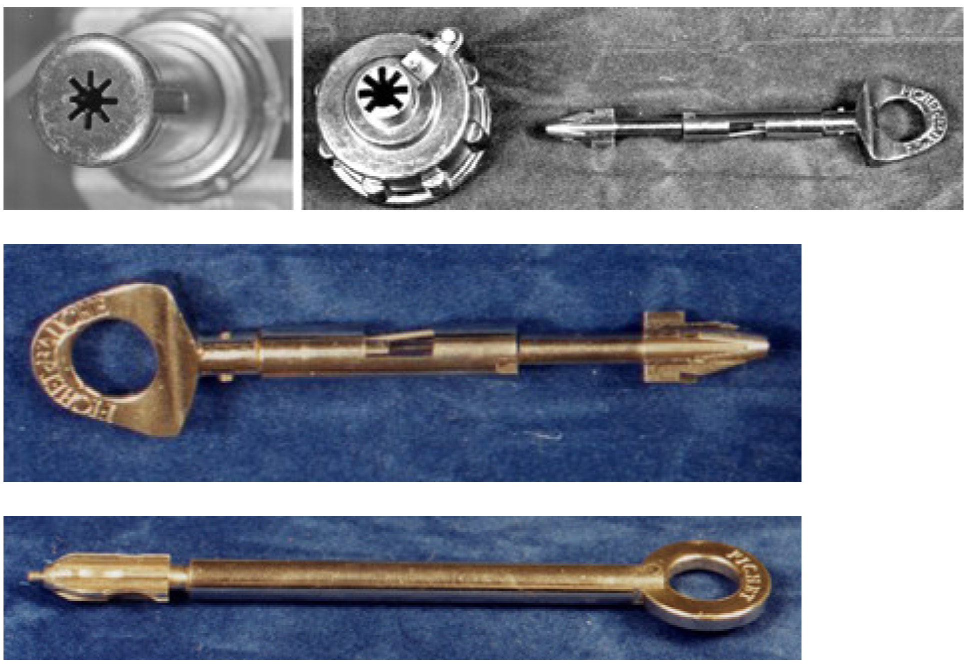


Figure LSS+3108 Note the unusual design of the key for the Fichet Monopole lock. Courtesy of John Falle.

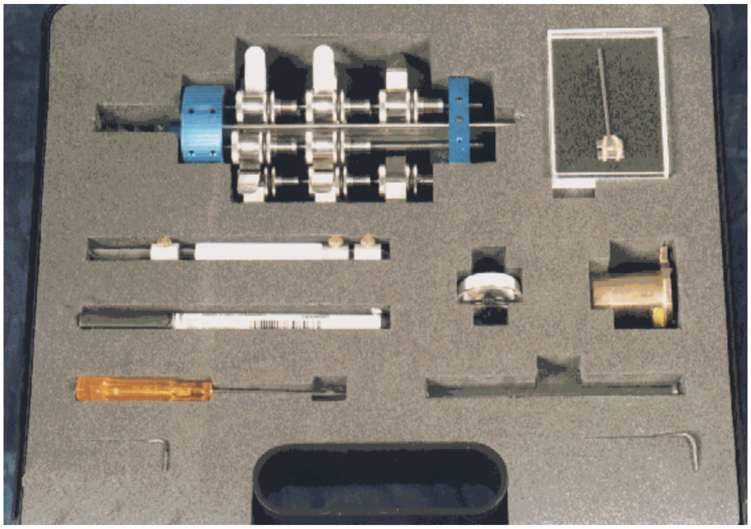
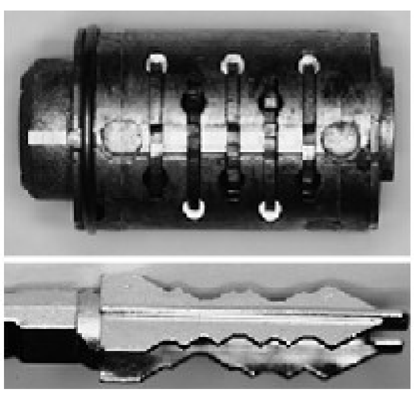
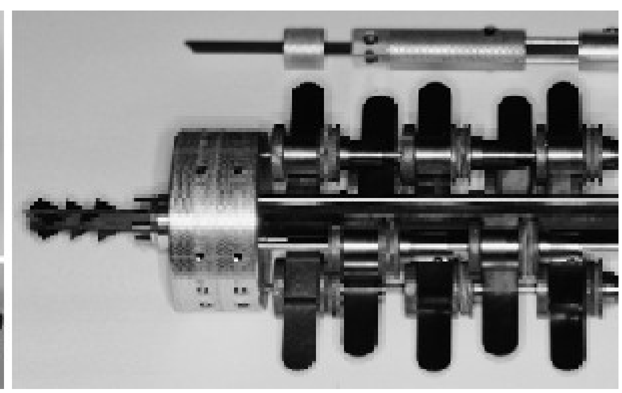
There are two features of the lock that need to be identified in order for it to be opened (**tilt** and **push**). The **tilt** feature is identified by the tilt gauge, which is extremely easy to accomplish. The **push** feature is defeated by way of a specially modified pick and this is easily accomplished if the lock was manufactured prior to 1997. If the lock is third generation, however, both features will have to be defeated with the modified pick; this can be very difficult. In the photographs below, the "H" series lock and decoder is shown.

31_4.4.1.8.1.A Fichet "H" Series







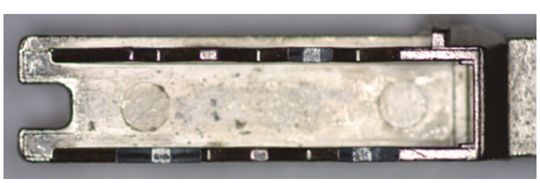


Figure LSS+3109 The decoder system for the Fichet H series lock. Courtesy of John Falle.

This Fichet lock contains ten small levers and two sidebars. The lock has been sold for many years and is extremely popular in many European countries. The decoder system consists of two separate tools which are both used during the opening procedure. The decoder will not only open the lock but will also result in the acquisition of a code.

 

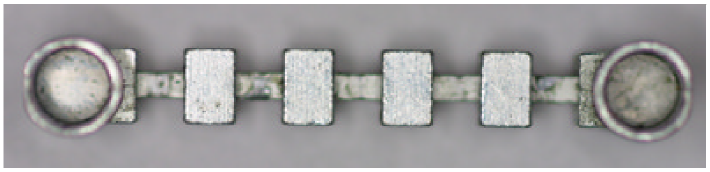

Figure LSS+3110 A perpendicular view. In the "H" version, the sidebar mates with the gates on each disc.
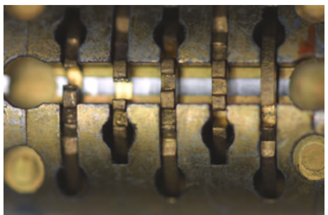
of the Fichet key.



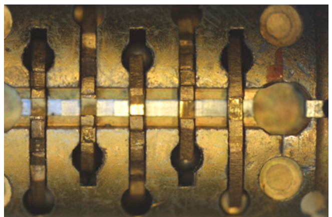


Figure LSS+3111 The Fichet lock contains two sidebars, controlled by five pairs of circular discs that pivot around a central pin. The bitting on the key causes each disc to rotate until its true gate is properly aligned with the sidebar. In the above photographs are shown the core which contains a slot on each side which provides a recess into which the sidebar can retract when the gates are properly aligned. From left to right (and in the linked exploded views), the discs are not properly aligned and thus will not permit the sidebar to retract; the gates are aligned; the sidebar is in a retracted position, and the sidebar is protruding, thus preventing the core from turning within the shell.

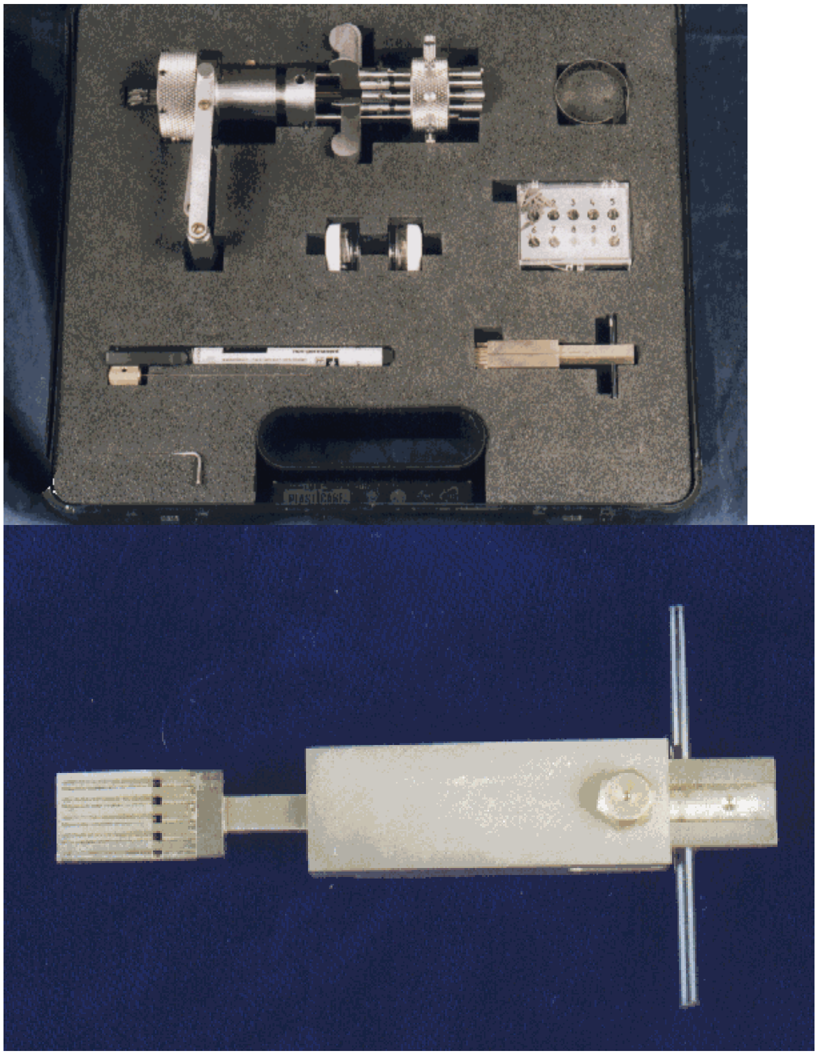
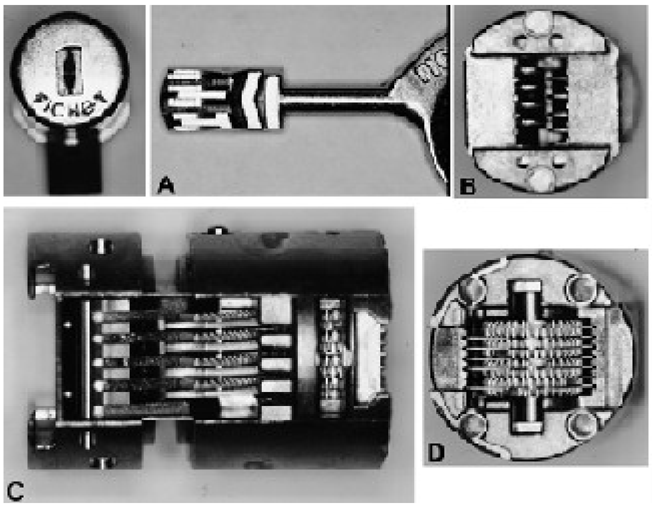
31_4.4.1.8.2 Fichet Pump (787) Decoder System





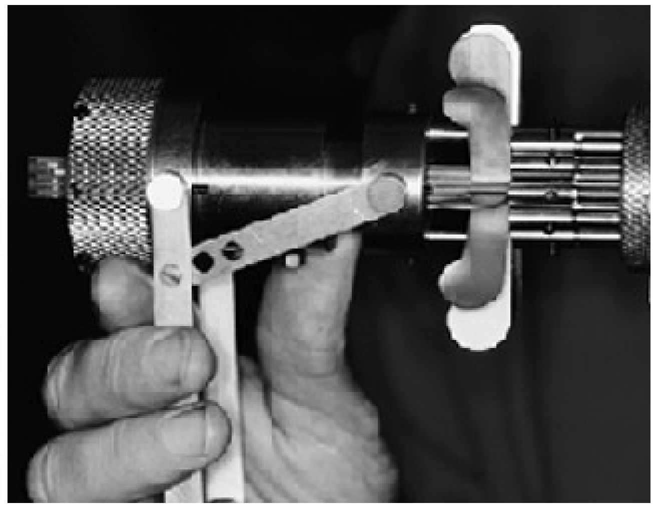


**Figure LSS+3112 The Fichet decoder system and variable Key which can be constructed to the correct
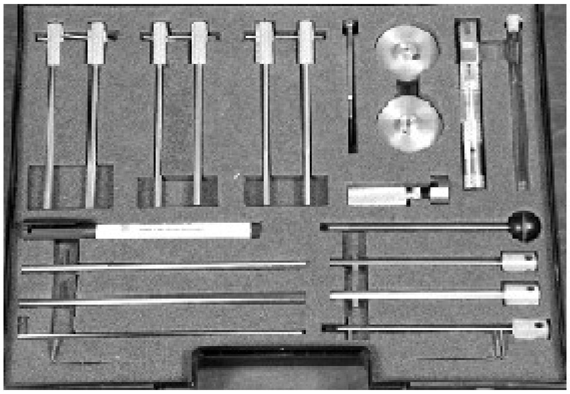
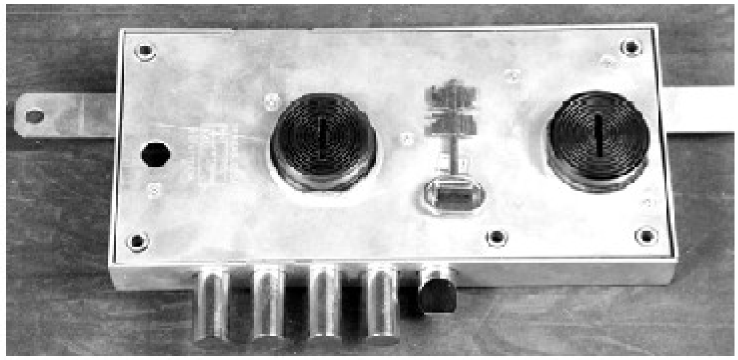
code and used to open the lock, once decoded. Courtesy of John Falle..**

The system is a very specialized decoder that is for use on the French made Fichet 787 Pump lock. This rather complicated mechanism contains ten small levers that are activated by the unusually shaped cuts on the key. The lock is only found in high-security applications. The decoder system consists of a specially designed picking tool which fits onto the body of the lock; the design of the pick allows the lock to be manipulated quite easily. By using the decoder gauges, the code of the lock can be easily determined. A variable key system allows the construction of the correct bitting pattern in order to open the lock.

The main limitation of the system is that of speed during extraction. The decoder is clamped onto the lock with eight locking screws. The clamping system is designed in such a way as to cause no damage to the lock, but if the user has to remove the decoder in a hurry, it will take at least thirty seconds to do so.



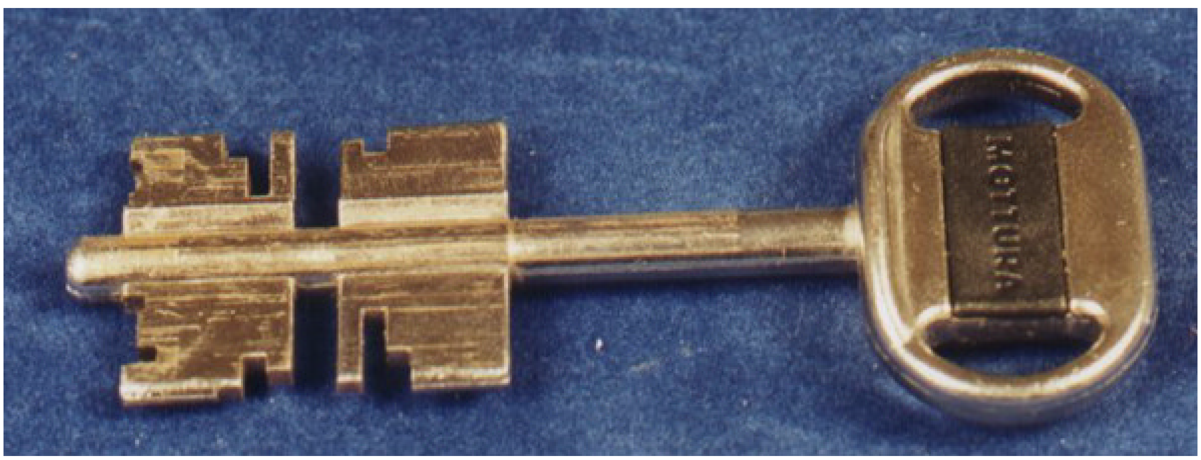


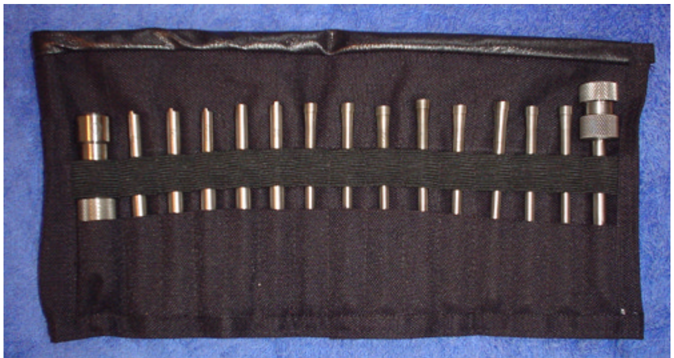
With only minimal training, the user should be able to pick and decode the mechanism in less than three minutes. There is also an eight-lever version of the lock, which can be bypassed with the same decoder in even less time. Up to five minutes will be required to construct the variable key, but this can be done in another location.

31_4.4.1.9 Mottura Serrablocca Pump Lock

This Falle system is designed for use on the Pump mechanism contained as part of the Mottura Serrablocca lock. This unusual design is a combination of two separate locks in the same body. The key has features of both a pump key and a lever lock key and has to be inserted into both keyways in sequence.

The lever portion of the mechanism has to be operated before the pump section can be turned. This can be accomplished with either a Pin and Cam system or the Euro lever lock Decoder described earlier. The Pump decoder is a quick and easy way of defeating this mechanism, and it will open the lock and produce a key code for future entries. This system will usually result in an opening in less than ninety seconds.





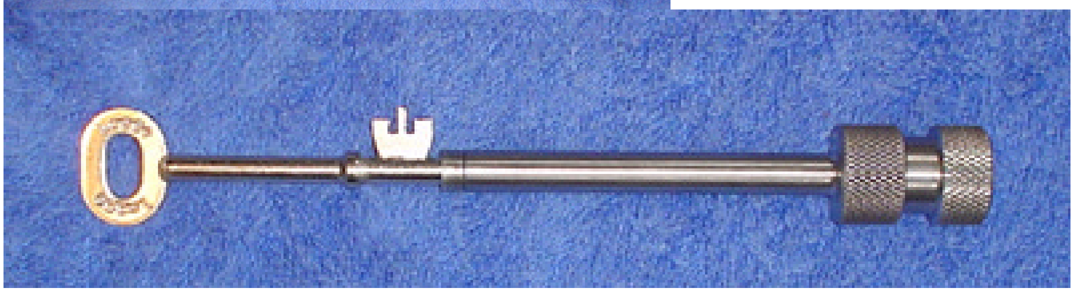


Figure LSS+3113 The Mottura double-bitted lever key. Courtesy of John Falle.

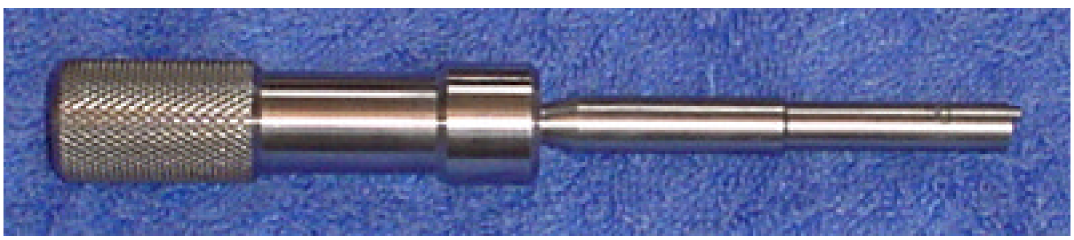

31_4.4.1.9A Key Turning System

LSS304: Key turning system for lever locks, by John Falle

A system for turning European lever keys from the other side of the lock is available from John Falle. In certain instances, the owner will have left the key inside the lock on the other side of the door. The kit is designed to grip the end of the key that is available through the keyhole. The system is neither a decoding nor picking tool.

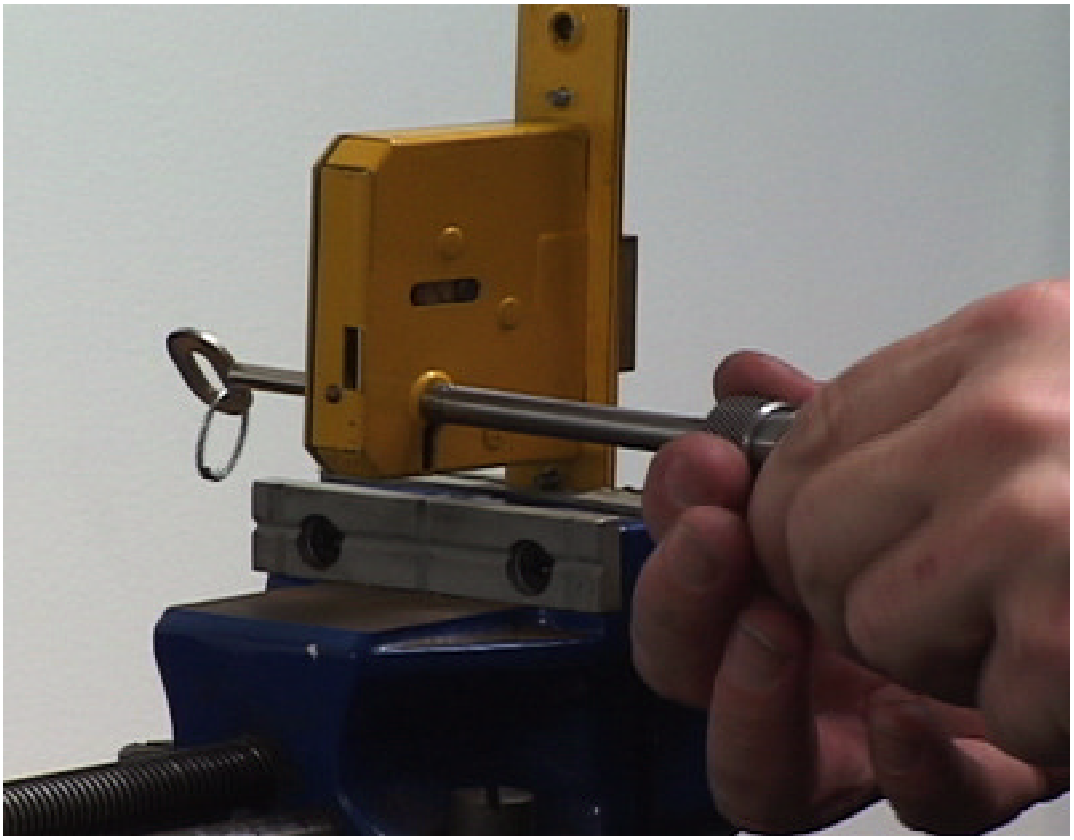

Figure LSS+3131. A key turning system for lever locks.

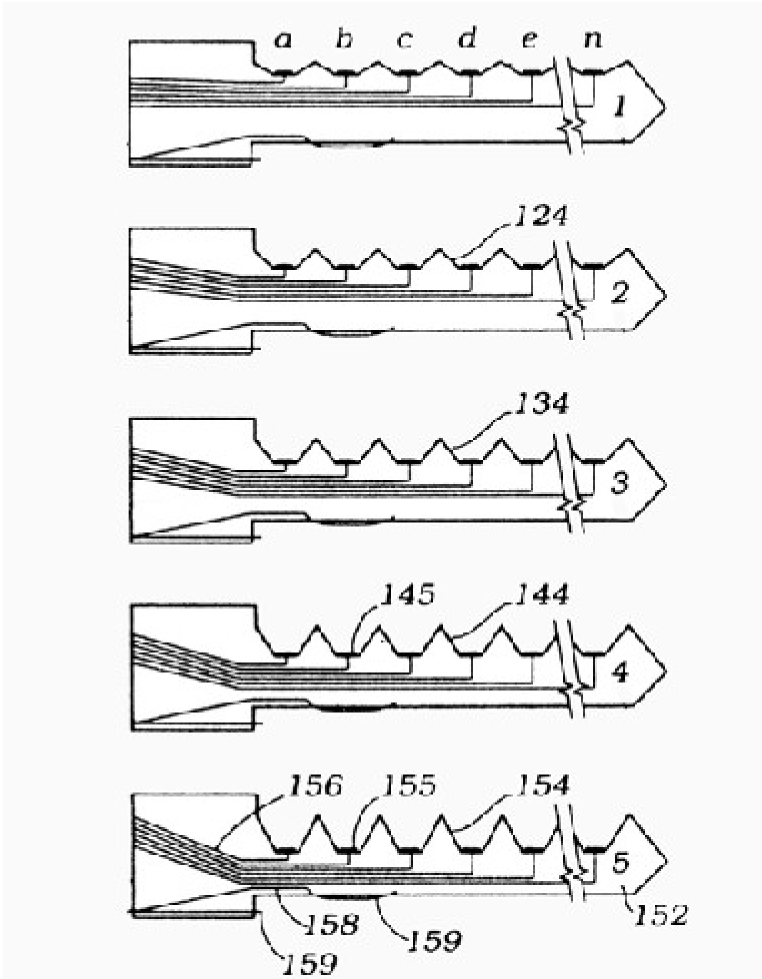
31_4.4.2 Wafer and Disc Lock Decoders

In **Section 3.2**, decoding and reading of wafer locks by the direct observation of active locking components was discussed. Those procedures were based upon the ability to actually see or measure the bitting for each wafer. In this section, we will concentrate on indirect measurement of the bitting surfaces, requiring an extrapolation of data in order to arrive at the proper code. Many United States patents have been granted for decoders of wafer and disc locks. Five primary patents have been issued since 1934 and are summarized here. In addition, sophisticated systems developed by John Falle are described.

31_4.4.2.1 Code Finding Devices

Several "code-finding keys" have been patented. Generally, the function of these devices is to determine the height of each wafer when raised to shear line. Simon developed a "code-finding key", in 1934 (**2015322(307)**) for determining the depth of each

wafer. The design utilized a key, with each depth-cut having several longitudinal segments. This allowed the device to be moved within the lock in an attempt to determine which tumbler was at shear line.



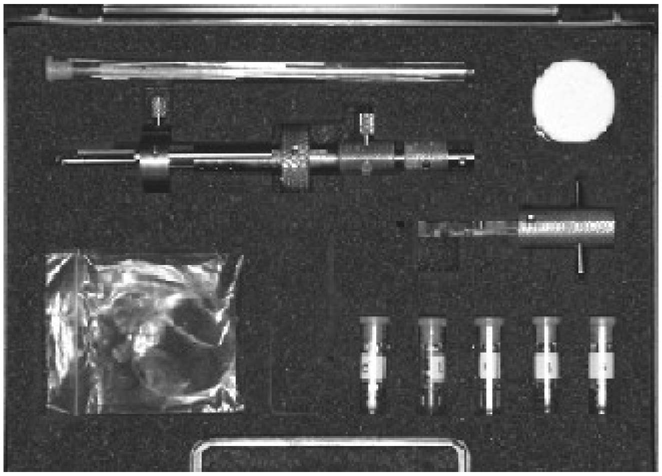
The following year, Hansen (**1991151(308)**) developed a decoding and reading device for wafer locks that utilized a sliding pick attached to a gauge. The feeler pick could be moved both horizontally and vertically to manipulate each wafer and read it. In 1937, a patent (**2066645(309)**) was granted to Rial for a more sophisticated wafer decoder. This instrument was comprised of a moveable pick that was attached to a gauge. The pick could be moved laterally to cooperate with each tumbler. As the wafer was raised to shear line, a reading would be taken to determine its depth.

In 1941, Hoffman (**2257054(310)**) invented a device for decoding a pin tumbler lock with a mechanical feeler that also allowed manipulation of the tumblers.

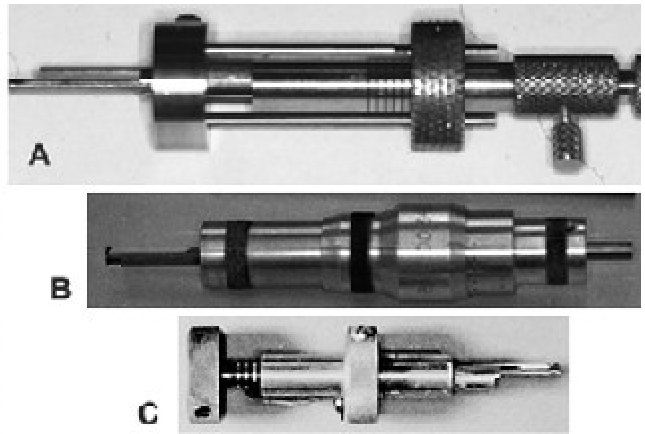
Tampke received a patent (**2727312(311)**) in 1955 for a device that was capable of decoding both wafer and pin tumbler locks. The tool would sense the position of the active locking component when it reached shear line and provide a display of the position of the tumbler that could then be correlated with a depth chart. Easley patented a decoder for a Schlage wafer lock in 1985 (**4517746(312)**). The lock was discussed in detail in the first edition of this text and remains in use in millions of homes and apartment complexes in the United States. It can be master keyed and utilizes three types of disc wafers: **combination**, **series**, and **master**. The decoding tool allows manual sensing of the shape of each type of tumbler so that a key can be generated.

In 1987, McConnell received a patent (**4680870(313)**) for a wafer lock decoding system using a feeler key and shim to determine tumbler positions.

In 1992, a patent was issued to Grant (**5133202(314)**) for a decoder that would sense the position of each wafer through the completion of an electrical circuit. A specially designed set of depth keys would have an electrical contact at the base of each tumbler position. Each key would be inserted and the conductivity of each wafer detected. Any tumblers at shear line would show a different resistance than those not properly aligned.

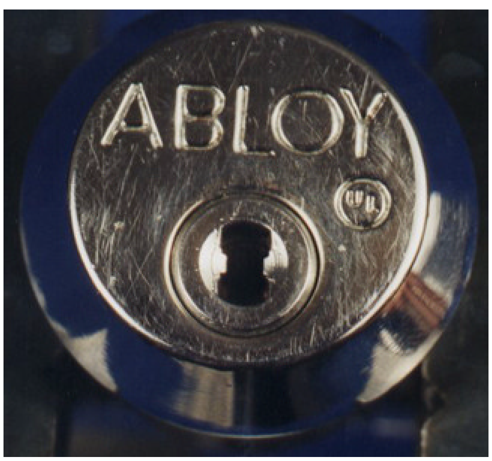


In 2000, a device was patented by Kang for a lock picking tool that utilized a clever reading tool that allowed recording of tumbler position (**6134928(315)**).



31_4.4.2.2 Abloy Disklock and Granit Decoder Systems

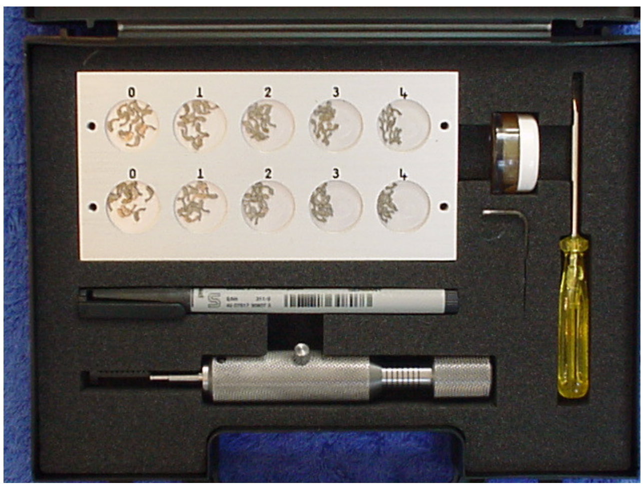
Forensic implications of picking or decoding the Abloy lock. Courtesy of Hans Mejlshede.



According to Falle, the Abloy and **Granit** disc lock decoding tool was perhaps the most challenging to conceive. This was due to the multiplicity of lock designs that incorporate slightly different disc patterns by both Abloy and **Abus**. It was almost impossible to develop one tool to open all of the Abloy locks.

The resulting tool opens all but two of the systems and decodes all but one of them. The Abloy lock is fully described in **Chapter 17.**

The system will decode and open all variations of the 6 mm diameter Semicircular keyway locks, with small, medium, or large discs having reversible and non-reversible design. It will decode and open all of the newer 7.5 mm diameter keyways, small and medium discs, irrespective of the format.



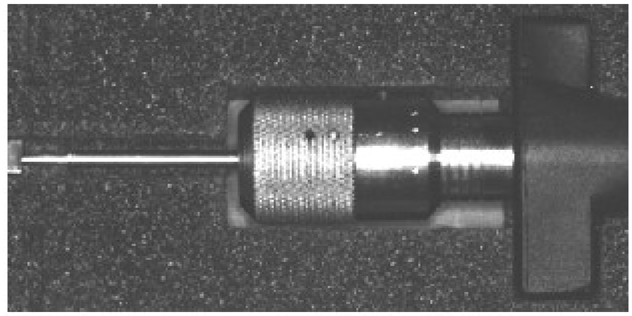


Figure LSS+3114 The different Abloy DiskLock models, and the Abloy pin and cam system.

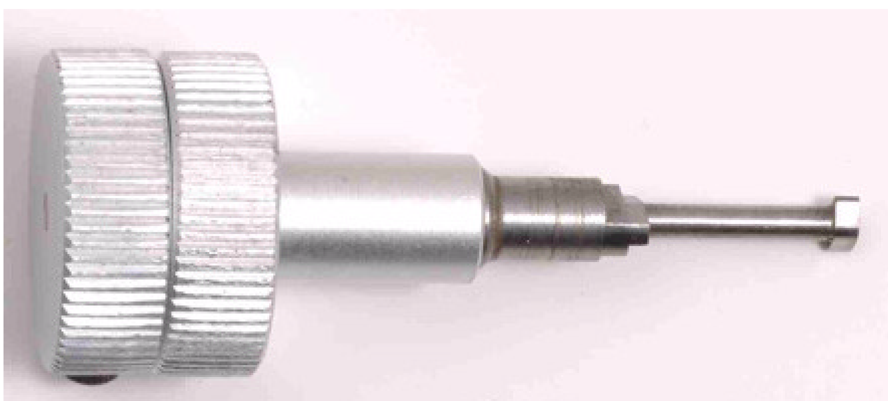
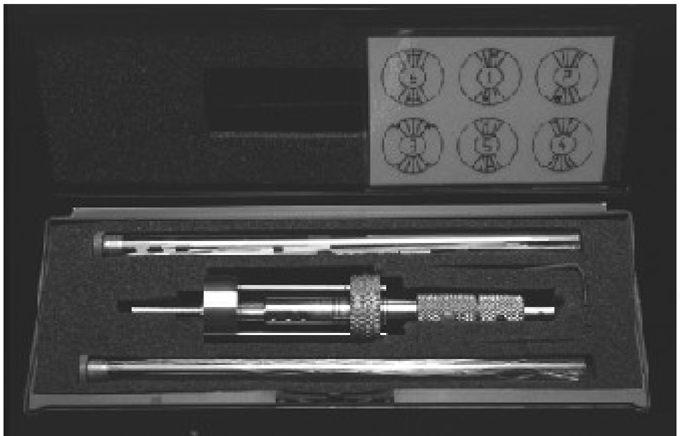
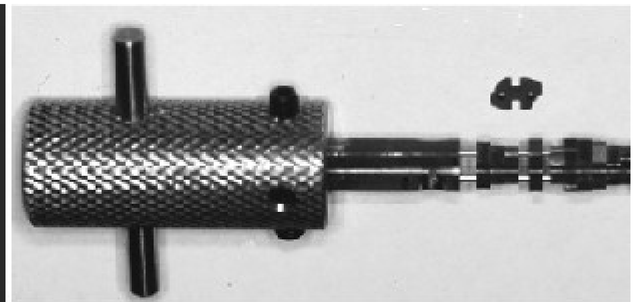


It will decode but **not** open the Abloy Disklock, but it will not decode or open the Abloy Disklock Pro. The fundamental differences between the **Disklock** and the **Disklock Pro** is that the **Disklock Pro** contains spacers of two different thicknesses. These hardened steel black spacers have a different thickness than the brass spacers. If a locksmith has inserted a combination of the brass and the steel spacers, the lock cannot be decoded. The tool will not work on copies of the Abloy system, such as the reproduction from the Orient.

The device is provided with an attachment enabling it to decode and open the Abus Granit lock that has gained such popularity worldwide. Abus produces the lock in four different configurations.

LSS301: Abus decoder, by John Falle





This Abus pick will open both the new and old Abus Plus. The tool was originally invented by Andreas Pabst.

31_4.4.2.2.1 Abloy Disklock Pro Decoder System

LSS303: Abloy decoder system, by John Falle

This system will decode the Disklock Pro. The system has been primarily designed for use on the standard profile keyway, although it may be effective on locks that have modified profiles, which vary in different countries.

The system is designed to decode but not open the lock. Decoding can occur within two minutes with practice.

31_4.4.2.2.2 Abloy Variable Key Generation System

The Variable key generation system is designed to be used in conjunction with the Abloy decoders described above. It enables the user to construct a working key to the code that is derived from the decoder system. The finished key is very precise and conforms perfectly to the specifications of the factory original.

The code must be correct for the key to function. The variable key is quite expensive. This is due to the maintenance of high tolerances during production, using a manufacturing procedure called wire erosion. Construction of the key is very easy and only takes a couple of minutes to complete.

31_4.4.2.3 Tibbe Lock Decoder

Figure LSS+3133 Ford Tibbe decoder and lock. This tool is produced by John Falle.

Falle has devised a combination pick and decoder for the **Tibbe** disc lock that was introduced in Ford and Jaguar automobiles in Europe about 1987. This lock, as described in an earlier chapter, functions in similar fashion to the Abloy disc mechanism. It is a modified sidebar mechanism that relies upon the rotation of discs rather than depth cuts.

The lock is currently produced in two versions: one with six discs and four differs (rotations from 0^{o}- 37^{o}) for each tumbler; the other has eight discs, with three differs (used in Jaguar). Each disc has a hole in its center with angular cuts on the side and a sidebar groove. When all discs are rotated and aligned, the sidebar drops into place. The key has two sides and four identical rows of bitting with a left and right row on each surface. This allows the key to be inserted for either orientation.

The decoder pick is primarily designed for use on the six-disc mechanism, although it may also be used with the larger lock.

The tool is really a modified two-in-one wheel pick, utilized for lever locks. Tension is applied by way of the torque bar. This is inserted into the lock, and hooks into the drain hole on the bottom of the plug. Once tension is applied, the pick can be used to manipulate the discs into the correct position for opening. The picking process involves feeling for true and false gates; the tool will constantly provide an indication as to which disc is being manipulated. Once opened, the direct code can be read from the dial markings on the body of the pick. A key can be cut using the HPC BlueSHARK key machine, and certain Framon cutters, with a special attachment.

31_4.4.2.4 Chubb AVA

LSS304: Chubb AVA pick and decoder system, by John Falle

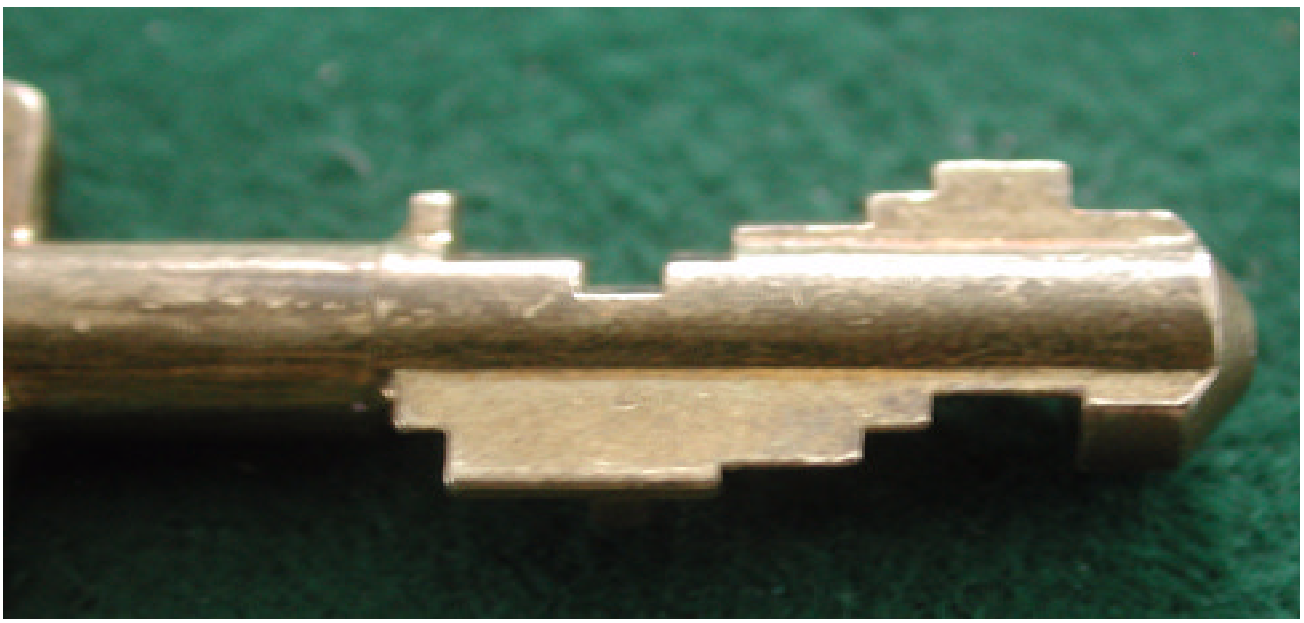


Figure LSS+3134 Chubb AVA key.

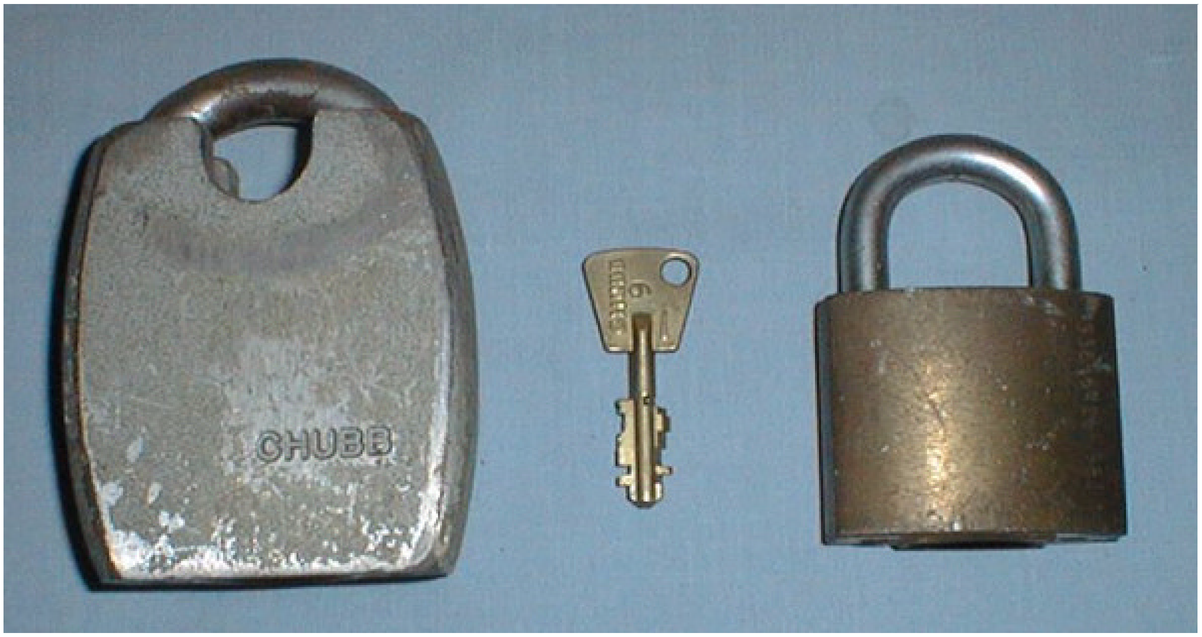
The modified wafer mechanism has been described elsewhere in this text. Falle has developed a **decoding system** that works on the ten-detainer Hercules padlock and other standard designs. The system is most effective on the smaller nine-detainer mechanisms, the Ford AVA, and the Chubb Guardian systems.



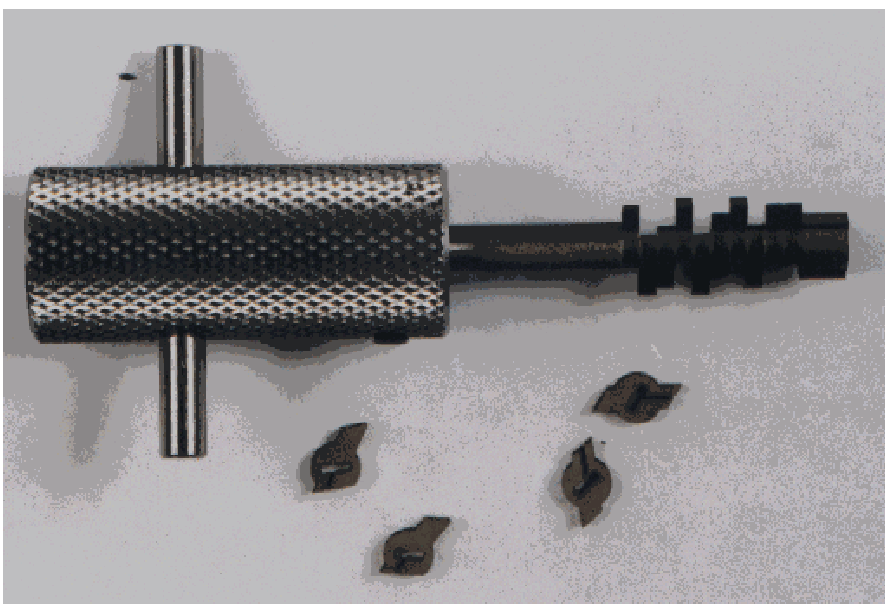


Figure LSS+3115 The Chubb Ava padlock. Courtesy of John Falle.

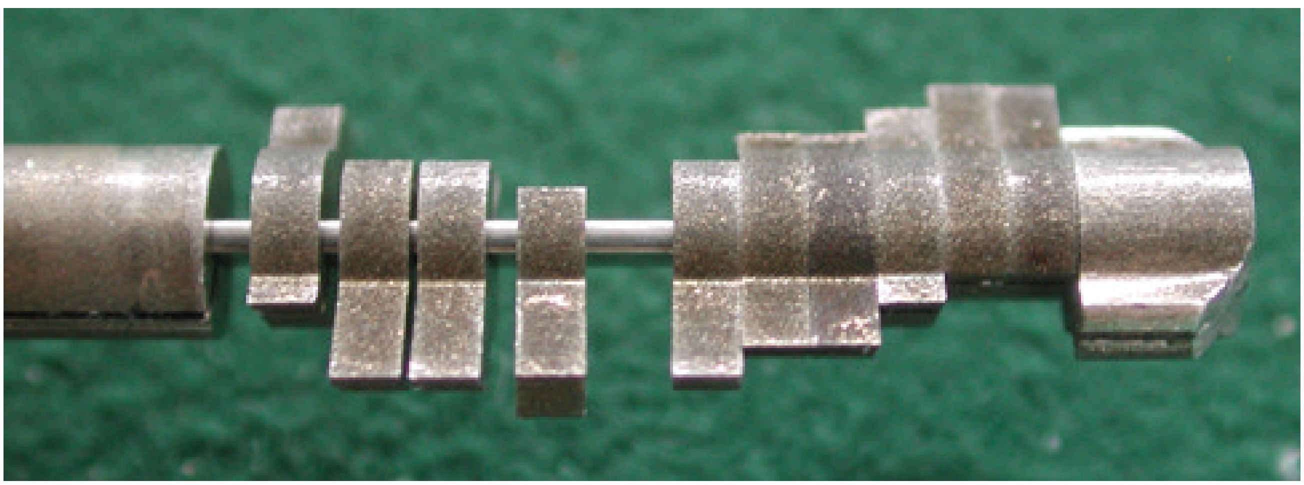

Figure LSS+3116 The variable key generation system for the Chubb Ava wafer lock. Once the lock is decoded, a simulated key can be produced with the same codes. Courtesy of John Falle.

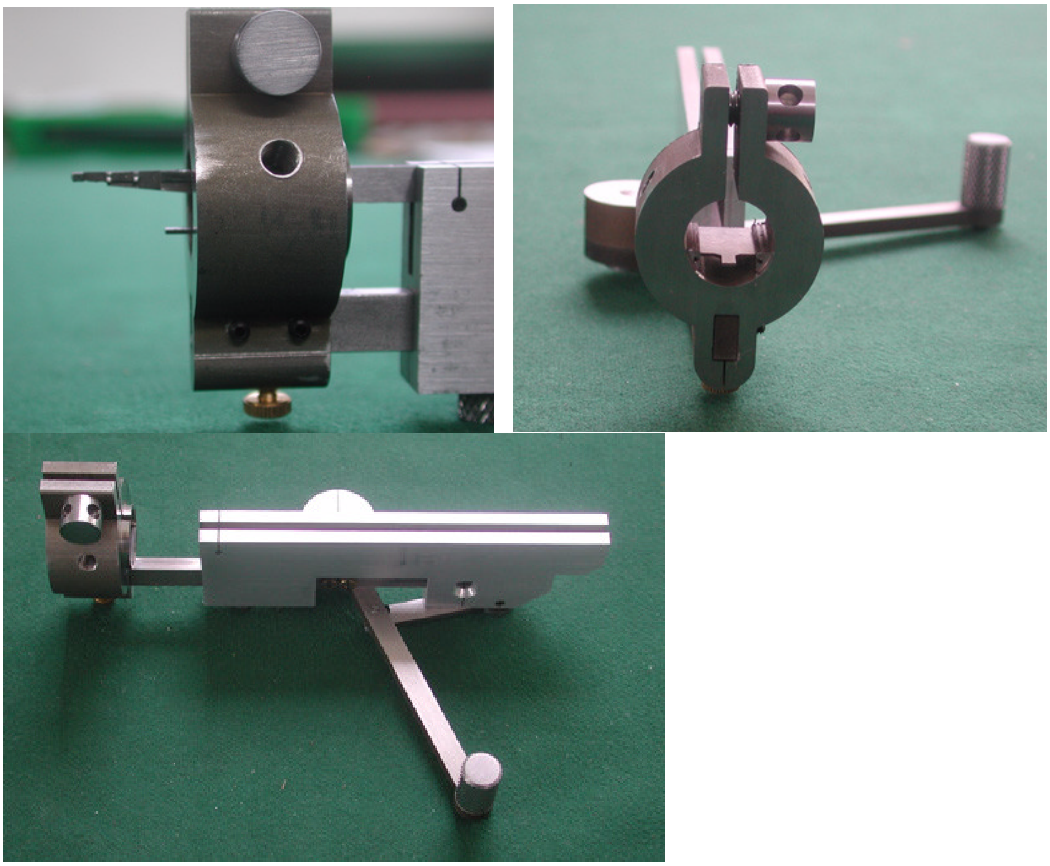
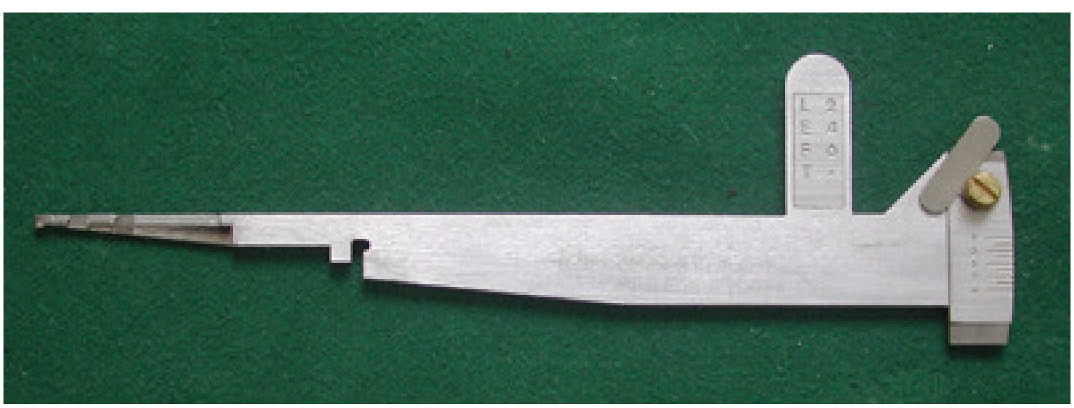
31_4.4.2.5 Evva 3KS Laser Track System

LSS305: EVVA 3KS pick and decoder system, by John Falle

Figure LSS+3117 The Evva 3KS system can decode and simulate a key. Courtesy of John Falle.

The 3KS has been described in **Chapter 17.** It is a sophisticated mechanism that incorporates twelve sliding detainers and two sidebars. The lock is produced to high tolerance and is considered to be highly secure against bypass. The decoder system will open this lock and also provide the user with a code, which can then be utilized to construct a working for later use. It is expected that a variable key system will be available for the 3KS.





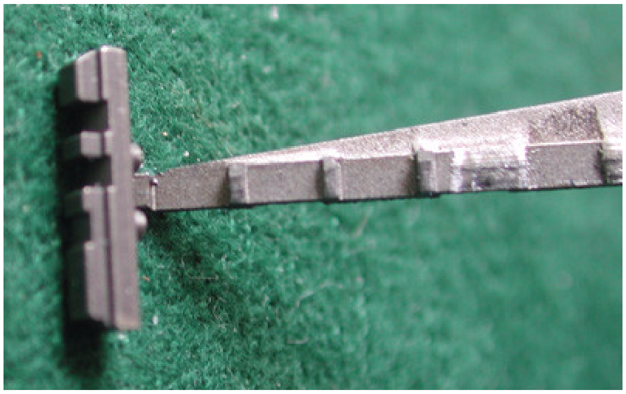


Figure LSS+3135 The 3KS pick and decode system allows the manipulation and decoding of each slider as they are moved into contact with the dual sidebars.

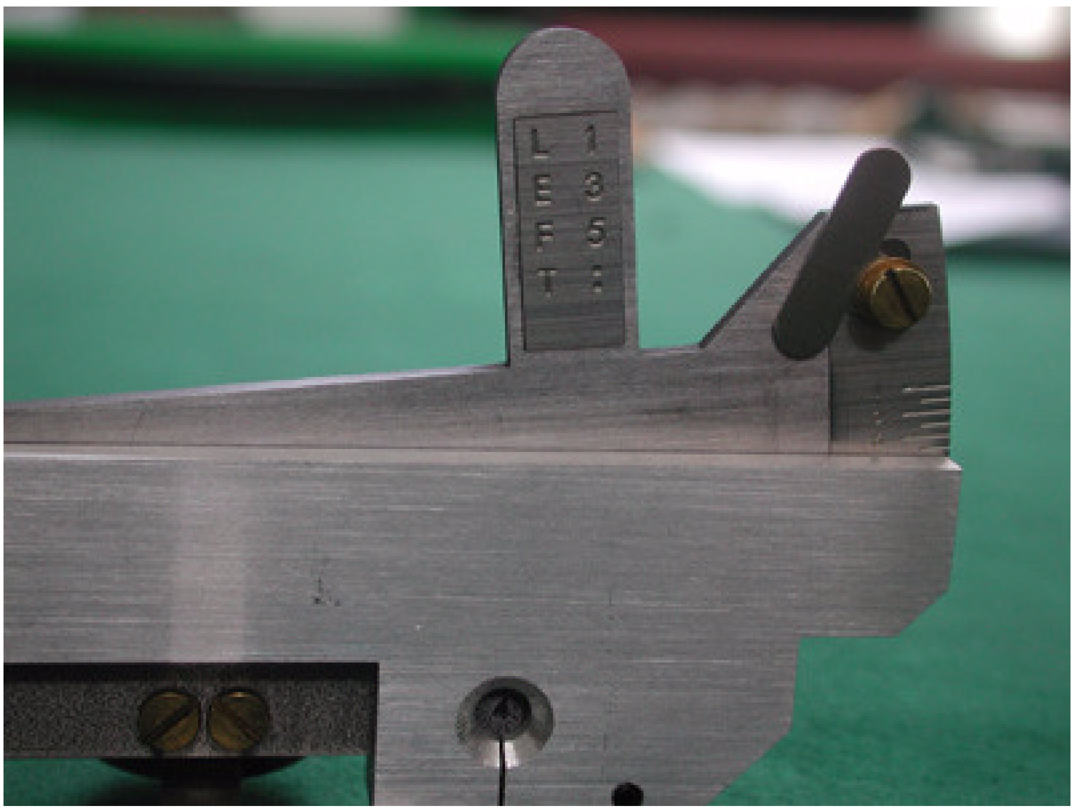
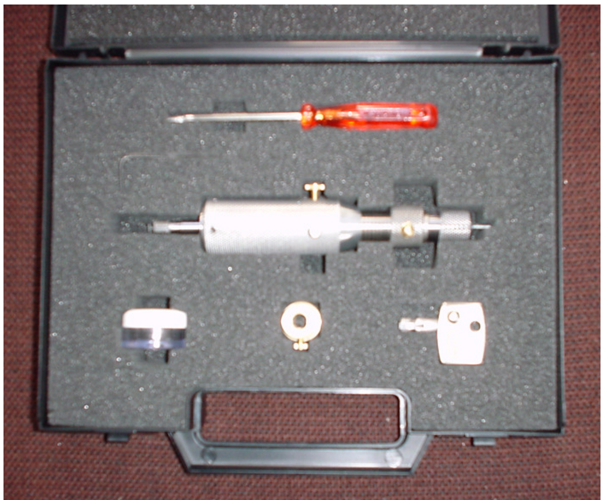
There are system limitations inherent in the decoder tool, which concern its fragility. Some of the decoder components are very weak and will not stand rough usage. The decoder must be used by a skilled operator who has been trained on this specific system. The system requires a minimum level of light during use. The process can require several minutes to complete.





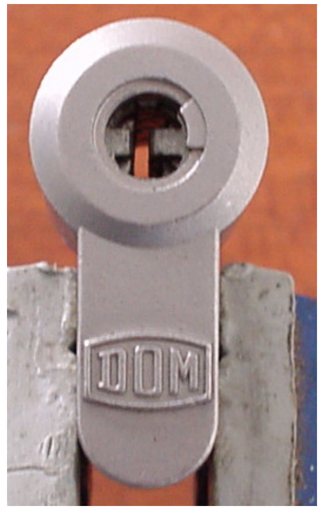


Figure LSS+3136 The slider probe has two distinct designs that allow movement of each wafer. The tool allows a direct reading of each wafer position.

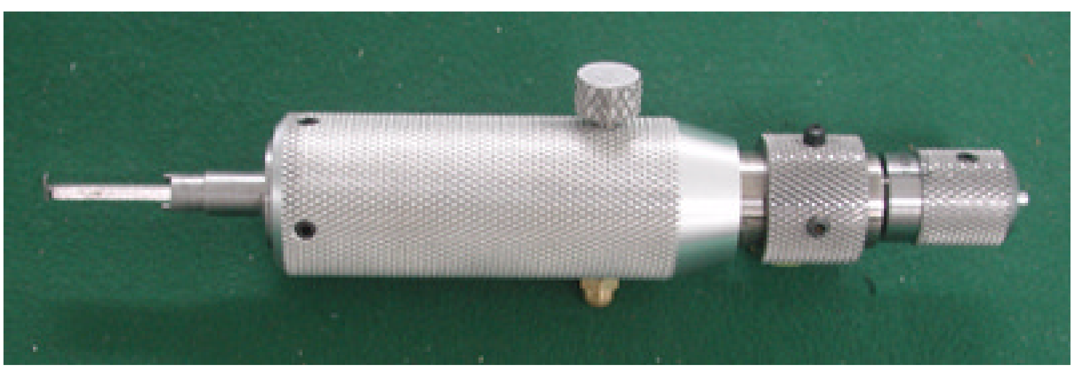
A skilled operator can usually open the a lock in under ten minutes. This period can be interrupted and the user can continue from the point of tool extraction. The process allows the lock to be decoded while it is being opened. This is a very specialized tool that requires proper training in its use.



31_4.4.2.6 DOM Diamond Decoder

LSS304: DOM Diamond decoder and pick system, by John Falle.

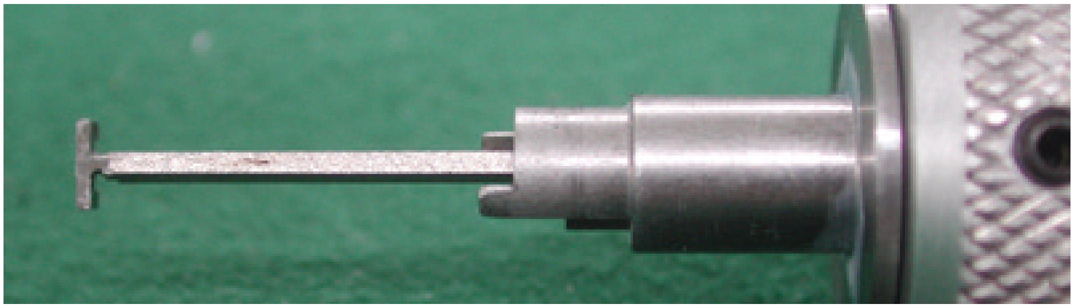


**Figure LSS+3118 The Dom Diamond decoder system by John Falle. The lock in some respects
resembles an Abloy because of the use of wafers.**

This John Falle decoder system is for use on the German DOM DIAMOND mechanism. The lock is very accurately engineered with high tolerances and contains ten rotary discs of an ABLOY type design. The lock is an engineering masterpiece but is very expensive and quite rare. The tool can easily open this lock and also provides the user with a code for future use.

Figure LSS+3119 The Dom Diamond key is very distinctive and unique with its surface of complex angles.

The main limitation of the system is speed. As with all decoder

picks, the time required will depend on the skill of the user. This tool is much easier to use than the Abus Granit decoder, and a skilled operative should be able to open the lock in less than three minutes. Once the lock has been opened, a further ninety seconds will be required in order to determine the code. There are no other machines available that can cut these keys to code. The only way to open the lock a second time with this system is to use the system as an auto-dialer. It is therefore recommended that the user always determine the code if a future entry is required.

This is a highly specialized decoder for use on a top security lock. The system would only be taught as part of an Advanced Entry Course where a full day would be dedicated to its use. The skilled user should be able to open the lock in less than three minutes.

31_4.4.2.7 Ford Galaxy Decoder

The John Falle decoder system is an extremely effective tool for use on the two-track wafer mechanism fitted to Ford Galaxy vehicles. The lock is also fitted to other automobiles including various models of Volkswagen and Audi. This decoder is extremely easy to use and not only opens the lock but also determines the code for future openings. The method employs a variable key that is an integral part of the decoder, and this can be used to open the car on future entries if required. The technique employed in this decoder is a variation of the Pick and Form technique used in other systems such as the Bi-Lock Decoder.

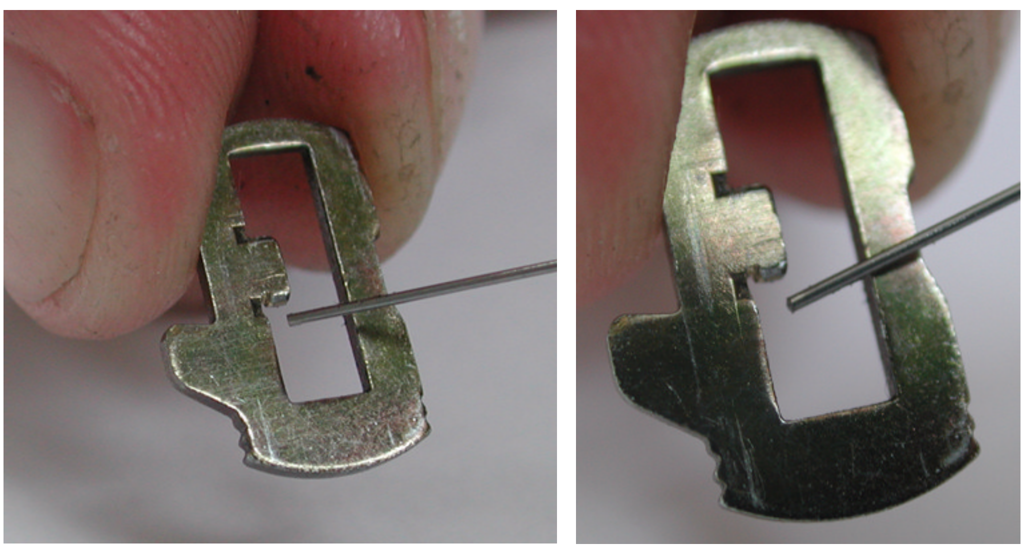

Figure LSS+3141 Ford Galaxy wafers, showing indication of picking

and decoding, indicated by pointer. Note slight indent during forensic examination.

The only limitation of this system is that it utilizes variable key shims of the cut-out variety. This means that each time the user decodes a lock, two shims are required and these cannot be reused. The operative will therefore need to purchase replacement shims from time to time and that will incur additional cost.

This system is very quick; the user should be able to open the lock and achieve the code within a period of two to three minutes. The technique is quite easy to learn and only requires about an hour of instruction.

LSS301: Ford Galaxy decoding system, by John Falle

31_4.4.3 Sidebar Decoders for GM and Ford Automobiles

Four principal U.S. patents have been granted for automobile lock sidebar decoders: (**4185482(316)**) 1980; (**4667494(317)**) 1987; (**5325691(318)**) 1994; and (**5224365(319)**) 1993. There are several methods to pick, decode, and open these sidebar locks as described in the patents. The locks can be bypassed in the following manner:

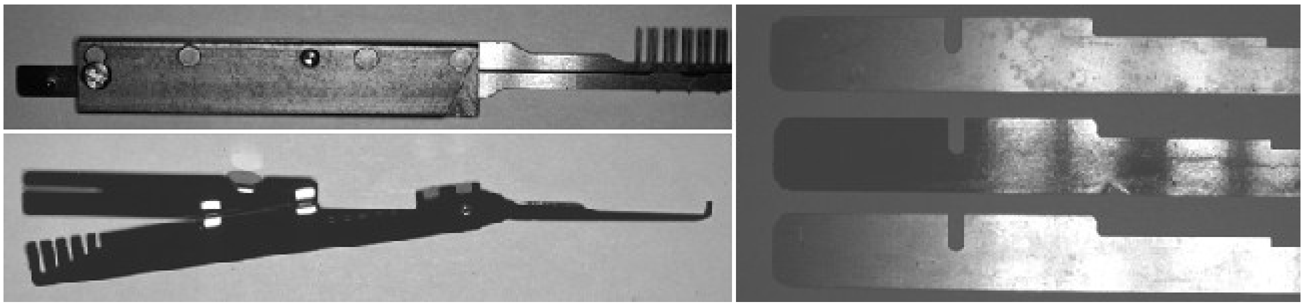
- **Obtain the code from the lock body or glove compartment cylinder. If this procedure is used, then the last two cuts must be determined through trial and error. Remember, in GM cars since 1974, the ignition cylinder is keyed differently than all other locks;**
- **Remove the sidebar and examine the wafers and position of the "V" cuts, then insert a blank and read the position of each tumbler;**
- **Place pressure on the sidebar, pick the lock, and read the depths using a decoder;**
- **Utilize a patented decoder to pick the lock and derive the code.**

In the case of the Briggs and Stratton lock, there are certain rules that will aid in the decoding process:

- **The original lock had four bitting depths;**

- **In 1966, an additional depth was added, bringing the total to five;**
- **The maximum difference between adjacent depths can be two;**
- **The maximum number of equal depths on a key can be no more than four;**
- **There are never more than three equal depth cuts adjacent to each other;**
- **The R&D decoding tool can be used to read the lock after picking.**

A-1 Security Manufacturing Company makes a set of picks for GM-10 cut locks that does not require drilling. The system allows pressure to be exerted on the sidebar; it is then a simple matter to move the gate of each wafer under the sidebar to allow the plug to turn.



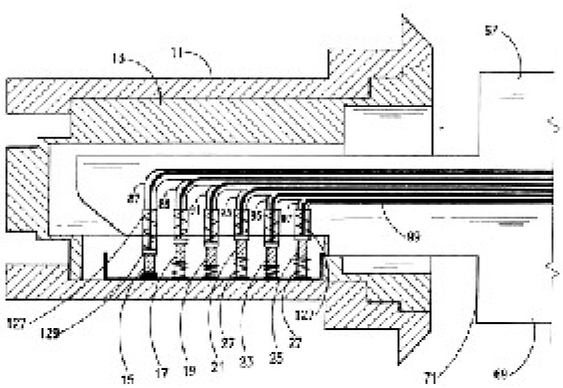
The A-1 GM 10 cut pick system, courtesy of Harry Sher.

31_4.4.3.1 Joosten Pick/Decode Tool for GM and Ford Locks

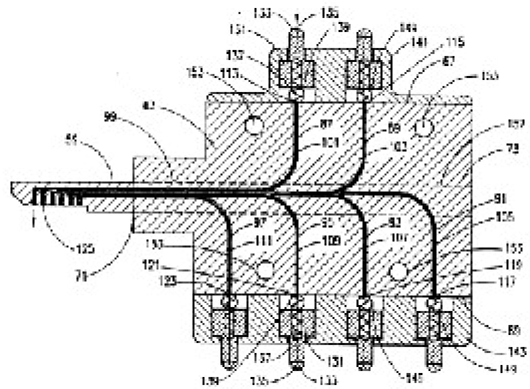
A Patent was granted to Doug Joosten, R&D Tool Company (**4667494(320)**), for two unique sidebar pick and decode devices. These instruments are for use with GM and Ford locks and provide

an easy method to open them. Because of their popularity, detailed information is presented in the Infobase and on **www.security.org**.

Exploded view 1, 2.



Pick tools for the sidebar lock, courtesy of Harry Sher.



The Joosten tool actually consists of six individual devices: Spring compressors (3), shutter retainer, spring retainer with slide, and decoder. A spring compressor is configured for insertion into the keyway. It raises all the tumblers to a radially outward position and compresses the springs that normally bias the tumblers inwardly. A spring retainer tool is inserted into the keyway in concert with the spring compressor tool. It engages the wafer springs to retain them in a compressed position, thereby freeing the tumblers for movement.

A tumbler-adjusting tool is inserted to grasp the wafers and move them to a position where the lock mechanism can be opened. A decoding tool is then inserted to measure the radial position of each tumbler. It provides a code number that can be used to make a new key. A dust cover holding tool is provided to hold open the spring-actuated dust cover.

31_4.4.3.2 Dobbs Sidebar Decoder

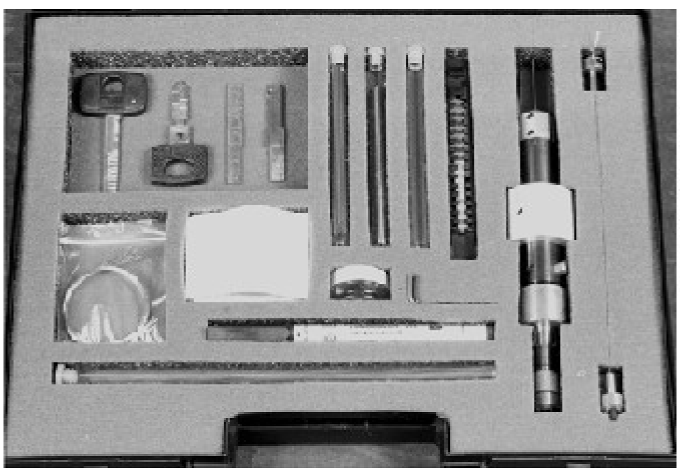
A patent (**5224365(321)**) was granted in 1993 for another type of sidebar lock decoder. This device utilizes individually controlled pins that decode the position of each wafer after manipulating the tumblers simultaneously into alignment with the sidebar.

Narrow passages within the decoder provide channels for plunger wires to control each wafer, and to rest at a reference point that corresponds to the location of each gate. Individual windows allow viewing of the depth of each plunger in its chamber. At least one graduated scale on each housing corresponds to the wafer depths of the lock. It indicates the position of each plunger in relation to its threshold reference position, when the wafers are manipulated into the "open lock" condition. A similar device is produced by MSC in Germany. The "Sputnik" allows the manipulation of individual tumblers through the use of fine wires. It is described elsewhere in this text.

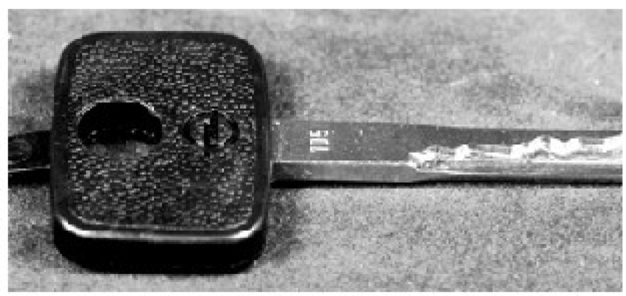
31_4.4.3.3   Embry Sidebar Decoder

A patent was granted in 1994 (**5325691(322)**) for a sidebar picking and decoding method that differs from that of Joosten and Dobbs. The device is comprised of a tool to apply torque, a picking tool, and a decoding tool. Torque is used to bias the sidebar out of its notch in the inner wall of the cylinder housing, and the wafers are then manipulated with the pick. The plug is turned slightly and the torque wrench is removed. The position of each wafer is then decoded. This system is unique in that it purports to afford a quick means to both pick and decode a General Motors sidebar lock.

31_4.4.3.4   Nail Sidebar Decoder



In 1980, Nail was granted a patent (**4185482(323)**) to pick and decode Briggs and Stratton sidebar locks. The tool used sliding shims with tooth-like projections.   Each would mate with an individual wafer for raising them and feeling movement. In operation, each of the wafers is raised so that their V gates would be positioned above the intersecting point of the sidebar.



As each wafer was released when the decoding tool was withdrawn, a change in resistance would be felt when the gate passed the sidebar. This information would be displayed on the tool and noted, thereby disclosing the depth code for that bitting position.

31_4.5 Laser Track Decoders

LSS302: BMW lock decoder system, by John Falle

Many foreign automobiles utilize a "laser track" locking system to improve security against picking. These mechanisms are actually modified wafer designs that require the discs to slide across the surface of the blank within tracks. All of these locks are similar in design. A patent was granted in 2000 to Magini for a decoding system for laser track locks (**6148652(324)**). This process allows the probing of all four tracks simultaneously.

The Falle decoder system is a modified Pin Tumbler Lock decoder described elsewhere in this chapter. Presently, the system is effective on the following lock mechanisms, with other attachments for additional locks under development:

Bypass of laser track or sidewinder locks. Courtesy of Hans Mejlshede.

- **BMW HUF (4 track HU 58, 59, and 63 profiles), and 2 track**
- **Ford Galaxy (2 track internal HU66 profile)**
- **Honda Legend (4 track internal)**
- **Lancia Alfa (2 track)**

- **Mercedes HUF (2 track HU41 profile, and 4 track HU39 profile)**
- **Nissan Infinity (4 track NSN9P and NSN10 profiles)**
- **Porsche 928 lock**
- **Saab (2 track)**
- **VW/AUDI**
- **Toyota Lexus (4 track internal)**
- **Vauxhall HUF and YMOS (2 track YM27 and HU43 profiles)**
- **Volvo HUF (2 track HU57 profile and 4 track)**

Figure LSS+3120 The Falle vehicle decoder system will open many laser track locks. Courtesy of John Falle.

The system is only capable of determining a code for the key and will not open the lock. Opening speeds can vary from lock to lock, but most vehicles can be decoded in less than two minutes.

Figure LSS+3140 BMW decoder produced by Silca.

31_4.6 Decoding Devices Using Fine Wires or Shims

A number of sophisticated decoding devices rely upon the insertion of fine wires or shims to obtain information about the active locking components. These instruments typically contain a shim for each tumbler or allow for the introduction of one very fine wire to measure each component in sequence, then tactually determine its position. Devices have been designed to pick and decode lever, wafer, disc, sidebar, and pin tumbler locks. Some are fairly simple in their operation; others are quite complex and sophisticated. Decoding devices introduced by Falle and others allow for the acquisition of a great deal of information, including:

- **Position of rotating discs and their gates in the Tibbe, Abloy, Ingersoll, Abus, and other locks;**
- **Determination of the height of levers;**
- **Height and rotation of pins in standard pin tumbler and Medeco locks;**
- **Determination of the height and position of pins within a dimple pin tumbler lock.**

Perhaps the most sophisticated device is the Falle pin lock decoder. This tool allows the introduction of a fine wire into the cylinder through a sheath in the form of a needle. The wire probe is positioned under each pin tumbler and then moved vertically to the break point between lower pin and driver. Precise indexing marks on the tool provide for the extrapolation

of the length of each pin. Similar and less precision devices were patented for the decoding of Medeco locks in 1976 (**3987654(325)**, **3985010(326)**) by Lock Technology Corporation.

In certain cases, information must be gathered from several locks in order to produce a composite key. Such is the case, for example, in a positional system where the master key is actually a composite of individual change keys. This situation is often encountered in magnetic card systems and dimple pin tumbler locks such as Keso. Information may be obtained from individual change keys or through electronic sensing means, wherein a number of locks are "read" to derive enough data to determine the code for the master key.

31_4.6.1 Pin Tumbler Lock Decoders

There have been many significant patents issued in the United States for various types of decoders for pin tumbler locks.

31_4.6.1.1 Pin Lock Decoders

In 1937, Abrams received a patent (**2087423(327)**) for a calibrated code finding key and pick tool. The device would gauge the height of each pin, and display the results on a dial attached to the tool. In 1944, Johnstone invented a decoding device (**2338768(328)**) that was comprised of a series of keys, each having different bitting patterns that could be interchanged to manipulate and measure the tumblers. Harwell, in 1955, was granted a patent (**2720032(329)**) for a simple device to determine the height of a tumbler, once picked.

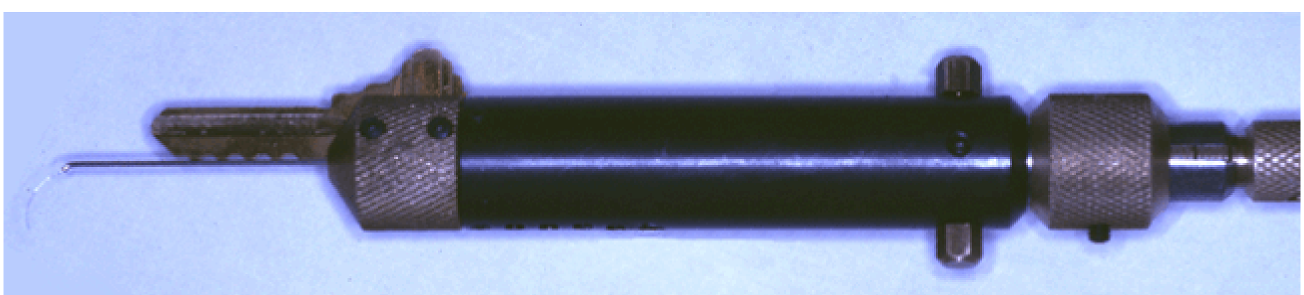
In 1957, this same inventor was granted another patent (**2791840(330)**) for a more complicated variation of his original device. Essentially, Harwell succeeded in producing an adjustable caliper system that would work with a large number of depth and spacing combinations. Naill, in 1974, was issued a patent (**3827151(331)**) for a decoder that utilized a series of fine shims, each with a projection at its tip resembling a diamond pick. All of the shims were contained within a frame and could be individually manipulated and contacted with each tumbler. The shims together formed a key that could be inserted into the keyway. The procedure required the lock to be picked; then each tumbler would be measured and a key produced from the derived code.

A patent was granted in 1985 to Smith (**4535546(332)**) for a unique

decoder that computed the length of a pin tumbler by compressing its corresponding spring by a known factor. This instrument was designed upon the premise that all driver pins were of the same length, and that all springs when fully compressed would occupy the same amount of space within a pin chamber. Although some locks may adhere to this rule, it is not true in every case. Many manufacturers employ **balanced drivers** to prevent the use of a comb pick and similar tools.

In locks that are described by the inventor, the length of each of the bottom pins can indeed be computed with this decoder. In practice, an individual plunger attached to a fine wire was forced upward against each lower pin until the spring was fully compressed. The tool contained a calibration mechanism that displayed the distance traveled by the plunger. A table was then consulted for the correlation between actual pin length and vertical travel. From this information, a key could be generated.

In some respects, this technique resembles the Falle Pin Lock Decoder, wherein a fine wire is extended to measure the dimension of the lower pin. In the Smith decoder the tumbler is measured by forcing it toward the spring, whereas the Falle decoder runs the wire up the side of the pin to shear line. In 1992, the Smith decoder, described above, was improved upon by a Greek inventor (**5172578(333)**). Bitzios developed a pin lock decoder based upon the same premise as Smith, but more complicated.



31_4.6.1.2 Universal Pin Tumbler Lock Decoder

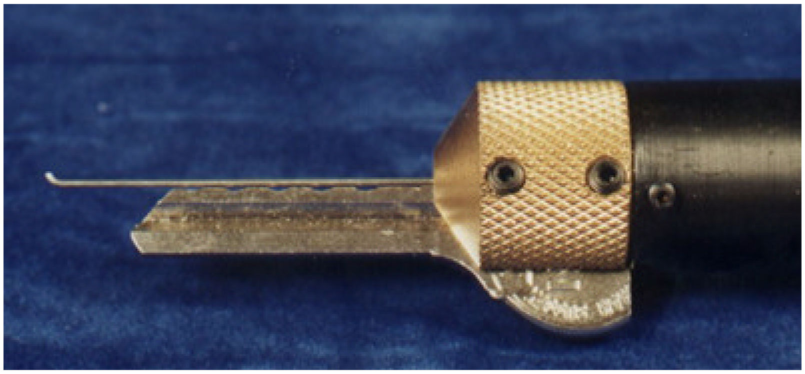
Figure LSS+3121 The Falle Universal pin tumbler lock decoder kit. Courtesy of John Falle.

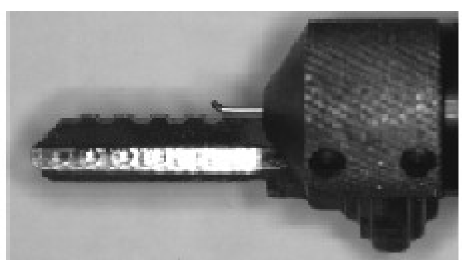
LSS302: Universal pin lock decoder, by John Falle

Falle introduced a revolutionary pin tumbler lock decoder during the early 1980s that achieved wide acceptance by law enforcement and intelligence agencies throughout the world. The device has gone through at least six generations of revisions and will work with many pin tumbler cylinders. The decoder actually measures the lengths of the lower pins without requiring disassembly of the lock. This information can then be used to construct a working key. See **LSS+/ˣ** for detailed operation instructions.

The tool consists of three primary components that provide a calibrated delivery system for a fine shim wire. The **main body**

contains the mechanism for holding a specially prepared blank key and wire tip. The **outer gauge** can slide and rotate, to control the position of the outer skirt needle that acts as a sheath for the shim wire. The **inner gauge** contains a series of 1 mm markings and controls the introduction of a very fine shim wire contained within the skirt needle.





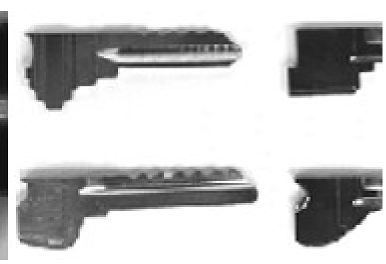


Figure LSS+3122 The pin lock decoder with the needle extended in the probe position. Courtesy of John Falle.

In use, the tip of the needle is positioned upside-down into the forward recess on the key blank. The decoder is then **inserted into the lock** so that the pins and the drivers are situated above the needle. The needle is rotated 180° into its upright position, directly underneath and to one side of the pin to be measured. With the needle in this location, the inner gauge is pushed forward, thereby forcing the fine shim wire up the side of the pin until it engages at the base of the driver.

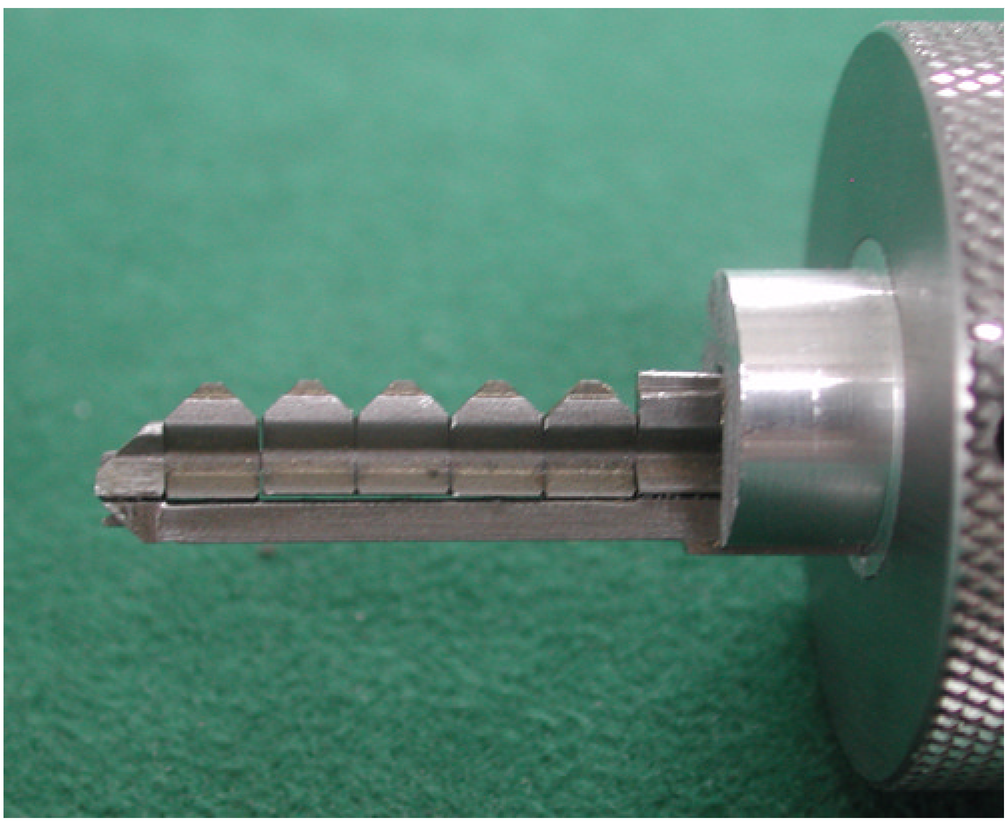
When the tip of the wire strikes the driver, the inner gauge will be stopped, displaying the distance that it has traveled. This distance corresponds exactly to the length of the lower pin. Once the reading has been taken, the wire is retracted back into the needle, the needle is rotated into its upside-down position, and the tool is withdrawn from the lock. This process is then repeated after repositioning the wire on all the remaining pins, in succession, until decoding has been completed.

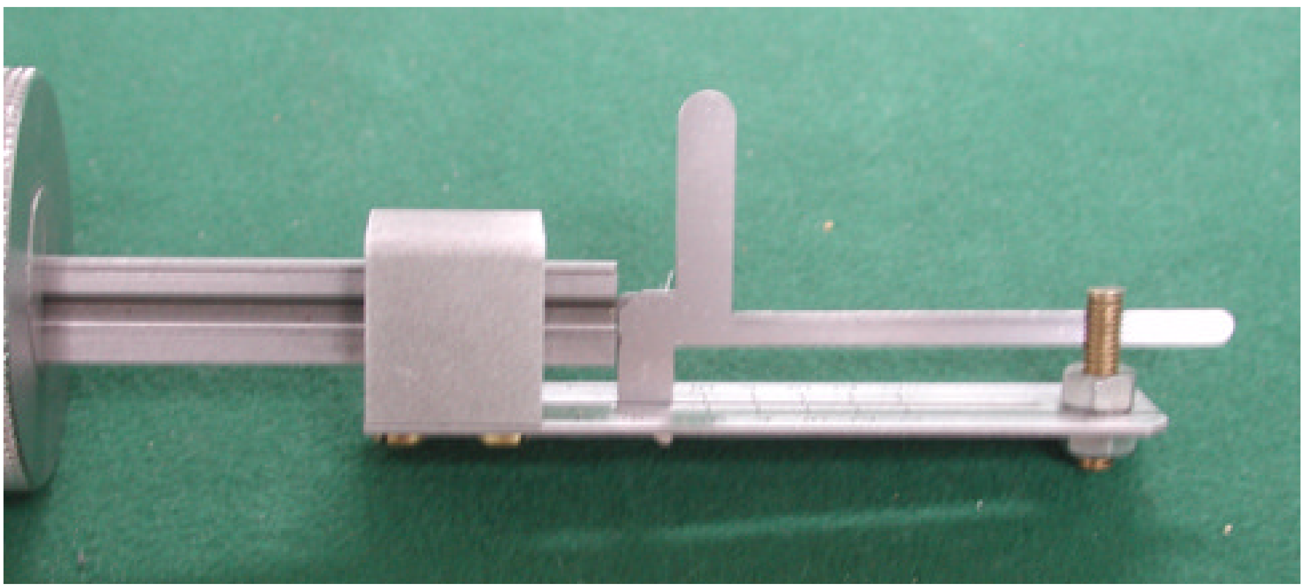
The data thus produced can be correlated with a unique set of known measurements provided for each lock manufacturer and model. Because there may be slight variances in the actual readings, some extrapolation is required. The data is translated to produce a working key, using one of the Falle variable key generation systems described later in this chapter.

31_4.6.1.2.2 Pin and Cam Pin Lock Decoder System

LSS305: Pin lock decoder system with pin and cam technology, by John Falle.

John Falle has introduced a significantly more sophisticated design of the original pin lock decoder system, described above. It combines the technology of the shim decoder with the advanced pin and cam system. The resulting technique allows relatively unskilled technicians to be virtually guaranteed of successful bypass of those locks for which the tool is designed.





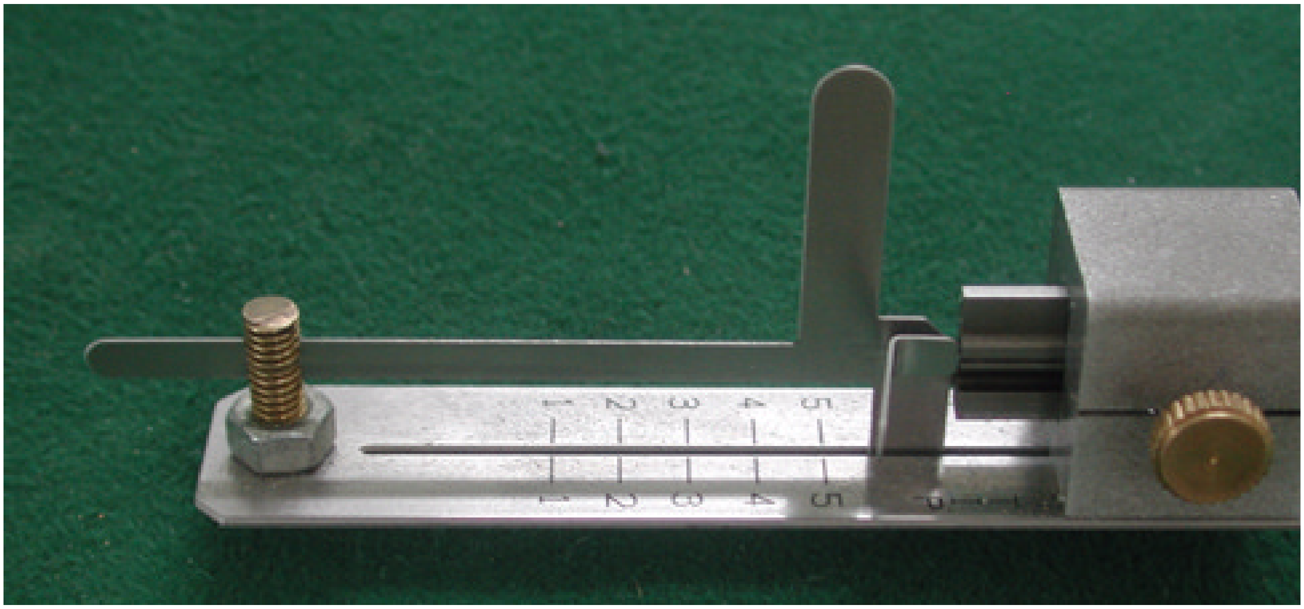


Figure LSS+3137 The decoder carrier allows the interchange of individual keyway differ segments, as shown. The pick-probe is moved under each of the segments to probe shear line.

In practice, the tool with special keyway profile and segment holder is inserted into the lock. A pick-probe is then run under each of the segments, which causes them to be slightly raised. The technician feels the relative movement of each differ segment and corresponding pin. Based upon the detailed description of the theory of impressioning presented in Chapter 30, it is easy to understand that whenever there is slight movement of the keyway segment, such movement indicates that the pin is at shear line. Likewise, whenever movement is blocked, the pin cannot be at shear line. Each tumbler position is sampled until the proper segment has been inserted for each chamber position. When this is accomplished, the lock will open, and has simultaneously been decoded.

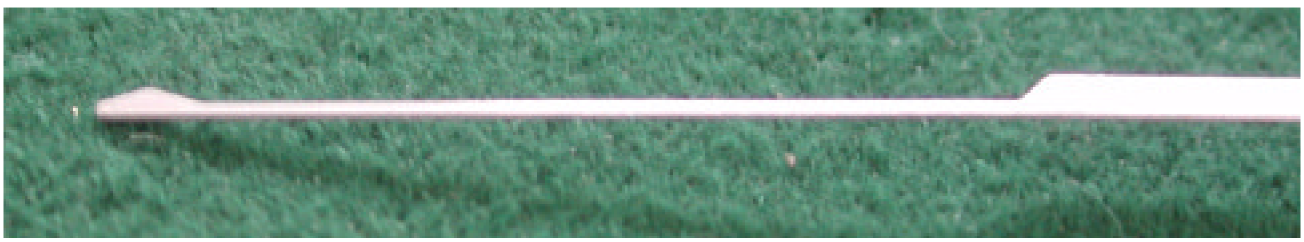

Figure LSS+3138 The calibrated pick-probe holder forms part of the decoding tool.
The pick is moved forward in order to contact each individual differ segment to move
it vertically, in order to probe the shear line.

This system, in the author's opinion, is clearly superior in its ability to defeat common pin tumbler locks in difficult N.D.E. conditions. The system is basically a Pin and Cam system for pin tumbler Locks but each system has been designed to work as easily and as covertly as possible. Instead of utilizing pins, the system uses specially designed Variable Key pieces which assume the shape of perfect key cuts. These Variable key pieces can be individually tested inside the lock to determine whether they are at the correct vertical level for each pin. Incorrect pieces can then be automatically changed by using the specially designed Var-key Container.

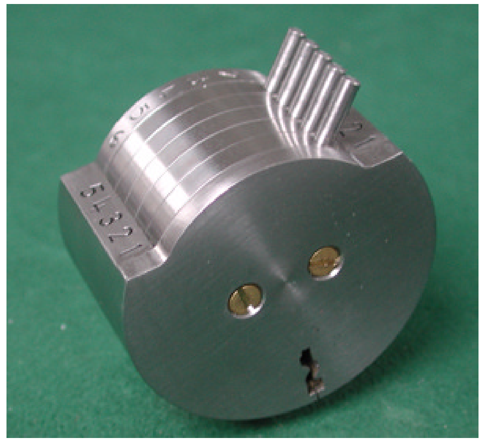

Figure LSS+3139 The tip of the tool is inserted into the Var-Key to select the proper depth segment. All possible differ pieces are contained within this self-contained unit.

In order to select the proper key differ segments, the user simply inserts the decoder tip into the Var-Key holder keyway and flicks the relevant lever to the next position. The device will change the segment to the next size automatically, with no risk of losing any components. The tool is then reinserted into the lock and the process repeated until the lock opens.

The method is quick, silent, easy to learn, and causes no damage to the lock whatsoever. It will not only open the target lock but it will also produce a perfect code for future use. There is no risk of compromise, nor any components that require calibration, or that can become damaged within the lock. The system can be used in conjunction with any other decoding and picking method, and when employed with the Basic Decoder, it can allow extremely rapid openings.

John Falle has managed to translate the difficult process of picking, impressioning and decoding of a pin tumbler lock into one seamless operation. The tool actually impressions the lock with interchangeable segments that simultaneously provide the correct code for each tumbler. The advantage over conventional impressioning is obvious to any skilled technician. Any decoding errors can be quickly corrected without the requirement of starting over in making a key. The system creates a key as the lock is picked and decoded. At the end of the process, a correct key is generated, the lock is decoded, and the lock can be opened and locked at will. Most locks can be defeated in less than three minutes, and more importantly in covert operations, this period can be interrupted without effecting the result. These systems are extremely easy to learn, and only take a few minutes to

master. Once the user has employed one system, he can use all other systems immediately without further training.

As with the original pin lock decoder, each system is designed for use on one specific lock with one particular keyway profile. The systems will work on locks which have five or six pins, and some systems will also work on reverse profiles.

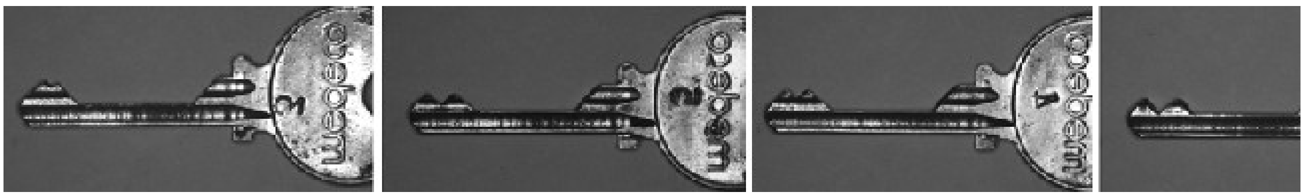
Systems will be limited to popular keyways, although special keyways may be requested.
The following systems are available for locks from the following territories.

UNION 5 PIN Standard Profile (United Kingdom).
YALE 5 & 6 PIN Standard Profile (United Kingdom).
SCHLAGE 5 & 6 PIN Standard Profile (USA).
LOCKWOOD 5 & 6 PIN Standard and Reverse Profile (Australia).
TESA / GAINSBOROUGH 5 pin Standard Profile (Spain).

The following systems may be developed in the future if there is sufficient demand:

ITALY.	**VIRO, CISA, CISA SP.**
SPAIN.	**LINCE, AZBE, UCEM, MCM.**
USA.	**CORBIN, KWIKSET, SARGENT.**
UK.	**MILA, GEGE, CHUBB, EVVA.**

31_4.6.2 High-Security Pin Tumbler Cylinders



31_4.6.2.1 Medeco Lock Decoder Systems

The original decoder for the Medeco lock was patented and introduced in 1976 by Idoni and Iaccino of Lock Technology Corporation (**3985010(334)** and **3987654(335)**). Since that time, a number of modifications have been made to the lock, making decoding in many respects more difficult. In all of the decoder schemes that are available for the Medeco, fine shim wires or blades are utilized to sense the length and rotation of each tumbler.

31_4.6.2.1.1 Medeco Cam Lock

A patent (**3985010(336)**) describes a means for decoding the Medeco cam lock. It will be recalled that this mechanism is based upon a single rotating pin contained within each chamber that has a

precisely indexed radial aperture. A sidebar, with corresponding complimentary protrusions, must be in perfect registration with all pins in order that it can retract into the plug. The decoder for this lock is comprised of three devices, each with a blade that is inserted into the keyway. The blades have one of three sloping front surfaces, defined as one of three angles to which the tumblers must be twisted for horizontal registration of their apertures.

Each blade will provide specific information relating to a tumbler, and an indication will be given that its front surface is located at a particular position. It will also determine the amount of elevation of the tumbler. This is caused by the camming action between the chisel-shaped tumbler bottom and the blade front surface (when the blade is advanced from its initial engagement with the tumbler to elevate it). Decoding of this lock requires that torque be applied to the blade during its advancement in order to bias the sidebar toward the tumblers. This will force the protrusion into the associated tumbler aperture when the aperture is able to register with the protrusion. This movement causes small but detectable resistance to further advancement and can thus yield a positive indication of registration.

When the angle of the front surface and the required tumbler elevation is known, the tumbler is decoded. The process is repeated for all tumblers. A composite segmented key can then be constructed to simulate depth and rotation. A similar scheme, developed by the author, utilizes a set of twelve precut keys, each having one depth-cut and rotation at the tip. The keys are inserted into the lock in sequence for each tumbler position, with torque applied. An attempt is made to move the key within the plug in an effort to engage the protruding pin of the sidebar. Generally, if the correct height and rotation has been attained, the sidebar pin will catch in the aperture, thereby providing an indication of depth and rotation information.

31_4.6.2.1.2 Medeco Pin Tumbler Lock

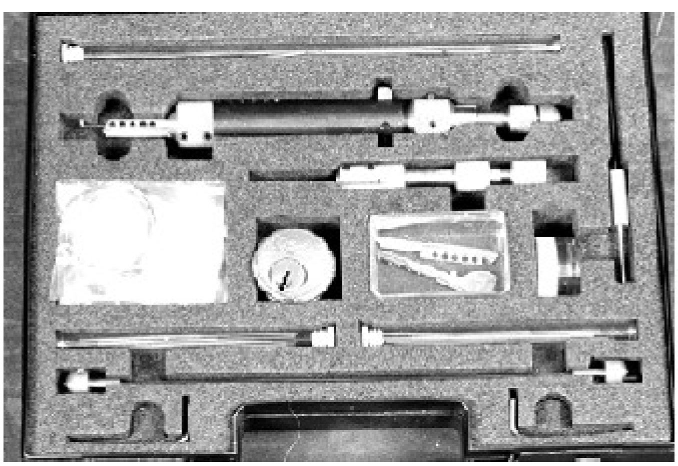
A second patent was granted to the same inventors in 1976

(**3987654(337)**) to decode the higher security Medeco pin tumbler lock and to defeat certain improvements implemented by Medeco in an effort to make decoding more difficult. It will be recalled that the high-security pin tumbler mechanism requires that pins be aligned at shear line, as with a conventional cylinder. In addition, each pin must be rotated to one of three angles by the key bitting, so that the vertical channels within each pin are aligned 90° to the sidebar protrusions in order that registration may occur.

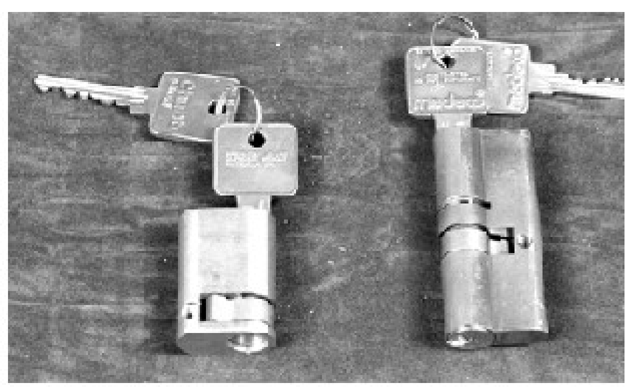
The operating theory of the decoder is based upon the presence of the sidebar channel in each tumbler and its accessibility to the wire probe from the base of the pin. This decoder will determine the depth of cut for each tumbler and the rotation of the pin. The device utilizes a wire probe that is manipulated along the channel to sense the position of the tumbler and chisel-point. It requires that a blade be inserted into the keyway in order to place a wire probe beneath the tumbler that is to be decoded. The wire probe is then advanced upwardly along the sidebar channel until it engages the stop at the top of the pin.

The depth of cut of the key bitting is a function of the length of the lower tumbler. The device can be calibrated to provide a direct readout of the dimension of each pin. The angle or rotation can be measured by hooking a wire probe within each channel and then twisting the tumbler until the stop engages the plug. The allowable amount of pin rotation is a function of the angular position required to register the tumbler groove with the sidebar. The device can be calibrated to provide a direct reading of the angle. Medeco has made significant modifications to the lock since the introduction of this tool, but it will still function on many of their cylinders.

31_4.6.2.1.3 Falle Decoder for Medeco Pin Tumbler Lock



LSS302: Medeco lock decoding system, by John Falle



Originally, channels for the sidebar pins ran the full length of the top pin, making decoding a relatively simple process. Medeco changed the design of the pin and introduced a high-security ARX pin, once the decoding scheme became known. The Falle system will decode the original and **Biaxial(338)** cylinder lock, where the channels run the full pin length. There is no decoder available for the cam lock.

Figure LSS+3123 The Medeco ARX security pin. Note the multiple false notches and channels.

The Falle system is a modified pin lock decoder with an added slot probe used to identify the pin rotation angle. As with the Ingersoll decoder, both the slot probe and the shim decoder require a specially engineered key tip.

Because the decoder is supplied with one key tip for each tool, the kit is only effective on one particular keyway which is the common commercial section. There are many different keyways in the Medeco system, some of which are highly restricted. Each key

tip requires very accurate machining in order to work properly. Falle requires five different blanks for a particular keyway in order to produce a custom tip.

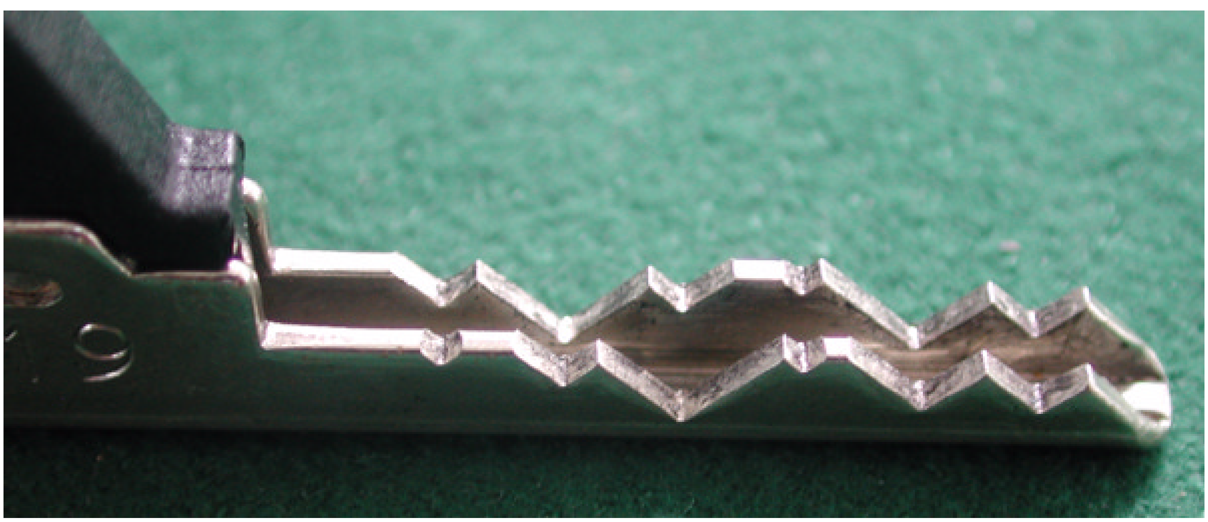


Figure LSS+3124 Key tips for the Medeco decoder. Courtesy of John Falle.

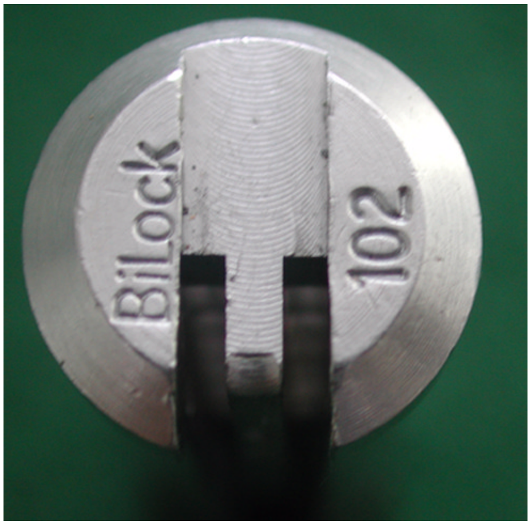
Both the Falle and Idoni decoders require that a probe be inserted and moved around the base of each lower tumbler in an effort to determine the rotation angle of the pin. Falle has also developed a decoder for the **Medeco Biaxial** system, using a slot probe. The length of each pin can be deduced and the rotation angle determined. The system is not effective on those locks that contain ARX pins. Because there are many different keyways, the operative will require specially prepared blanks.

31_4.6.2.2 BiLock Decoder

LSS303: BiLock decoder system, by John Falle



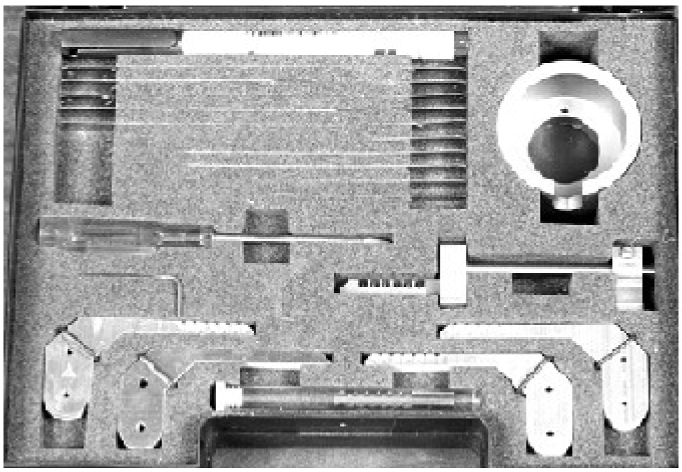


Figure LSS+3125 The BiLock key and cylinder are unique. The system is comprised of dual sidebars, as shown below.

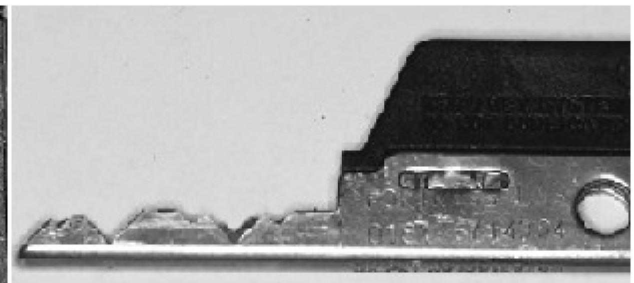

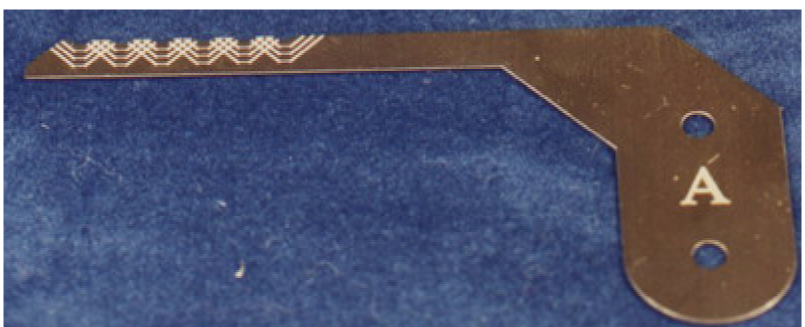

Figure LSS+3126 The BiLock plug contains two sidebars that must retract in order for the plug

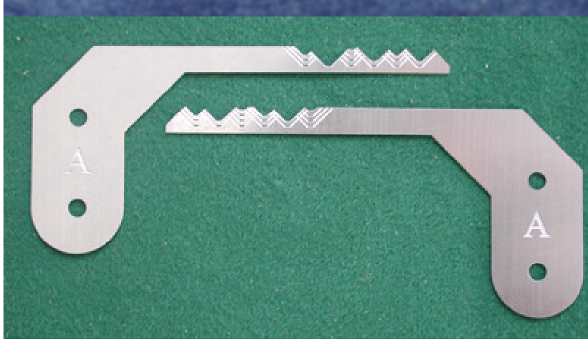
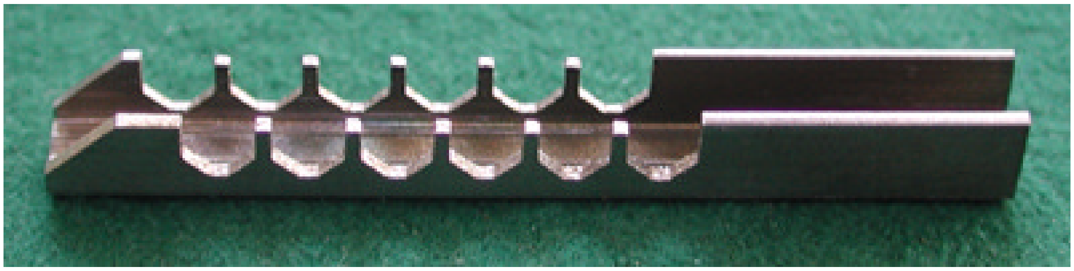


to rotate. The individual pin has a detent to receive the protruding peg from the sidebar,
resembling the design of the Medeco cam lock.

The decoder is designed for use on the Australian BiLock that is now available in Europe and America. The system is very effective against both the staggered and parallel pin versions of the mechanism. The Falle tools will open the lock and produce the precise bitting code for use on future entries.



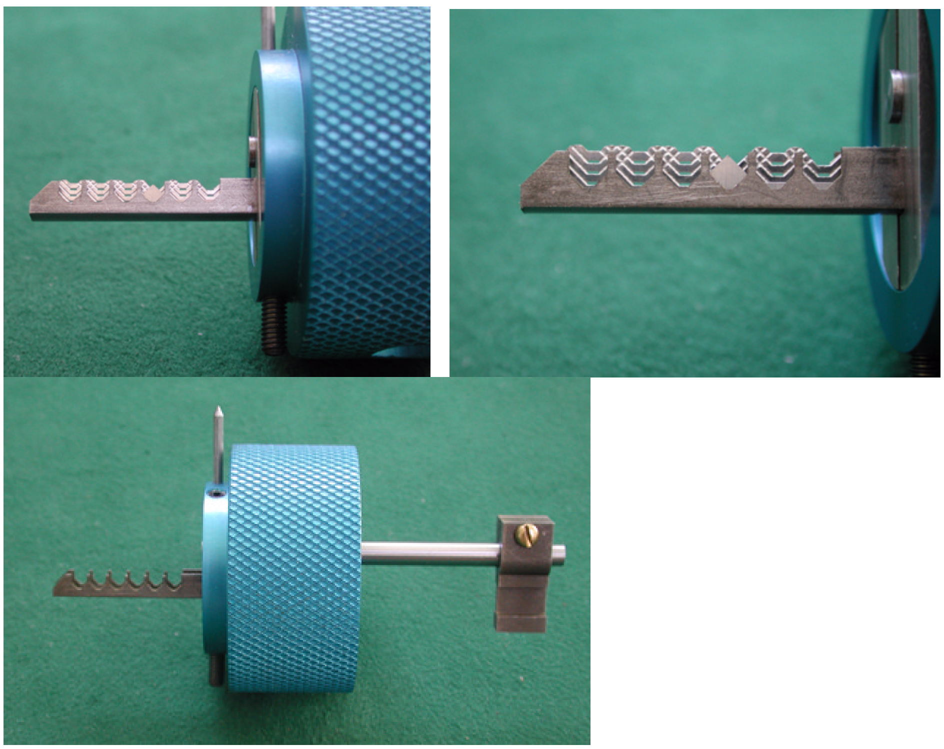


Figure LSS+3127 Individual probes are utilized based upon the variable key generation system. Shown is a blank key, and two that have been cut by code. The carrier is also shown.

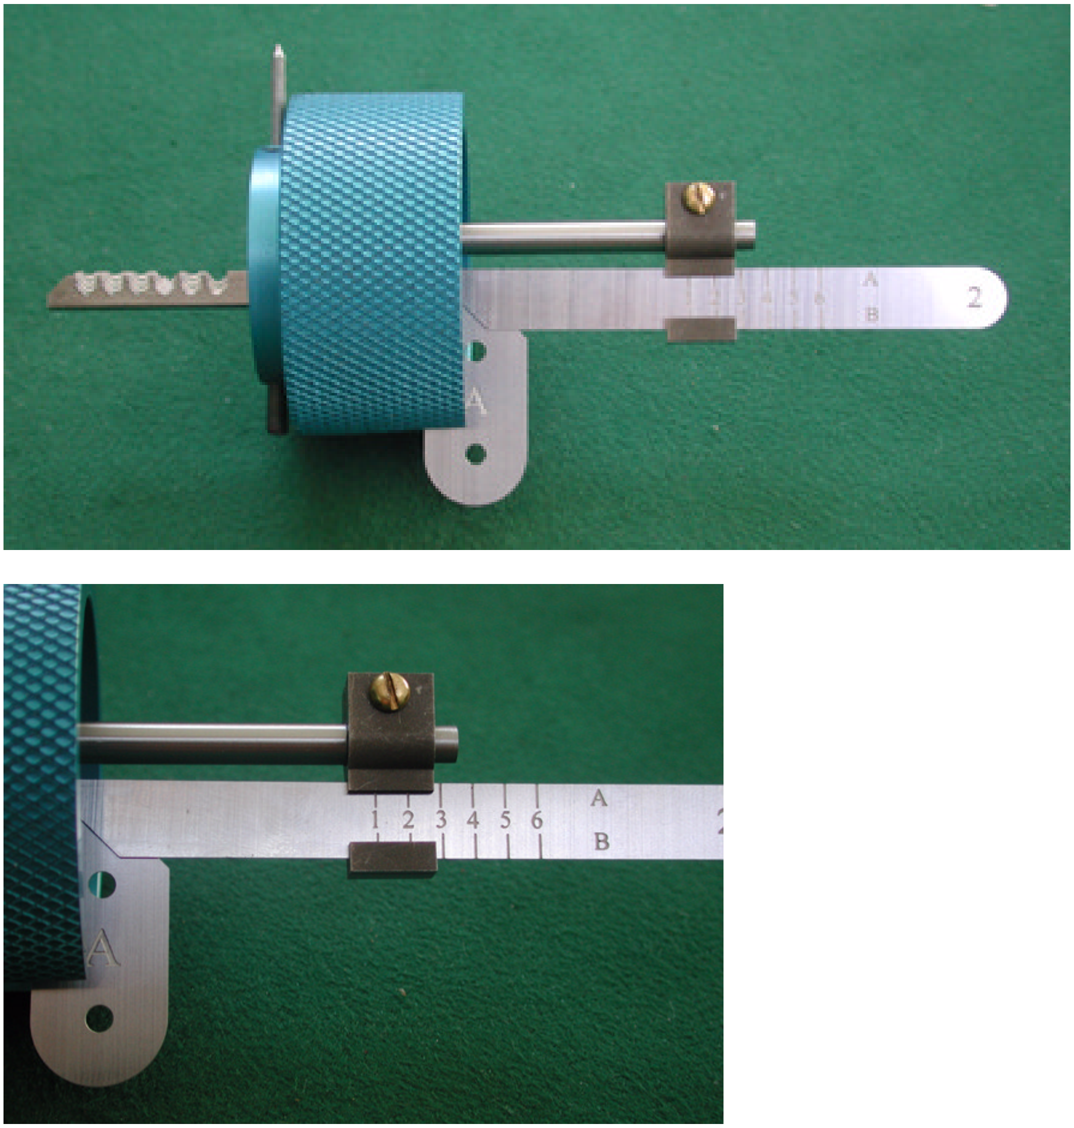

Figure LSS+3128 The John Falle BiLock decoder and pick system will open the lock and produce a key that can be reproduced.

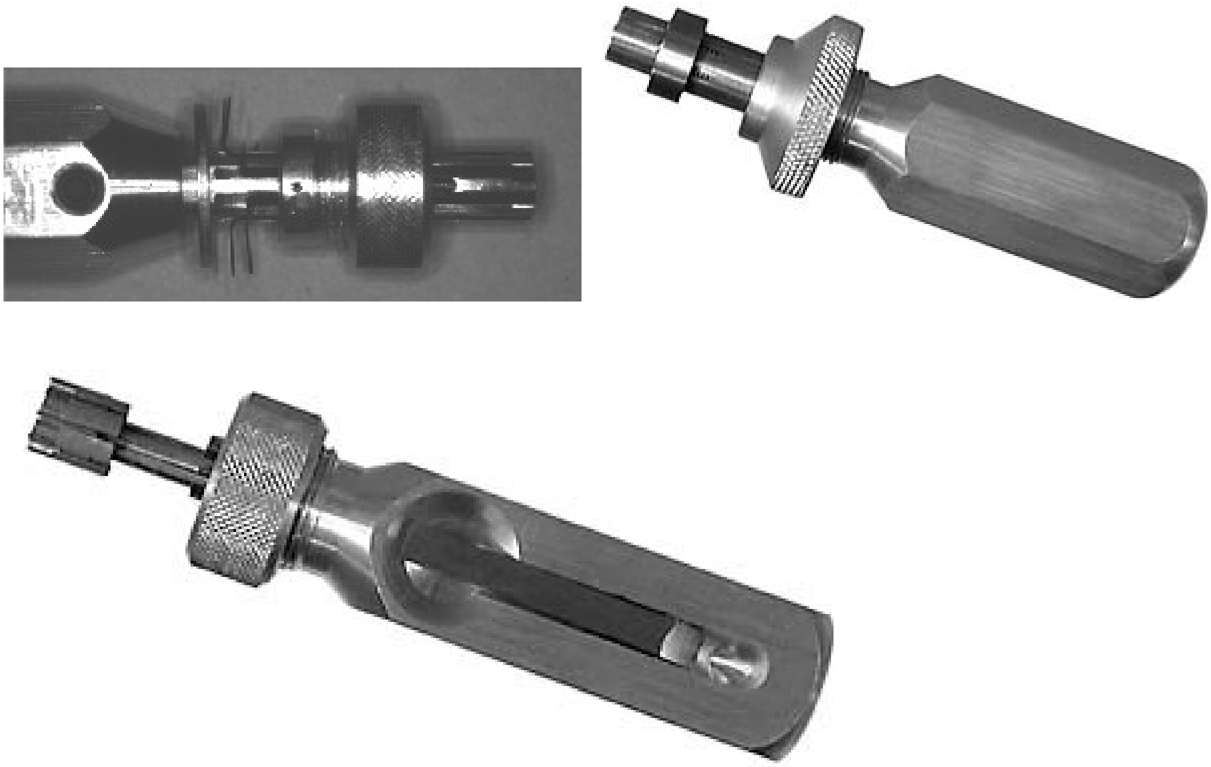
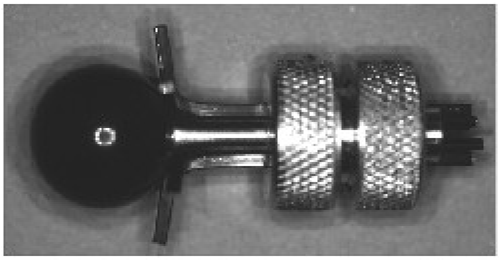
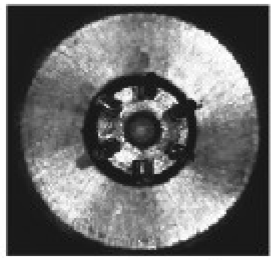
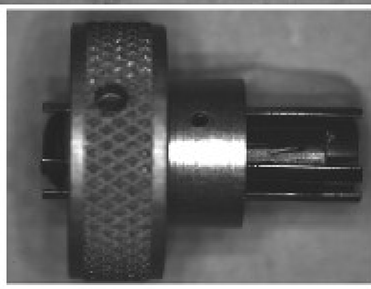
31_4.6.3 Axial Pin Tumbler Lock Decoders

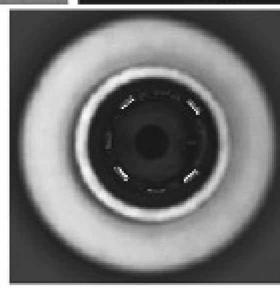
Axial or tubular pin tumbler locks such as Chicago Ace are produced in many configurations and can be easily identified: all have their pins located around the circumference of the keyway. Their design is based upon function and security issues, including the number of active and dead pins, security tumblers, and the interface between pin and key. These devices are extremely popular in vending, access control, alarm, telecommunications, and related industries.

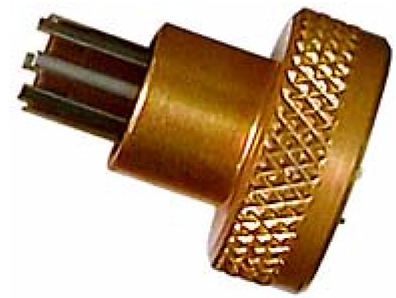


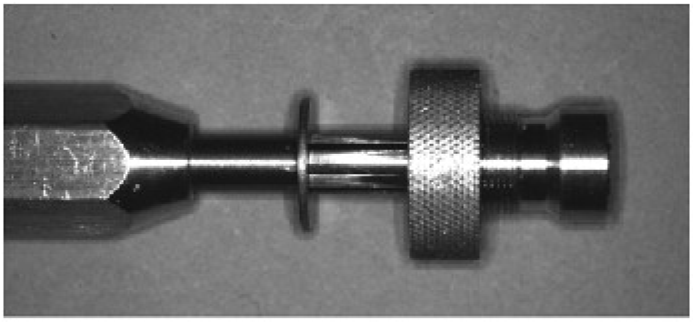


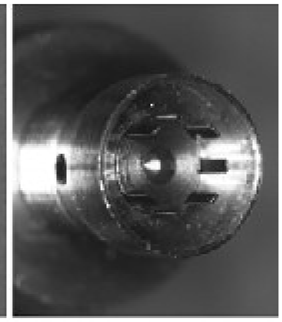












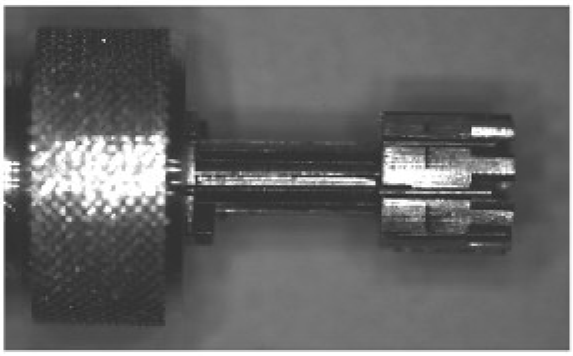


Figure LSS+3142 HPC and other vendors produce complete lines of axial picks and decoders to open virtually every variety of this mechanism, even the high-security UL listed lock.

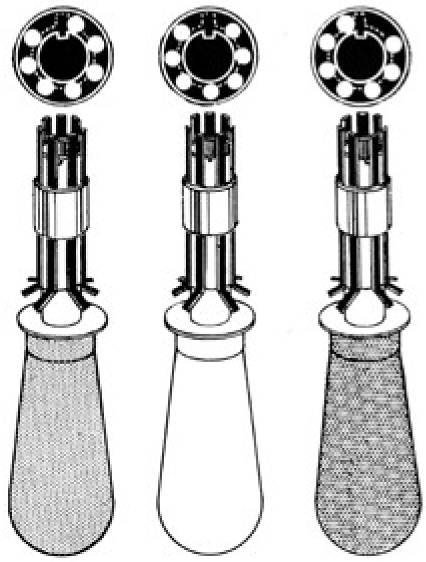
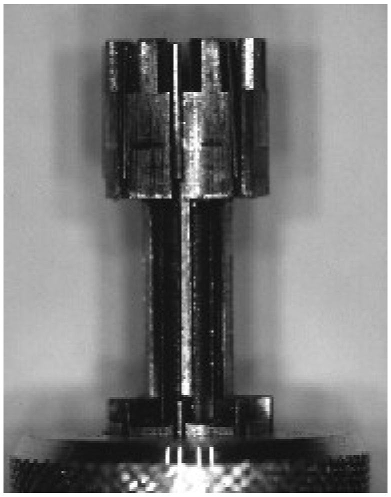
Decoders are available for almost every configuration, at least in the United States. HPC and other companies offer a wide array of tools to quite effectively pick and decode these mechanisms. The picks are available for both regular and high-security cylinders containing seven to eleven tumblers in standard and "peanut" diameters.

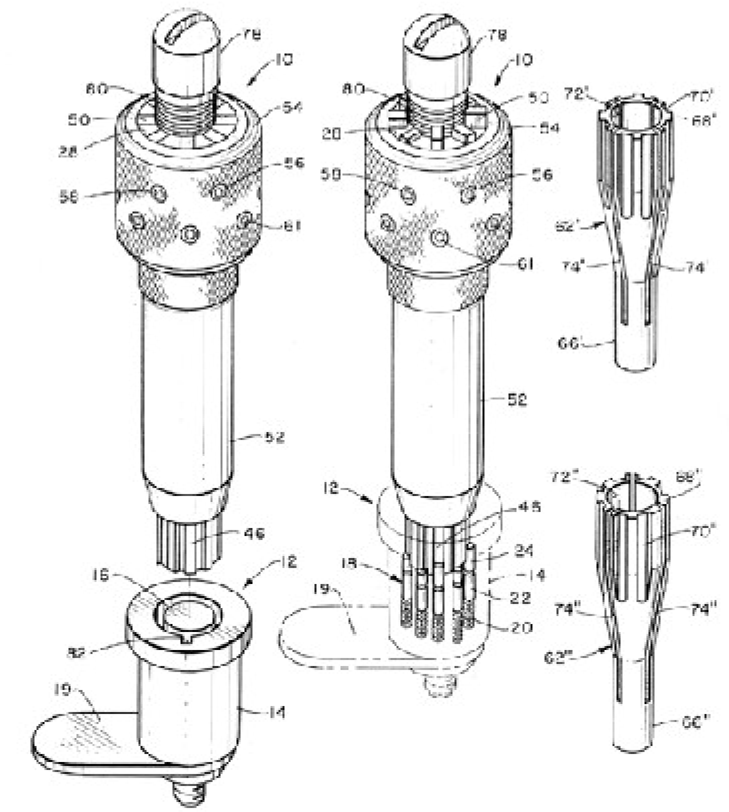
Most of the devices employ moveable shims that are “pumped” in a series of “bind and depress” motions until each pin reaches shear line. Other tools allow the individual manipulation of each pin, somewhat resembling a “rotary” pick. Locks are picked and impressioned in one motion. Once the lock is open, the tools can be decoded to determine the depth of each pin based upon the position of the shim.





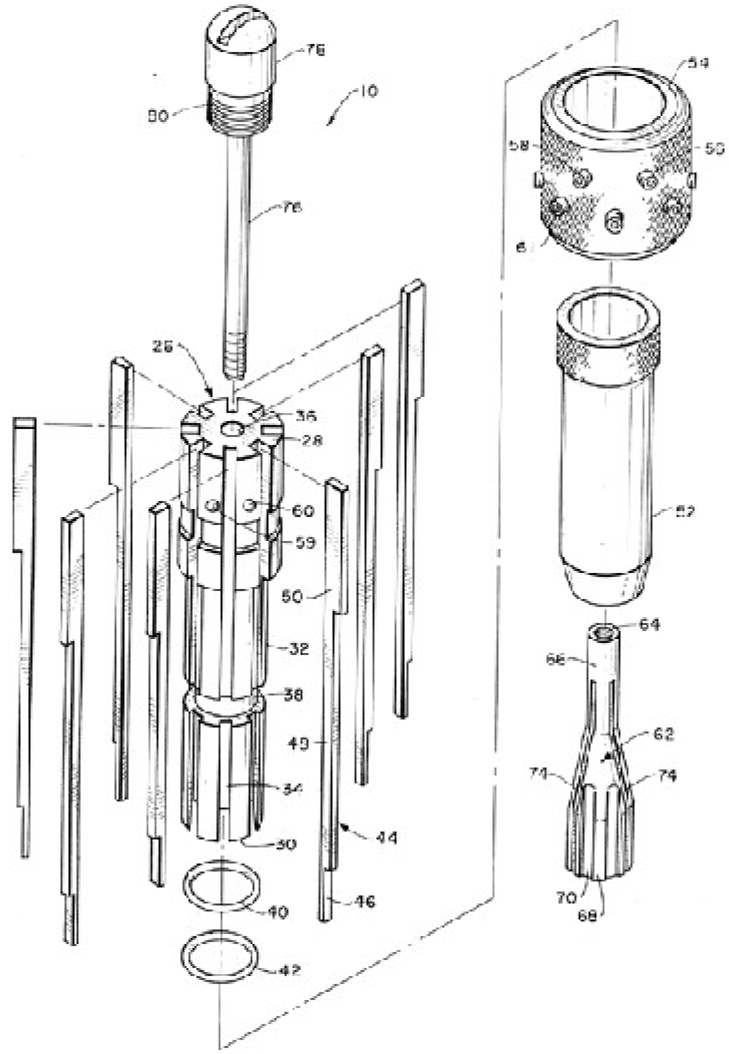
Exploded view 1, 2, 3.

Four primary patents have been issued for axial pin tumbler pick and decoding tools since 1937. In that year, Tarrie (**2070342(339)**) developed a device to open the tubular lock manufactured by the Chicago Lock Company. This tool was the basis for the subsequent inventions relating to picking, impressioning, and decoding this type of mechanism.



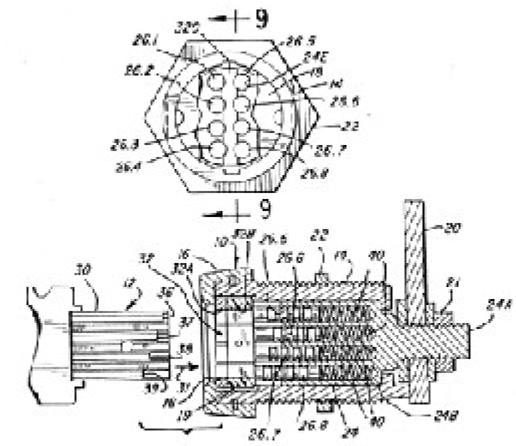
The decoder was designed for the original seven-pin lock. It utilized sliding shims to first pick and then decode the position of each tumbler. In 1953, Wilson (**2655808(340)**) improved upon the Tarrie device, providing individual adjustment and locking for the seven extendable feeler pins. Once the lock was picked, each feeler could be secured in a position to allow the decoding and duplication of a key.

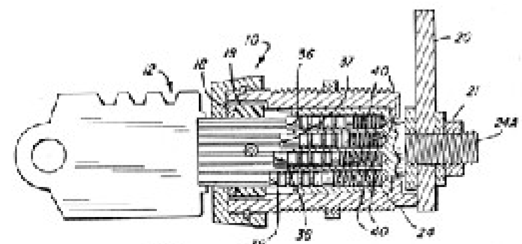
In 1966, Gruber (**3251206(341)**) patented the most famous of the axial decoding tools. This device also utilized sliding shims that could be individually manipulated by the user. Their movement was restrained and controlled through the use of a circular rubber or plastic collar so that when the tool was inserted into the lock, the shims would slide backwards in concert with the force of the pin tumblers.



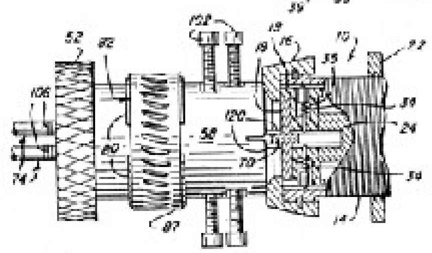
The Gruber tool was placed into the keyway so that the sliders would abut the first set of tumblers. The tool would then be depressed and twisted in order to tension the plug. As the tool was moved forward, the shims would retract in correlation to the position of a pin. Each shim would stop moving when its corresponding tumbler was engaged at shear line. Once picked, the position of each pin was identified, based upon where the sliders had stopped. It was a simple matter to decode their length and produce a key.

In 1978, Hughes (**4094176(342)**) received a patent for an even more sophisticated decoder. This device would allow reading any axial lock with any number of pins by interchanging the head that contained and controlled the individual sliders. The entire tool could be disassembled and reconfigured for a lock with a different number of tumblers. Once picked, the tool would display the results using a decoding gauge that formed the rear portion of the device.





Exploded view.



In 1986, a rather complex tool was patented (**4617813(343)**) by Christopher for picking and decoding the Chicago Tubar series eight-pin tumbler axial lock. The Tubar differed from the traditional axial mechanism in that two rows of four tumblers were arranged in a coplanar fashion. The lock is more particularly described in Chapter 17.

31_4.6.3.1 Axira Radial Pin Lock Pick and Decoder

LSS302: Axira lock decoding system, by John Falle

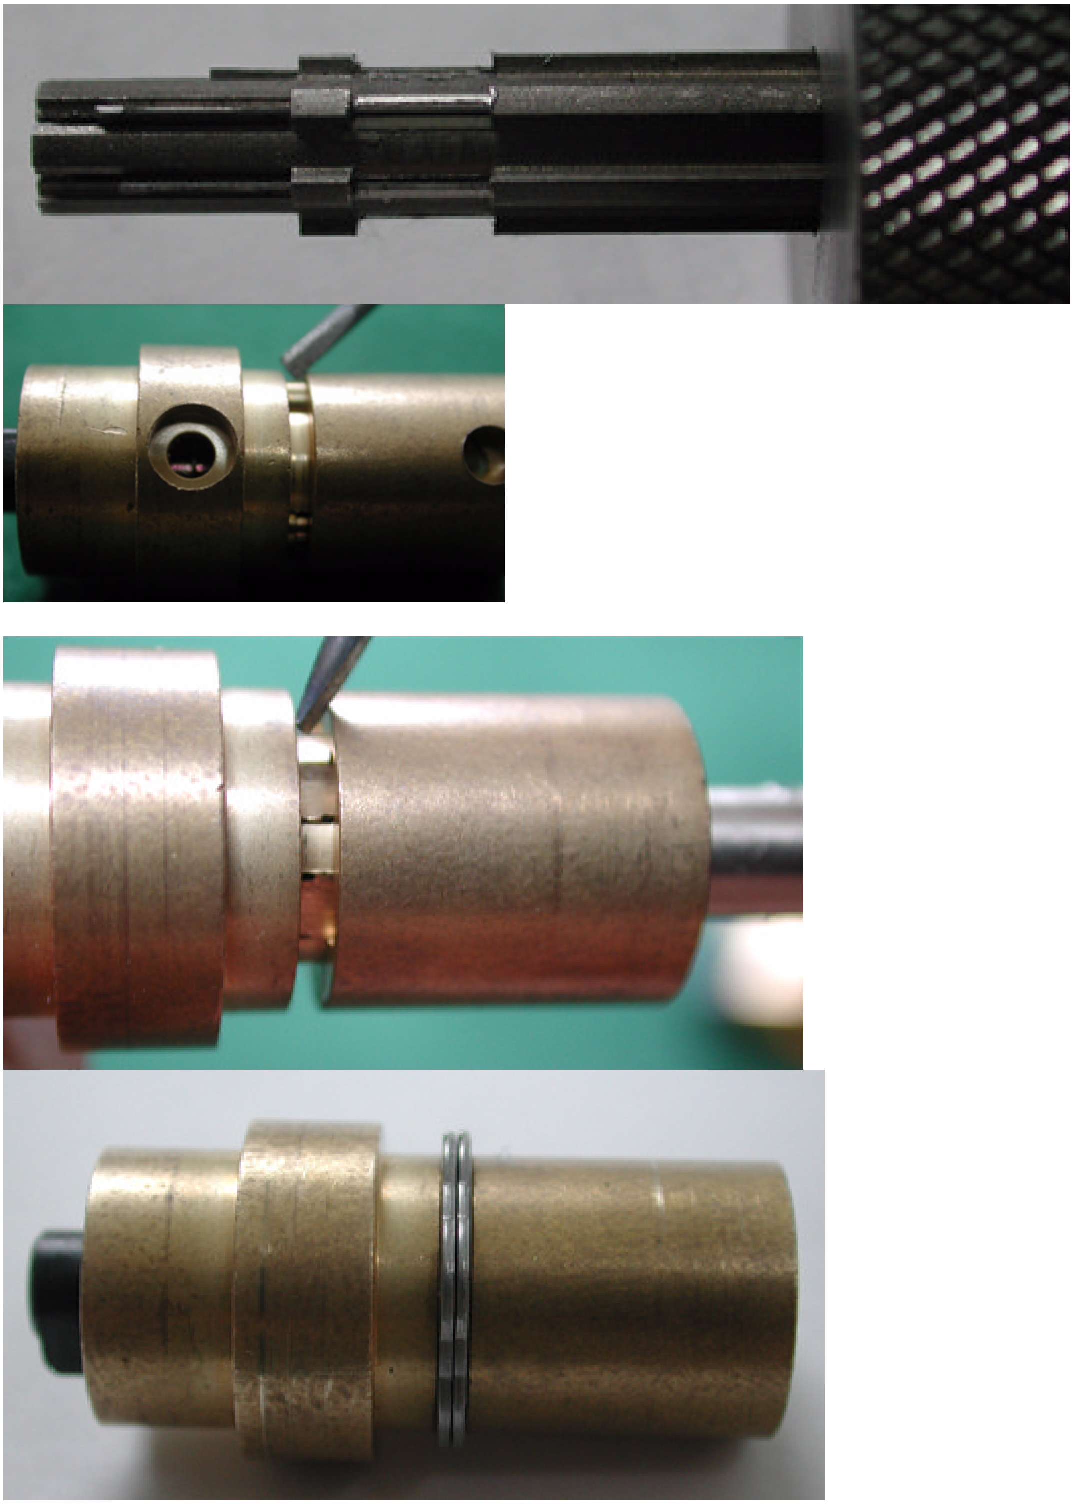

Figure LSS+3129 The Axira lock is similar in design to the Picard. The Falle decoder works in almost

identical fashion for both locks.

This John Falle decoder is a sophisticated picking tool for use on the AXIRA Radial pin lock. This mechanism has a particularly modern design and requires an advanced tool in order to open it. It is believed that the lock originates from France but is also common in Italy and Spain. The tool is both a pick and also a decoder; the lock must be opened before the code can be determined. Although the lock contains only five detainers, they are heavily notched. The Falle system is the only method available to open the Axira.

As with all picking tools, the main limitation in this system is speed. A skilled operator should easily be able to open the lock within four or five minutes, but this time can be interrupted. The design of the tool allows individual pins to be locked into position, thus allowing the decoder to be quickly removed in an emergency. The tool can then be reinserted and the user can continue the picking procedure. If the user requires a code in order to make a key, this can be done in less than one minute and can be achieved at an alternative location.

If the user is familiar with radial pin picks, then no significant training is required. Otherwise, a few hours of instruction are required to become competent.

31_4.6.3.2   Picard Decoder

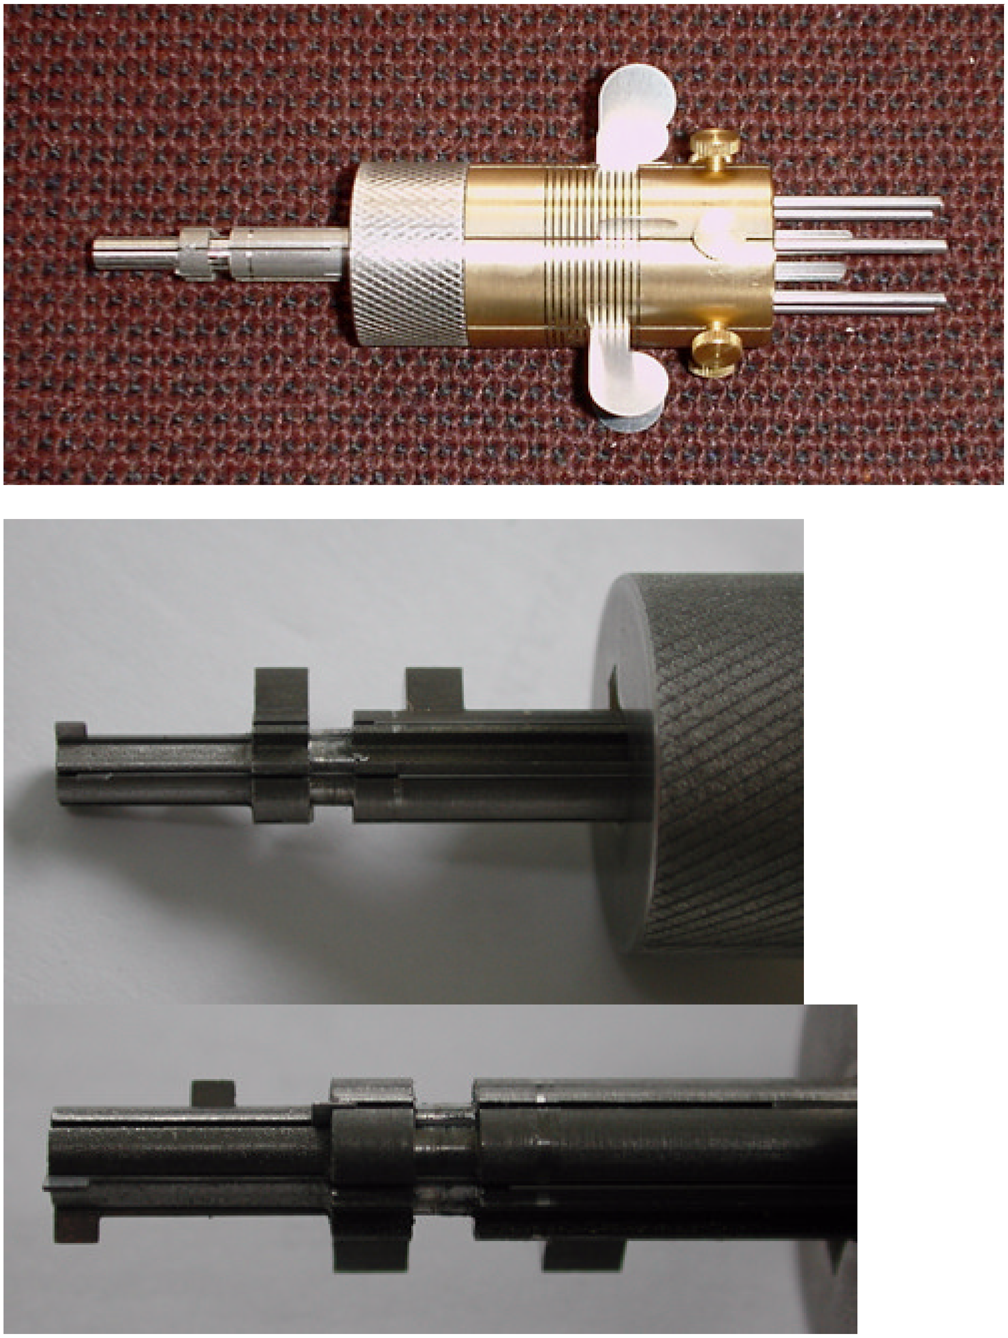

Figure LSS+3130 The Picard pick and decoder tool by John Falle.

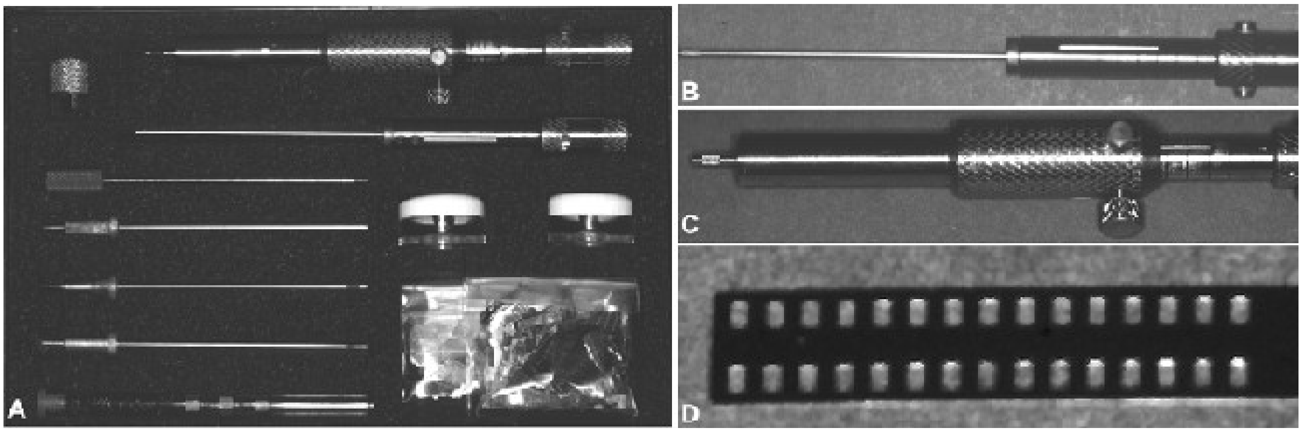
The John Falle decoder is of a very similar design to the Axira device. The **Picard** lock is also of French origin and like the Axira, it contains five tumblers of a radial pin design. This **decoder** will open the lock and also provide a code for future entries.

The only limitation to system use is speed. Before the lock can be decoded, it must be picked and the time this takes will depend upon the skill of the technician. This lock is a great deal easier to pick than the Axira. If the user is interrupted during the bypass procedure, the tool can be immediately extracted. On reintroduction, the picking process can be continued from the point of interruption. The time required to pick this lock should not exceed two minutes. A further one or so minutes will be required to attain the code, but this can be accomplished at an alternative location.

If the user is familiar with the picking of radial pin locks, then no training will be required in the use of this tool. If not, then the user could learn this system as part of an Intermediate or Advanced course in only a few hours.

31_4.6.4 Dimple Pin Tumbler Lock Decoders



Dimple pin tumbler locks are unique in their design because there are several rows of active components that must be picked and decoded simultaneously. As noted elsewhere in this text, many of these locks can be easily picked, impressioned, or decoded using a variety of techniques. These locks generally contain two, three, or four separate rows of pin tumblers, each facing a surface of the key. For example, the Keso, produced in Switzerland, has three rows with up to fifteen pins. Dimple locks have become extremely popular, and are now produced in many countries.

Falle produces two types of dimple decoders that are discussed in this chapter. The standard system will decode locks produced by DOM, Ezcurra, MCM, UCEM, Keso, Tesa, Azbe, and Lince. Dies can be developed for virtually any dimple configuration.

31_4.6.4.1 Core Shim Decoder

The core shim decoder, by Falle, was initially designed to function with dimple pin tumbler locks, although it is expected to be modified to operate with conventional cylinders as well. See **Chapter 17** for a discussion of dimple mechanisms. Falle devised an extremely innovative system that relies upon a simple technique described in **Chapter 26** regarding the disassembly of pin tumbler cylinders using a shim. The process of inserting a fine shim wire at the rear of the plug (at shear line) while concurrently removing a blank key to force the wire between each

pin set has been simulated by Falle.

Exploded view 1, 2.

The tool is designed to introduce a shim through the bottom of the keyway to travel between the plug and shell. The shim is thin enough to revolve around the outer circumference of the plug. Using a geared mechanism, it is forced to move from the base of the keyway 180° to where the pin-stack intersects plug and shell.

The decoder consists of a hypodermic tube with two slots on either side of its tip. The distance that the tube is inserted can be calculated by reading the markings on the gauge body. This allows a precise determination as to which tumbler is being probed by the shim. On the side of the tube, a slot is located where the blank key is inserted into the lock. Contained within the tube is a miniature gear that can be rotated by turning a knob at the rear of the tool. A micro-perforated shim, measuring exactly 10 mm in length by 4.5 mm in width and resembling a 35 mm filmstrip, is fed into the slots. It can be extended and retracted by the gear.

In use, the shim and the tube are inserted into the keyway at a position as far to the right as possible against the inside of the plug. The shim is then extended around the outer ridge of the plug until it contacts the sides of the pins. If the diameter of the plug is known, then the point at which the shim reaches the sides of the pins will always be constant. A series of step-keys are next inserted into the lock. When the correct bitting depth raises the target tumbler, the shim can be extended further so that it goes between the pin and the driver, thus verifying the correct depth. Once the first pin has been decoded, the shim can be extended to the second pin and the

procedure repeated for all pins.

31_4.7 Tactually Decoding the Tumbler Positions

The design of some decoding tools relies upon the manipulation of tumblers to sense their size, distinct type, and position. The operation of the Schlage wafer decoder, described earlier, depended upon the manual sensing of the shape of the corners of each type of wafer in order to determine the combination. The Falle Abloy decoder likewise relies upon the sensing of true and false gates on each of the discs in order to rotate them to alignment.

Some of these devices are quite complex and require a high level of skill to operate successfully. The Falle Medeco decoder and the earlier device described in the Idoni patent is an excellent example. These tools demand extensive knowledge of the internal workings of the lock and the ability to translate subtle measurements and feelings into code data.

31_4.8 Picking and Then Decoding the Lock

Most decoders described throughout this chapter require that the lock be picked prior to decoding. Essentially, these devices provide for a method to measure each active locking component once it is positioned at shear line (or equivalent). Some instruments can decode the size of each component without the necessity of picking. The axial pin tumbler lock pick/decoder described in **Chapter 29** allows a precise determination of the length of each pin during the picking process. Such data can then be translated to produce a working key. The Falle pin lock decoder allows for the extrapolation of the length of each pin without picking. Using this tool, a fine shim is introduced into each pin chamber in order to compute the distance from the base of the pin to the bottom edge of the driver.

31_4.9 Other Means of Deriving Tumbler Combinations

Based upon their design, information about individual keys and key systems can be extrapolated and compiled from one or more locks that have been picked or disassembled. The author, for example, was able to pick an extremely popular lock cylinder used in the lodging industry and then decode the master key for an entire system by reading the tumbler positions with a borescope

or otoscope in **one** lock. In another case, the author covertly captured the signatures of several magnetic card locks within a complex, and was able to derive the master key code by making a composite key from all of the data. Described below is a technique for decoding and extrapolating the bitting of the top level master key (TMK) within a master key system. The reader should thoroughly review the materials detailed in **chapter 11** in conjunction with the materials that follow.

31_4.9.1 Shimming a Pin Tumbler Lock with Depth Keys

LSS203: Matt Blaze on shimming a cylinder to determine all pin segments

A pin tumbler lock may be decoded without disassembly by shimming the cylinder. Standard shimming practice has been described elsewhere in this text. The following procedure is slightly different because the goal is to **decode** the lock, rather than simply to open it. This is accomplished by inserting a fine shim stock between the shell and plug while using a set of depth keys to determine the depth of each split. This technique may be especially useful in operations that require the covert determination of all pin splits within each pin stack. This would generally occur when attempting to derive the top level master key when it is not feasible to disassemble the lock, and a change key is not available. The disadvantage to disassembly is the inability to reconstruct the master key system if the pin stack combination for any chamber is lost or altered. Shimming eliminates this problem.

A set of depth keys must be prepared prior to the procedure. Each individual depth key is cut in all bitting positions for a single depth. If, for example, a Schlage five pin lock were to be decoded, then ten depth keys would be cut with the following codes: **00000 11111 22222 33333 44444 55555 66666 77777 88888 99999**. Because Schlage uses ten different depths for our target lock, a total of ten keys must be prepared. Each key is cut so it is completely flat across the bitting surface for ease of insertion and removal. Then, each key is marked on one side to indicate the position of each chamber and how far the key has been inserted into the lock.

In practice, the cylinder is removed from the door and the rear tailpiece is taken off. A shim wire is inserted into the gap

between plug and shell, and the first depth key is inserted fully into the plug while applying pressure with the shim against the pin closest to the rear of the lock. Each chamber is tested for each depth with each of the different keys until the shim can be pushed across the shear line for that specific pin. When a pin segment is decoded, the reading is noted, and the shim slightly withdrawn so that the decoding process can be **repeated** for that specific pin. When all possible depth codes have been tested for the first pin, the shim wire is forced to the second chamber and the process repeated. The depth keys are now inserted to reach the fourth chamber, because the fifth chamber is blocked by a shim wire between top and bottom pin. In like order, each of the chambers is tested by inserting the depth keys to the third, second, and first chamber positions. When all five pins have been sampled, all of the possible **combinations** of pins have been determined. With that information, the codes for change keys, master keys, and top level master keys can be determined for any lock or groups of locks within the system, and which are associated with the target lock.

31_4.10 Decoding and Extrapolation(344) of Master Key Systems

31_4.10.1 Introduction

A great deal of emphasis has been placed upon methods to make locks more secure against picking, impressioning and decoding. Manufacturers have concentrated on sophisticated designs to insure that high security cylinders cannot be compromised by such techniques unless extremely sophisticated tools and procedures are employed, such as described in this text. In covert operations, however, it is preferred to take the path of least resistance and reduce the exposure to detection. If there is an alternative to the more sophisticated methods of entry, then they should be exploited whenever possible.

From the author's perspective, it is far better to secure a key that will open all locks that lead to the target rather than taking the risk to open one lock at a time by picking, impressioning, or decoding. The following material relates to a circumvention of the traditional techniques of entry within a master key environment in favor of obtaining the top level master key, thus gaining access to a desired location with minimal risk of detection. Obtaining the TMK will allow a compromise of system security for any cylinder that is associated with the top level

master key.

Most buildings are master keyed: some systems are very simple while others are quite complex. Some utilize conventional technology while others use secondary locking systems for enhanced security. All conventional cylinders can be master keyed with a variety of schemes to generate secure bitting for the required keying levels.

How many times have you visited a building and attempted to use the restroom, only to find that it was locked and required the use of a key? No problem, because you were always able to obtain the key from the receptionist. Or, how often does the telephone repairman, computer specialist, HVAC maintenance, alarm system personnel, or other service people have or obtain keys to locked areas. It is a sure bet that within most facilities those rooms are not only locked, but they are on the master key system. The result: anyone that has access to a change key can obtain the TMK and open every lock in the system. But what about employees? If they have an office or require access to any locked area, then they have or can obtain a change key.

As explained in previous sections within this chapter, there are many ways to obtain change keys other than as an employee. Keys can be copied, borrowed, purchased, or stolen using a variety of techniques. All that is required for the successful neutralization of any conventional master key system is the possession of a change key and access to one or more cylinders. Such access does not have to be authorized, because very little time is required to sample a cylinder during the decoding process. It is simply a matter of how many passes are required to fully decode and extrapolate the TMK bitting.

The reality is that virtually any conventional keying system can be easily and covertly compromised at the TMK level by an individual with little training or skill and even fewer tools. Anyone with a change key and blanks has a good chance to obtain the TMK. System compromise can occur during one attack, or over a period of time. The cost to accomplish the task may be less than five dollars. It is therefore critical for anyone charged with the responsibility for securing a master keyed installation to understand the threat. Most systems are vulnerable; there are few countermeasures. This is especially important in the post-911 environment, where the protection against penetration of secure facilities is even more critical.

There are many misconceptions regarding master key systems and their compromise. These myths are examined in **chapter 11**, in section 11_5.3.7.4. Although it is virtually impossible to derive the code for a master key from inspection of one change key alone, it is a simple matter to derive the code for the TMK by **using** the known bittings from one change key to probe a lock within the system. The reader will learn that another belief that the lock must be disassembled to derive the master key code, is also false. The possession of one change key eliminates the requirement to take the lock apart. The reality is that any conventional system can be broken by anyone having a change key, access, and a few blanks. The following discussion will detail the procedures to accomplish this task.

In the materials that follow, the theory, data requirements and procedures will be detailed to allow the reader to extrapolate the TMK for any conventional master key system. As will become evident, the process is simple, straightforward, and does not require very much technical ability. In past years, there have been a few articles regarding the decoding of master key systems, but none have offered an extensive treatment of the subject.

The reader was introduced to master keying theory in **chapter 11** and **chapter 16**. The material in those chapters dealt with both the theory of conventional master key systems and the methods of deriving useable combinations for simple to complex installations. The concepts of multiple shear lines as well as different keying algorithms to derive the top master key (TMK), master key (MK) and change key (CK) were explored. The reader is referred to section 11_5.5 for a detailed explanation of the methodology of the total position progression and rotating constant systems. A thorough grasp of these theories is required in order to understand the concepts presented in this section and the security threat that is posed by any conventional master key system from decoding and extrapolation techniques detailed herein.

From the materials in chapter 11, it can be readily appreciated that the ability to compromise the TMK is virtually absolute by anyone with access to one master keyed lock, its change key bitting codes and key blanks for that lock. That is because in the correctly sequenced TPP or RC system, there can only be one or two possible shear lines created by each set of pins in a chamber. This critical factor will render all conventional systems liable to penetration.

The following discussion will present detailed information as to the required procedure to successfully extrapolate and decode the top level master key within any conventional keying system. The author wishes to acknowledge the assistance of many persons, including Matt Blaze (AT&T Labs), Harry Sher, and Brian Chan (UC Berkley) for their assistance in developing the material in this section.

31_4.10.2 Overview of Methods to Compromise a Master Key System

Many methods have been described in this and other chapters as to how to obtain key codes and to covertly open locks and safes. There are several methods to compromise a master key system. These include:

- **Access to the master key to copy, photograph, or physically decode;**
- **Access to one or more cylinders (with or without a change key) for the purpose of decoding the pin segments. The lock may or may not be disassembled for this process;**
- **Falle pin-lock decoder to measure pin segments through the use of shim wires;**
- **Falle pin-and-cam pin-lock decoder. This tool allows the probing of each tumbler for its position at shear line. It will also allow the operative to quickly decode a master keyed cylinder to extrapolate the TMK and to generate a key;**
- **Shim the cylinder with depth keys to determine the code for each pin segment. This method requires access to the cylinder shear line for the insertion of a shim wire;**
- **Visual inspection of the pin tumblers;**
- **Optical devices to view the tumblers;**
- **Radiographic techniques;**
- **Analysis of one or more change keys to reverse engineer the system;**
- **Extrapolation and decoding through the use of a change key, as described in this section.**

31_4.10.3 Decoding and Extrapolation of The Top Level Master Key

LSS203: Brian Chan on TMK extrapolation

LSS203: Harry Sher on the decoding of a top level master key

LSS203: Matt Blaze on the extrapolation of a top level master key

LSS203: Harry Sher on covert methods of entry

31_4.10.3.1 The Theory of Extrapolation of the TMK

It is expected that the reader has reviewed the materials presented in **chapter 11** with regard to master keying theory for different progression techniques. The underlying principle that allow the derivation of the top level master key within a conventional system is quite simple and is also the reverse application of the use of "system keys" developed by Chan and examined in detail elsewhere in this text. Essentially, every conventional master key system relies upon the creation of virtual shear lines through the use of split pin keying. All traditional cylinders have one physical shear line: that place between the plug and shell where pins must break in order that the plug is free to rotate. Within the master key environment, each pin segment within each pin stack creates a virtual shear line or another break point. Accepted master keying algorithms utilize split pin segments to create different combinations or bitting patterns that can open a given lock. In total position progression and rotating constant, methodology, no more than two lower pins will be present in each chamber to create the change key **and all master key combinations.** The permutations that are generated for master keys (including the TMK) are derived as the result of the combined use of the different shear lines that are created by the combination of lower pins within each chamber.

Incidental master keys rely upon a **composite** of break points of change and master key values for their creation. The top level master key, however, does not rely upon such combined use of virtual shear lines between it and any change key. Rather, it requires that no TMK depth value be shared with any change key in the total position progression system. It follows that no virtual shear line that is used by a change key can ever be used by the top level master key. This is the critical issue that allows

locks to be decoded: each virtual shear line that is created can either be for a change key **or** TMK. It follows that if the **change key** is used to sample each chamber, then if another virtual shear line is discovered, **it must be associated with the top level master key.** There are a few exceptions to this rule but they are rare. Controlled cross-keying or selective master keying that utilize double pinning would create the exception.

The extrapolation of the TMK requires that each chamber of a cylinder be sampled individually to test and determine the height of each bottom set of pins through a comparison process with the change key value for that position. The change key provides the constant measurement for each chamber in the form of the depth of bitting associated with each position. That constant is equal to the length of one of the **lower pins(345)** within each chamber. The length of the remaining lower pin (which is required to make the TMK operate) can be determined by altering the bitting depth of the change key by one increment for the specific chamber, then probing the pin stack to determine if the master pin is at shear line. If it is not, the bitting is again altered until the proper depth is determined. This process is repeated for each individual chamber until all have been derived.

31_4.10.3.2 Overview of the Process

The procedures detailed in this section apply equally to systems that have two or more keying levels as long as the change key is associated with the TMK. Reliability and complexity of the process is assured for both total position progression systems and rotating constant systems. As discussed subsequently, issues may arise which can make the decoding of a lock and generation of keys more complicated. These include:

- **The master key system does not utilize total position progression or rotating constant schemes;**
- **The master key system utilizes more than two lower pins (bottom pin and master pins), thereby creating more than two virtual shear lines;**
- **The "change key" that is being utilized to decode the system is actually:**
    - **a master key;**
    - **a change key or master key for a different group of locks that are not associated with the target lock;**
- **The sampled lock is not related to the lock that is to be**

opened;

- **The lock to be opened is not on the master key system;**
- **The lock to be opened is not associated with the top level master key.**

These and other issues are discussed throughout this section. It can be seen that although a low skill level is required to actually decode a target lock, a significant amount of intelligence regarding the target may be required in order to successfully produce a key that will open the intended lock or group of locks.

31_4.10.3.3 Security of Master Key Systems

The security of a master key system is based upon its hardware, method and type of progression, levels of keying, design of the TMK, system control, and other issues that are listed below. All will affect the ability to decode the TMK and produce a working key as well as the overall security of the system.

- **Master key and change key design, following standard protocols for the derivation of all combinations within the system;**
- **Design of the top level master key;**
- **Total number of useable combinations within the system. This number is affected by the type of progression and minimum depth increment (one or two-step), the number of available chambers, and MACS rules;**
- **Type of master key system (total position progression, rotating constant);**
- **The number of individuals that have access to master keys and top level master keys;**
- **The security of keys, locks, and code data;**
- **Inability to gain access to a cylinder to disassemble it;**
- **Ease in decoding a disassembled cylinder. This is particularly relevant in the Corbin master ring lock because of the ease in determining the master key code by analyzing all pins that break at the ring shear line;**

- **How long ago was the system implemented. The average life of a master key system is fifteen years, although many have been in use for a much longer period;**
- **Secondary locking system and security enhancements;**

- **Ability to alter sidebar codes within one master key system;**
- **Access control systems that are operated in parallel with mechanical locks;**
- **Proprietary keyways that are protected by patent and copyright;**
- **Difficulty in replicating blanks. This may be especially difficult if side millings, overhangs (Schlage Everest), and specially designed ward patterns and activation of sliders (Medeco M3) or mechanically linked sidebars have been implemented. However, secondary locking mechanisms and the apparent difficulty in replicating restricted blanks may not actually provide the expected level of security;**
- **System monitoring and restrictions with regard to any person having access to keys or locks;**
- **Whether common areas that are accessible to the public are on the TMK. For instance, a locked bathroom that is part of the master key system can allow the system to be easily compromised;**
- **Ability for change keys to be modified to become a master key or TMK;**
- **Unauthorized access to code data for the system;**
- **Security of cylinders, in terms of their ability to be easily removed without notice. Remember, a cylinder does not have to be taken apart to be decoded;**
- **Implementation of two or more systems of physical security within the lock that operate independently and in parallel with each other.**

31_4.10.3.4 How Do You Know that the TMK Has Been Decoded

The initial thought of many security professionals that have examined this procedure is disbelief or a lack of understanding as to how one can be certain that the TMK, rather than an incidental or intermediate master key has been decoded. In evaluating the methodology for this process, the reader can determine mathematically that indeed the process can only yield the TMK **if a change key is used as the sample for decoding.** Remember that within the TPP scheme, the CK is really a composite of the intermediate level MK and CK bitting, and the intermediate master key is a composite of the TMK and CK bitting values. In the case of the change key, it will never utilize a specific depth and position that has been designated for the TMK. In the RC and PPP systems, this is not the case because the value of one

or more chambers will not be progressed and thus will be common to all levels.

Within a conventional system where there is only one physical shear line, there can only be one result. This of course does not hold true where there are two physical shear lines, such as with the Corbin master ring or interchangeable core, discussed elsewhere in this text. Likewise, a positional system cannot be **decoded** by this procedure but is open to compromise by other techniques analyzed elsewhere in this text.

The extrapolation technique relies upon the fact that there is a maximum of two lower pins in each chamber (bottom pin and master pin). The use of additional pin segments (master pins) would complicate the process and create additional possibilities of virtual shear lines for each chamber and the required generation of more keys to accurately decode the TMK. It would also necessitate the testing of more than one cylinder to verify that indeed the TMK has been produced. The technique of double-pinning is not prevalent in most master key systems.

Sectional keyways do not pose any significant problem so long as the master blank can be obtained or milled and there is only one TMK for the entire complex, regardless of the number of sectional keyways that are employed. Even high security systems that incorporate sidebars can be decoded. Rules regarding MACS, key bitting design, number of change keys and master keys or levels, or the number of locks within the system will have no effect upon the ability to decode and extrapolate the TMK. Regarding MACS, it may require a higher degree of knowledge of the manufacturer specifications to change the cutter angle where required to compensate for MACS violation in the test keys.

If a change key is utilized as the constant, then the TMK will most certainly be derived. Conversely, if any incidental master key (other than the TMK) is used as the standard for sampling, then up to 31 different keys for a five pin lock, or 63 keys for a six pin lock would have to be produced in order to determine the top level master key. One or more of these keys will open the target lock.

If sample keys are cut by code, then the keying system must use standard depth codes in order for decoding to be accomplished. If irregular depths were selected or a specific manufacturer utilizes more than one constant depth increment for the same kind of lock, then information must be determined with regard to each

depth and its correlation to a direct bitting code, or keys must be filed by hand, much like impressioning. Examples: Corbin-Russwin utilized different depth increments in their System 70 and pre-System 70 cylinders. Likewise, Best utilizes different increments for their A2, A3, and A4 removeable core locks.

31_4.10.3.5 Other Issues

There are a number of system keying issues that can make the decoding process more difficult and present potential obstacles for the covert operative in deriving the TMK. These relate to hardware, method of progression, special keying requirements, security enhancements, and levels of keying. All such issues must be taken into account prior to and during the extrapolation process. A number of common problems are summarized below.

- **A target lock may be single-keyed, which means that it will not be combinated to work with any keying level. Likewise, a lock may be part of a master key system, but be non-master keyed (NMK). Although in this case one would expect the lock to be controlled by one or more master key levels, it will not. In either of the above cases, the TMK will not work in the target cylinder;**

- **A lock that is directly associated with a specific master key level but none other would allow the derivation of that level only (in sampled lock). Thus, in the example of a four level system where a change key is directly associated with the grand master key, then only that level could be decoded through the process described in this chapter;**

- **If a master ring cylinder is utilized, it will be impossible to derive the TMK from a change key. This is because the lock contains two distinct physical shear lines. If access is provided to a master key, then it can be used to derive the TMK, because all levels of master keying must utilize the ring shear line.**

- **If the master ring lock is disassembled, it is a simple matter to derive the TMK;**

- **The number of levels of keying within a system is irrelevant to the decoding process;**

- **The sequence of progression is irrelevant to the decoding**

process, but may be important if several change keys are available for analysis (if trying to predict how the KBA was derived);

- **If visual key control(346) is utilized within a facility or standard sequence of progression correlates to locks keyed in sequence and placed on doors in a specified order, then it is a simple matter to compute codes for several locks in a defined order. If a contract installation is completed and the installer utilizes locks that have been keyed using the SOP, and those locks are sequentially installed, then the system can be decoded;**

- **A rotating constant system can be difficult to visually decode by evaluating several change keys because there may be no apparent consistency in the sequence of progression or constant (held) chambers;**

- **If the cylinder is maison-keyed, added problems can arise because there may be several master pins in one or more chambers, thereby increasing the number of possible keys that may have to be generated. It must also be verified that maison-keyed cylinders are part of the master key and TMK;**

- **If there are selective master keys or cross-keys for a cylinder that is being sampled, then additional master pins will be present in one or more chambers. This will make the decoding process more difficult because of the increased number of permutations that may be required to derive the TMK;**

- **Sectional keyways may be utilized. Unless a blank for the top level keyway is available, the TMK may not work in the keyway of the target lock.**

- **There can be no TMK if the system is not master keyed. However, in all master key systems, there will be a TMK, whether it is cut or not;**

- **Secondary locking systems or other security enhancements may make the decoding process difficult if not impossible. Special hardware such as the Medeco Biaxial or M3 may complicate the process;**

- **The decoding process will be very difficult if non-standard depths have been utilized, because sampling of each chamber may fail to detect the master pin. In such an event, impressioning skills may be required;**

- **If single-step and two-step progression rules have been violated, then the decoding process will be more difficult because there may be a failure to detect master pin values unless every possible depth is tested. Likewise, if parity rules are violated within the KBA, then every possible depth may need to be tested;**

- **If the number of pins within all cylinders within the system is not the same, then difficulty may be encountered in decoding a specific lock if it is not consistent with the target cylinder. The sampled cylinder must have the equal or greater number of pinned chambers as the target lock;**

- **If an incidental master key has been unknowingly obtained in the belief that it is a change key, then the process of decoding becomes more complicated because there is no assurance that the TMK value, rather than a change key, has been decoded for any specific chamber;**

- **Decoding a rotating constant system may cause confusion when no master pin is found in one or more specific chambers. It should not make any difference for the decoding process as to which chambers are found to be constant, even if a different progression pattern has been utilized for the sampled and target lock. In fact, if enough different locks were sampled for those chambers that were common between the change key, master key, and TMK, then theoreticlally the TMK could be derived in that manner;**

- **If a non-standard method of master keying has been utilized, especially if double-pinning of one or more chambers is present, then the decoding process will be vastly more complicated because of the potential number of permutations that are generated in the sampling process;**

- **The number of keying levels is not relevant unless a non-standard master keying system has been implemented;**

- **If extra master pins have been added to a pin stack, then added permutations are created, requiring that additional keys be tested. In such an event, the TMK cannot be readily identified from one cylinder, and more keys must be generated to account for the added number of permutations.;**

- **If a master ring is implemented, then the decoding process will not work (if a change key is utilized). In such a case, a master key can be used for the decoding process, but a total of 63 trial keys may be required in a six pin lock;**

- **If sidebar (Medeco Biaxial) or slider codes (Medeco M3) vary between master key level, or between the target and sampled lock, then the process can become more difficult to accomplish unless those codes can also be determined;**

- **Key interchange issues within the Biaxial lock that relate to certain fore and aft cuts that rest on the ramps of a specific cut and may indicate that a certain angle and depth has been correctly decoded, when in fact it is a false positive. The problem relates to a fore cut, for example, that rests on the ramp of the key that has an aft cut. The pin may appear to be at shear line, but it really is not. This issue has been discussed elsewhere in this text.**

31_4.10.3.6 Data Requirements for Decoding

As with any covert operation, a prior analysis of the system to be compromised is always recommended. Although the process detailed in this section is relatively easy to accomplish, a significant amount of intelligence should be gathered regarding the target lock and master key system in order to make the decoding process more efficient and reliable in terms of time and resources. Although not critical, it is suggested that the following issues be evaluated and addressed prior to attempting to decode a cylinder.

- **Relationship between the target locks to be opened and the lock that is to be tested with the change key bitting test keys;**
- **Conventional or positional master key system;**
- **Has a Medeco Biaxial or other system been implemented that**

allows a variance of sidebar codes within a master key system? The term "sidebar code" as used in this context refers to the rotation angles of pins, finger pins (such as Schlage Primus), or side millings (such as Assa) whose combination must match that of the sidebar;

- **Has a standard method of progression been utilized for the system (total position progression, rotating constant, partial position progression);**
- **Is the target lock on the master key system;**
- **Is it certain that a change key is available and that the change key is associated with the target lock;**
- **Have standard depths been utilized;**
- **Estimate of the required security of the system;**
- **Change key code of the sampled lock;**
- **Identification of the lock manufacturer;**
- **Is a maison-keying system implemented;**
- **Was the master key system established by the manufacturer or by a local locksmith;**
- **Number of keying levels. This becomes especially important if a master ring system is in place, because double-pinning at the ring shear line may be required;**
- **If construction keyed cylinders are utilized, there may be a potential to lock out the use of certain keys during the extrapolation process. See the discussion in chapter 11;**
- **Information from systems that have implemented visual key control can provide intelligence as to keying levels. Thus, if GM or AA12 is stamped on a key, for example, it provides information regarding the number of levels and keying groups; Other special function cylinders can affect the decoding process. This would include limited rotation, hotel function, prison function, and key change cylinders such as Instakey;**

Obtain all manufacturer data for the specific cylinders under attack, to include:

- **Tolerance between plug and shell;**
- **Rules and limitations with regard to keying;**
- **Number of useable differs for the master keyed cylinder, based upon a key bitting array for either TPP or RC schemes;**
- **Keyway protection with regard to ability to duplicate keys;**

- **Ability to replicate or obtain blanks;**
- **Depth coding and computation of the space between depths (minimum depth increment);**
- **Likelihood that a single or two-step progression would be utilized in the master key system;**
- **Integration of high security locks with conventional profiles, such as Schlage Primus and Medeco bilevel (available in Europe);**
- **Cross-keying issues and whether there are more than two virtual shear lines created by the master keying scheme. Although this is extremely rare, it can occur;**
- **Utilization of standard or non-standard bitting depths;**
- **Violation of MACS rules;**
- **Use of non-standard cuts that may require a cutting wheel with a special angle to generate test keys. This is a MACS problem, because generation of certain test keys may create depth combinations that were never meant to be cut. In such a case, the cutting angle must be altered to compensate for the problem;**
- **Identification of the keyway(s) used within the complex;**
- **Identification of all sectional keyways and the TMK keyway, or the highest section;**
- **Number of active chambers within each lock;**
- **Whether the master key system was created by the manufacturer or by a local locksmith;**
- **Number of master key levels;**
- **Special design rules for change or master keys;**
- **Applicable MACS rules by this particular manufacturer;**
- **Use of secondary locking systems, such as sidebar, magnetic or electronic;**
- **Use of trap pins or functions that would change the combination if a pin was lifted to an improper depth and the plug was rotated. This condition can occur in the Corbin construction lockout system, described elsewhere;**
- **Use of special key change functions that could alter the pin stack;**

31_4.10.3.6.1 Information From the Change Key

A great deal of data can be obtained from an evaluation of the change key itself, assuming that the manufacturer has been identified. Much of that information will provide an insight into

the type of master key system, the potential number of test keys that will be required, and an idea of how the master key and change key levels are progressed. Keys can still be generated if the manufacturer or identification of the blank cannot be ascertained. See the information on the Easy entrie profile milling machine, below.

Information that can be derived from the change key includes:

- **Identification of keyway and available blanks;**
- **Identification of sectional keyways and all of the potential sub-sections as well as the keyways that control each section and which would be utilized for the TMK;**
- **Number of active chambers within each cylinder;**
- **Whether a one or two-step progression is utilized;**
- **Parity system;**
- **Depth and spacing data;**
- **Change key code;**
- **MACS rules;**

31_4.10.3.6.2 If the Sample Key is a Master Key

Although it is preferred to obtain a change key for the decoding process, it is not vital to the success of the operation. A change key will produce the TMK, assuming that the cylinder is part of the master key system. In the event that an incidental master key is utilized, the same procedure is followed but the result will be different and more complex. In a cylinder that utilizes a true total position progression system, there will always be one master pin within each chamber. In a five tumbler lock, this means that a total of thirty-two (2^5) different combinations will be decoded. Thus, one or more of the possible permutations will open the target lock(s). However, if an incidental master key is utilized for the decoding process, then the results may be varied, because such keys may be a one, two, three or four pin master key. However, there will still the same number of permutations, based upon the number of chambers and lower pins in each chamber. See the discussion in **chapter 11** regarding row, block, horizontal group master, vertical group master, and page master key.

31_4.10.3.6.3 Information from a Change Key and

Master Key

If a single change key and one master key are both available for comparison, much more information can potentially be learned about the target system. The ability to compare bittings within the same area of a facility can often provide valuable insight into how the system was designed and progressed. The data listed below may be particularly relevant when reverse engineering a system. Information that may be obtained from a comparison of the two keys includes:

- **Whether the system is a rotating constant or total position progression. Generally, this cannot be derived from just two keys, but if several samples are available, then it may be possible to make an educated guess as to which systems has been implemented;**
- **The possible progression sequence;**
- **Which chambers have been progressed for the master key and change key;**
- **How many chambers have been progressed;**
- **The possible total number of master keys that can be assigned within the system;**
- **The number of possible change keys under each master key that can be assigned;**
- **System parity;**
- **The possible depths that have been defined for the TMK, based upon their non-use in the master key and change key;**
- **Any depths that are found in the change key will not normally be used in the TMK. This is not the case for the master key. In fact, a comparison of the master key and change key can identify depths that are used in the TMK. Remember: the master key and TMK will share at least one or perhaps two or three common depths that will usually not be common to the change key;**

31_4.10.3.7 Inferences and Assumptions About the TMK or Master Key

LSS204: Brian Chan on assumptions regarding master keying

Based upon information that can be gathered about the target lock and its location, certain facts about the master key system and

the top level master key can be deduced, inferred, or assumed. These include:

- **The first cut toward the bow of the TMK will not be too deep, in order to insure its structural integrity;**
- **The key bitting will not assume a stair-step pattern, either ascending or descending;**
- **At least one of the cuts will be shallower than any change key cut, and one cut will likely be deeper than any change key cut to prevent jiggling;**
- **None of the bitting depths in the change key will appear in the TMK if a true total position progression system has been implemented. In the partial position progression system, this is not the case. There may indeed be one chamber that is shared between all keying levels. Similarly, if a rotating constant scheme is employed, one or more depths will be shared between the top level master key and change key. The constant or shared pin can be in any position, and may vary between locks within a system;**
- **Based upon manufacturers specifications, depth increments, and from an analysis of at least two change keys, in some cases, it may be determined whether a one or two-step progression has been utilized. A measurement of the depth coding for the change key will yield this information. The covert operative will then know whether every depth (single-step progression) or every other cut (two-step progression) must be tested;**
- **A visual inspection of the pin stacks (stack probing) may yield some information regarding shallow cuts. If splits in the pin stacks can be observed, then an educated guess can be made as to the depth of each pin that is viewed;**
- **The color of a pin may yield information as to its length. This may be especially true if after-market pins have been used and the color coding for each depth for that vendor is known. Caution: color coding for a manufacture may be different, based upon whether there is a .003" or .005" difference between pin lengths. Pin kits may use one format or the other;**
- **If the change key can be inserted into locks within different areas of the facility, this would provide a good indication that sectional keyways are not in use;**
- **Based upon the change key, the number of active pin chambers within the target lock can be ascertained;**
- **The number of pins within the lock will usually be from four to**

seven;

- **There will usually be a total of between four and ten depth increments;**
- **There will be the same number of pins in every lock in the system. This is generally the case, but may not always be true, depending upon the security requirements of the system;**
- **The change key design and blank information will indicate whether this is a conventional master key system, and whether high security enhancements, such as sidebar, are being utilized;**
- **Based upon manufacturer, information should be available to indicate whether a master ring is being utilized, which would frustrate the process. Master ring cylinders are generally larger in diameter than standard configurations with one physical shear line;**
- **Letters may be stamped on keys or locks that may yield information about keying levels. See chapter 11 regarding the Standard Key Coding System;**
- **Special rules will apply to Medeco Biaxial systems. See section 31_4.10.6;**
- **Depending upon the manufacturer, the presence of a sidebar may not prevent the system from being decoded;**
- **The system probably does not employ master rings;**
- **The presence or absence of security pins will not affect the decoding process;**
- **There will likely be one TMK for all locks within the facility, even if different sectional keyways are employed;**
- **If considering a government or other high security installation, it may be assumed that certain locks will not be on the master key system, and thus, neither the target lock nor locks within that group may be compromised. Locks that may not be master keyed might include perimeter access, non-administrative areas, locations where explosives or weapons are stored, and areas where critical information is contained;**
- **Standard depth coding and increments can be assumed, unless intelligence about the facility indicates otherwise;**
- **There is no rule with regard to the position or order within the pin stack of bottom and master pins. Any assertion that the bitting of the change key will be below or above that of the master key or TMK is false;**
- **There is no guarantee that the target lock is not single keyed (SKD), or not master keyed (NMK). In such a case, it will be impossible to derive the TMK;**

- **If a lock is directly associated with a keying level below the TMK but not with the TMK, then it will not be possible to extrapolate the TMK directly. In this instance, it may be necessary to generate more permutations. The likelihood in this instance will be that the target lock will not be on the TMK;**
- **It is not necessary to probe the depth value of the change key for each position;**
- **In a single-step progression, every possible depth (other than that of the change key for a specific position) must be tested;**
- **In a two-step progression system, all odd or even depths (other than that of the change key) must be tested;**
- **If a rotating constant or a TPP system(347) is implemented and all chambers are not progressed (PPP), there may only be one depth in any one chamber. In such case, the value of the change key bitting for that chamber will be shared with the master key and TMK;**
- **One depth in any chamber would indicate that the master key scheme is rotating constant or partial position progression;**
- **Unless the system is extremely large, only one or two chambers will be progressed for the master key; the remaining chambers will be progressed for the change key. Note that this is not a hard and fast rule, because some large systems may have many master keys and few change keys, so the key division would be different;**
- **In a Biaxial system, rotation patterns may be varied for different keying levels or groups of locks. This can make the decoding of the TMK virtually impossible;**
- **It is likely that chambers (positions) are progressed in order, rather than staggered;**
- **It is likely that the first one or two chambers will be progressed for the master key, although this is not a fixed rule;**
- **Any depths that are used in the change key will not be found in the TMK within a TPP system. This is not true for depths utilized in a master key in a total position progression system;**
- **If the cylinders contain six pins (regardless of the division employed) there will generally be a total of 64 potential master key combinations. If several change keys are available, then it may be possible to accurately guess the division of the key, although without further information, such a determination is not reliable;**
- **If a number of change keys are available for evaluation, they may not provide any meaningful information if they are associated**

with different master key levels;

- **Sidebar systems that utilize side millings can make the replication of keys more difficult but will generally not affect the decoding process, assuming that there is only one sidebar code that is utilized for every cylinder in the system. This may not be the case if the Medeco Biaxial or M3 system is implemented;**
- **Stair-step patterns are not utilized;**
- **There should not be three adjacent equal depth cuts on one key. Most manufacturers will allow two consecutive depths, however;**
- **If there is not a master pin in one or more pin stacks, then the lock is part of a rotating constant or partial position progression system;**
- **TMK values for each position can be above or below those of the change key;**
- **All depths for each position, other than the change key value, must be sampled. This depends upon whether a one or two-step progression is employed;**
- **Plug or key markings may provide information about the system and levels of keying. See the discussion in chapter 11 regarding the Standard Key Coding System;**

31_4.10.4 Decoding a Target Cylinder

The information presented in the following sections will provide the tactical and operational procedure to derive the top level master key for most conventional cylinders. The preceding materials in this chapter and in **chapter 11** provide the underlying theory of the extrapolation process. The procedure requires that a change key be available that is part of the master key system within the target facility. The procedure may also be accomplished with a master key, but it is more complicated. The availability of blanks for the target lock is also required. These may be obtained through normal channels or may be created in the event they are restricted. Detailed information is provided in **chapter 8** regarding the creation of blanks through the use of profile milling machines. Note that in certain instances, patent protected profiles may need to be replicated. The reader is cautioned that the generation of certain keyways may violate federal patent statutes.

31.4.10.4.1 Variables in the Process

It is important to understand and anticipate the variables that may be encountered in any process of covert entry. There are a number of conditions that can make the decoding of the TMK more difficult or impossible. Each of these factors has been discussed in earlier sections relating to this subject and must be taken into account prior to and during any operation to derive the top level master key. The primary variables to obtain the TMK include:

Sectional keyway: If a different sectional keyway is utilized for the sampled lock and the target cylinder, then the derived TMK from the sample cylinder will not be able to enter the keyway of the target lock.

Selective master key or cross-keying: See **Double pinning**, below.

Rotating constant or partial position progression system: IN a rotating constant or partial position progression system, then one or more depth values of the TMK will be common to the master key and change key. The practical implications of this condition will require that every possible depth be tested in order to determine the TMK value. Recall that in the TPP system, the values of the TMK depths are never shared with any change key, and thus, the specific depth for each position of the change key does not need to be sampled in order to derive the top level master. However, in the RC or PPP system, one or more chambers may only contain one bottom pin (no master pin).

An interesting permutation of this issue would occur if a selective master key (SMK) or cross-keying of one or more cylinders was utilized within a rotating constant or PPP system for certain progression patterns. Then, one or more chambers would contain two lower pins: one pin would be equal to the shared value of the change key, master key, and top level master key, while the master pin would be utilized to turn on or off a selective master key or create a cross-key. This could be very confusing to the operative because he might wrongly assume that the TMK utilized the second pin for a specific chamber, resulting in the misidentification of the system as TPP rather than RC or PPP and the generation of a key that was not the TMK. Note that the integrity of an RC system is based upon the premise that a single pin will be in one or more chambers. If that rule is violated, then key interchanges that result will be impossible to analyze.

Master ring: A master ring will prevent a cylinder from being

decoded through the use of the change key. This assumes that (1) all change keys operate at the plug shear line, and (2) all master keys and top level master key functions at the ring shear line. If the system has more than two keying levels, then double-pinning may be required at the ring shear line. It may then be possible to derive the TMK, if a **master key** is available. However, it is not possible to utilize the change key that is operating at one physical shear line (plug) in order to determine TMK values at another physical shear line (ring).

Double-pinning in one or more chambers: If double-pinning exists in one or more chambers, then additional permutations of possible TMKs will be generated. Double-pinning can be present if selective master keying or cross-keying is required.

No master pins: A lock that is single-keyed or non-master keyed would usually not contain master pins in any chamber. A master ring lock would act as if it did not have any master pins. A **Medeco cam lock(348)** only has one set of pins, and relies upon bores within each pin to control the sidebar. Finally, if an error is made in the KBA that results in the duplication of a TMK value for the change key or master key, then only one bottom pin may be present for a specific chamber. In such an event, the cylinder can still be decoded.

Master keyed but not on the TMK: A lock that is master keyed but is not associated with the top level master key cannot be decoded for the TMK, but may allow derivation of one or more master keys. Some locks may be combinated for certain master key levels, but will not be operated by the TMK. In such an instance, decoding will yield incidential master keys, but not the TMK.

Violation of minimum depth increment rules: If the .023" minimum depth increment rule is violated and depths have been programmed into the KBA that do not meet this specification, then change keys and the TMK may utilize depths that would not normally be tested through the extrapolation process. In such a case, every depth that the manufacturer makes available within the specific cylinder must be tested against the change key.

Single-step progression where a two-step progression is expected: See the preceding section. If it is expected that a two-step progression has been utilized in writing the key bitting array, but in fact a single-step progression was employed, then every depth must be sampled rather than every other depth. There are cases where single-step progression is utilized where the minimum

depth increment is less than .023", but this is compensated for by tightening manufacturing tolerances.

Different depth increments for the same type of lock produced by the same manufacturer: A manufacturer may utilize different depth increments for the same type of lock. The Best A2, A3, and A4, and the Corbin-Russwin System 70 present such an example.

Parity rules not followed between the TMK and change key: If parity rules are not adhered to between the values of the TMK and other keys within the system, then all depths for each position must be tested against the change key.

Non-standard depth coding: If non-standard depth coding is employed, then a measurement of the bitting for one or more change keys may be required to determine all potential depths that may have been utilized for the TMK. This information may be theoretically extrapolated from one change key by measuring each of the individual positions and the increment between depths and then adding or subtracting the value of such increments to determine the total number of depths and their measurements.

Different sidebar bitting codes for the TMK and change key: If there are different sidebar bitting codes, slider codes (Medeco M3), or other security enhancements that distinguish the change key from the top level master key, then it may be impossible to derive the TMK unless those unique bitting patterns can be simulated in order to generate master key blanks.

Error in the KBA from which combinations for the TMK and change key were derived: A discussion of KBA errors was presented in **chapter 11, section 11_5.3.6.3.** If an error is made within the key bitting array (as shown in the above section) wherein a value of the TMK is repeated for use as a change key or master key, then for that position and combination, a master pin may not be present. This condition could lead to an erroneous conclusion that the system was RC or PPP. The results of such an error may not be relevant.

31_4.10.4.2 Tactical Considerations in the Decoding Process

There are several methods to decode the TMK that will require either a single session with the sampled lock or multiple sessions. Although a change key is the primary means for

extrapolation, the lock may also be shimmed to derive all pin stack information, or the Falle decoding system may be utilized. The decoding processes that are detailed in section **31_4.10.4.3** will describe procedures relating to the different methodologies.

The following general issues must be addressed and verified prior to any decoding procedure:

- **Determination that extrapolation is the best method to derive the TMK, and an elimination of picking, impressioning, and alternate decoding methods as more desirable procedures;**
- **Verification that there is only one master key system;**
- **Verification that the change key is to be used for sampling;**
- **Verification that the proper blanks have been obtained;**
- **Label each system key by chamber position in order to avoid confusion. A tactical situation may dictate a different procedure;**
- **Any secondary locking mechanism, such as a sidebar, must be the same for both the change key and top level master key;**
- **Within what time frame is the decoded TMK required. This will in part determine whether a lock is sampled in one or multiple sessions;**
- **Verification that the number of pins in the sample and target lock are the same;**
- **Verification of the depth coding for the sample lock;**
- **Only one change key or master key is required. Note that it is not as desirable to generate the change key through impressioning or picking and decoding, because the product may be an incidental master key. A key may be obtained by an employee, or as a duplicate obtained from an employee or service person. It may also be a stolen key or borrowed and copied or decoded;**
- **Access (whether authorized or unauthorized) to a cylinder that is associated with the top level master key;**
- **If sectional keyways are employed, then verification must be received that the proper blank is available for the target lock;**
- **Ability to reproduce bittings for each sample key. This may be done by hand file and a micrometer or a decoding device, such as the HPC HKD-75 or a code cutting punch such as the pack-a-punch or key machine;**
- **If the Falle pin-lock decoder is being utilized, verification that the proper keyway has been supplied;**
- **Determination of the number of samples that can be obtained**

from the test lock at one time, or over a period of time;

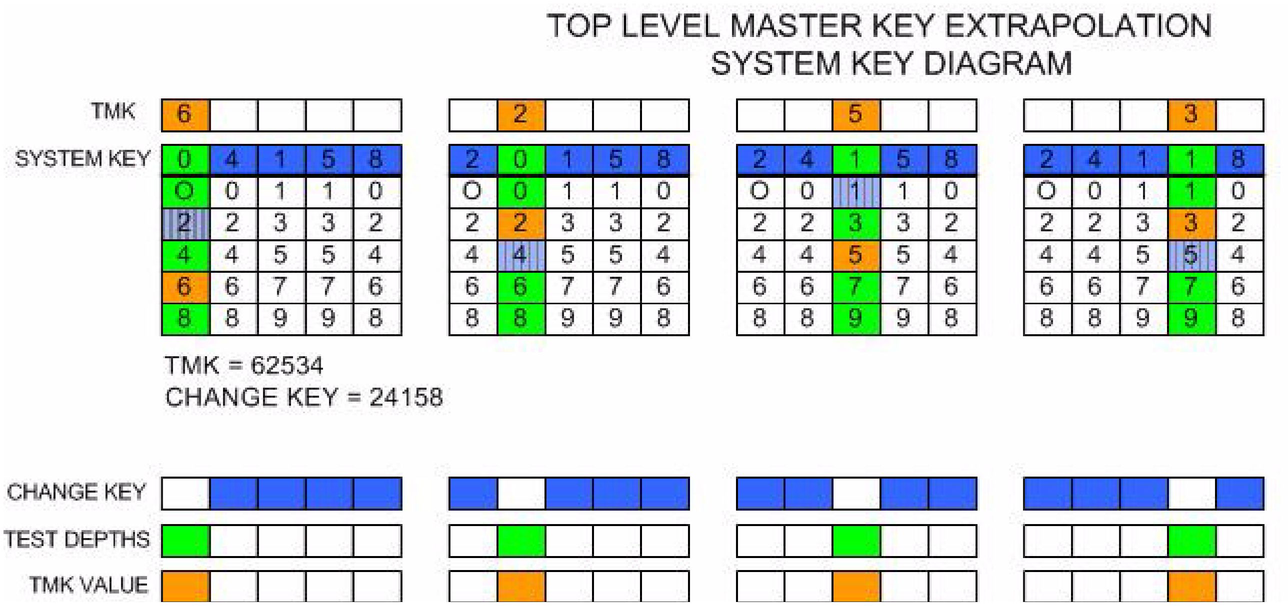
- **Access to more than one cylinder, if required;**
- **Sufficient number of blanks to complete the sample process;**
- **The time available for the decoding process and any time constraints on the process;**
- **The visibility of the sample and target lock;**
- **An analysis of the work area where the decoding is to occur in order to determine power requirements, lighting, visibility, sound transmission, video surveillance, alarm systems, and likelihood of interruption;**
- **The specific location of the target and sample locks;**
- **The number of locks to be tested and verified;**
- **If reprogrammable locks are installed, such as Instakey, then bottom pins or master pins may be inadvertently removed or parked, thereby changing the combination of the lock and providing a false positive indication of the TMK;**

31_4.10.4.3 Decoding Methods

The following methods may be utilized to derive the top level master key within a conventional master key system:

- **Decode the TMK with a change key in one session while at the test cylinder;**
- **Decode the TMK with a change key in multiple sessions, requiring several individual samples to be taken from one or more cylinders;**
- **Decode the TMK with a change key in multiple sessions with precut system keys;**
- **Decode the TMK with a master key in one session. In actuality, up to 32 or 64 keys would be generated in this process, but the actual value of the TMK (which key was the TMK) would not be known;**
- **Decode the TMK with a master key in multiple sessions;**
- **Shim a cylinder to determine the composition of each individual pin stack, generate all possible permutations of the TMK at a remote location, then visit the target lock in one or more sessions to determine which of the generated keys will actually open the target lock. Just because the lock can be opened does not mean the top level master key has been utilized to do so;**
- **Utilize the Falle pin-and-cam pin-lock decoder system to decode**

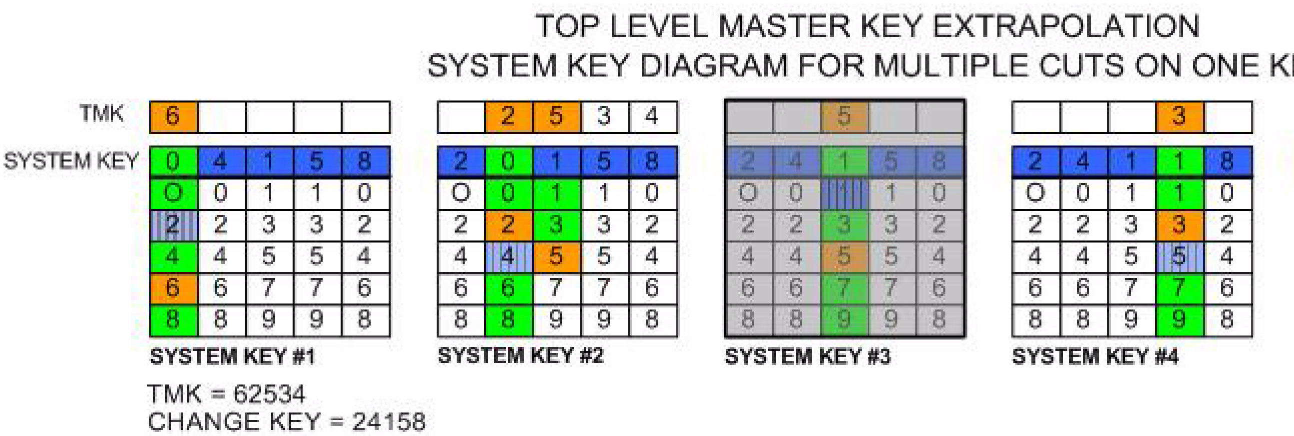
and possibly generate a working TMK during one session;
- **John Falle Pin lock decoder (original model).**



Each method is described below.

31_4.10.4.3.1 Decode the TMK With a Change Key In One Session;

In this technique, a TMK is produced in one session by decoding each pin stack in succession. The minimum number of blanks that will be required will be equal to the number of chambers within the lock, although this number can be reduced if multiple chambers are sampled on one key. This depends upon whether TMK cuts are above or below those of the change key. If they are below, then more than one chamber can be tested, although there is a danger in this shortcut if double-pinning of a chamber is present. At the conclusion of the process, one extra blank may be needed to cut the compiled values of the TMK.



In preparation for the procedure, keys must be precut for the lock, to equal the number of chambers. We shall use a five pin Schlage cylinder as an example, with a change key code of **24158** and a top level master key of **62534**. Recall that the shallowest cut for a Schlage lock is 0; the deepest is 9. Schalge minimum depth increment is .015", so a two-step progression is utilized. Parity must be maintained and can be assumed to be the same for the change key position and that of the TMK.

Five system keys would be produced for this lock as shown in the diagram: **04158 20158 24158 24118 24150**. Note that the shallowest cut is placed on the bitting surface for each chamber to be tested (shown in green). Refer to chapter 11, section 11_5.6.2.1 for a detailed discussion of system keys, as introduced by Chan. The keys that must be cut in our example are system keys but their purpose is to test for the TMK rather than for the change key.

The diagram shows a modified key bitting array, with all possible depths entered into the matrix under the system key code. Each system key is the change key with one bitting position set at 0 to allow a sample to be taken for each available bitting value. Each grid represents one key. The depths marked in green are each cut in sequence, with all other depths for that particular system key (blue) remaining constant. The depth that is equal to the change key is not cut (shown in cross-hatch blue). As the system key is tested for each available depth, the lock will open when the TMK value is cut (shown in orange). Note that all depths are tested (other than the change key value) to insure that double-pinning has not been implemented. At the conclusion of the process, five keys will have been cut, and the top level master key will have been derived. A sixth key can then be generated by code for the TMK. The exception to this rule would be where multiple cuts are made on one system key.

Multiple samples may be made on one system key, depending upon the change key bitting, which system key is utilized, the value of the next TMK depth, and which chamber is sampled. In the diagram below, four system keys are required to sample a five pin lock. In this example, if each new test key is cut to the derived TMK depths as they are decoded, then five keys will be required.

Two chambers can be sampled in system key #2 because the bitting value of the change key in the third position is shallower than the TMK value. Thus, the "1" cut in position "3" can be tested for a "3" and "5" (the value of the TMK). System key #2 cannot be utilized to sample the fourth position because the bitting value of the change key is "5", which is lower than the "3" assigned to the TMK. In our example, Schlage has a MACS of 7. If a TMK position value was 9, for example, and the adjacent depths included a 1, then it would not be necessary to cut that value because it would create a MACS of 8. Thus, in our example, adjacent cuts of 09, 08, 19 would not be utilized and could be skipped.

In practice, a file, pack-a-punch, code cutting machine, or code punch can be utilized to physically cut the system keys and test each depth for each chamber. At the conclusion of the process, the composite is cut on a new blank and tested in the target lock, (or more than one lock if the target is not available).

31_4.10.4.3.2 Decode The TMK With A Change Key In Multiple Sessions

The same procedure is employed as in 31_4.10.4.3.1, but each depth for each position is tested during a separate session, reducing the risk of detection and the potential of being caught with key cutting implements or blanks. The lock is sampled for each position and each chamber and the appropriate depth cut is made on the system key for that chamber. At the conclusion of the procedure, a system key will have been produced for each position. A composite TMK can then be generated by code.

31_4.10.4.3.3 Decode The TMK With A Change Key In Multiple Sessions With Precut System Keys

The change key can be used to generate system keys in advance of decoding that will allow a rapid determination as to the TMK value for each position. This procedure will allow a lock to be decoded in one session or over a period of time, depending upon the sensitivity of the operation and whether an operative can run the risk of being caught with multiple system keys. In either scenario, a set of keys are generated to provide all possible permutations of each positional value. In our original example in section 31_4.10.4.3.1, the change key code was 24158. Based upon a two-step progression, the even values would be 0,2,4,6,8 and the odd values would be 1,3,5,7,9. Four system keys are required for each position, replicating the process used by Chan and discussed in **chapter 11**. The system keys for this cylinder would require a total of twenty blanks and would be cut as follows:

SYSTEM KEYS FOR CHANGE KEY 24158				
POSITION #1	**POSITION #2**	**POSITION #3**	**POSITION #4**	**POSITION #5**
04158	**20158**	**24358**	**24118**	**24150**
44158	**22158**	**24558**	**24138**	**24152**
64158	**26158**	**24758**	**24178**	**24154**
84158	**28158**	**24958**	**24198**	**24156**

Each key would be tested in sequence against the test or target cylinder. For each position, one of the four keys will open the lock if the master key system was derived through total position progression. If a rotating constant or partial position progression system is employed, then one or more systems key sets will not work for a particular position. That would indicate a held position that was common to the change key, master key, and TMK. This fact should be noted, and the value utilized when generating a composite TMK by code.

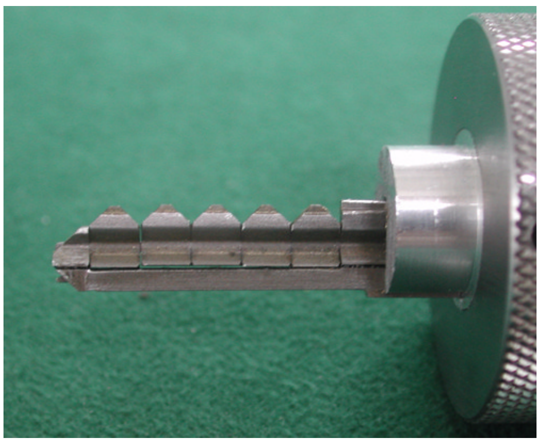
31_4.10.4.3.4 Decode The TMK With A Master Key In One Session

Decoding a cylinder using a master key rather than a change key

becomes more complicated because composite combinations are being evaluated, rather than the clear distinction that exists between the change key and top level master key. In order to utilize the master key to determine the TMK, a two-step process must be completed: each position must be probed for all values, then all permutations must be produced in order to test the lock. Recall that the **master key** is actually a composite of the division of the key: one part is assigned to the master key and the remaining portion is **shared** with the TMK. If the master key is utilized for extrapolating the TMK, then the problem becomes one of determining which decoded value for each position is part of the TMK/MK and which belongs to the master key/change key. Up to 64 permutations will be produced in a six pin lock that is set up on a total position progression system. Each of these permutations may need to be produced and tested against the target lock to determine the true TMK. If the system was established using a rotating constant, then there will be fewer permutations but the process will require the same procedure.

31_4.10.4.3.5 Decode The TMK With A Master Key In Multiple Sessions

The same process as explained in 31_4.10.4.3.4 is carried out, but in multiple sessions. Each



31_4.10.4.3.6 Shim A cylinder

LSS203: Matt Blaze on shimming a cylinder to determine all pin segments

A cylinder can be shimmed and decoded by using a set of depth keys but without the need for disassembly. This topic was detailed in section 31_4.9.1. The process requires that a set of depth keys be produced for the target cylinder. A shim is inserted at the back of the lock and each depth is probed for each position, beginning at the tip of the key (rear of the plug). Notation is made of each value that allows the shim to pass. When all chambers have been probed, a replication of each pin stack will have been produced. Test keys can then be cut by code for all permutations. A cylinder containing six pins that is set up for total position progression will generate a total of 64 combinations (2^6). One of these will be the top level master key.

31_4.10.4.3.7 Utilize The Falle Pin-and-Cam Pin-Lock Decoder System

The John Falle pin-lock pin-and-cam decoding system described in section 31_4.6.1.2.2 can be utilized to generate system keys if the correct profile is available for the tool. As shown below, the Falle system can replicate each bitting value for each position, eliminating the requirement to physically cut each system key.

This sophisticated tool allows the code for the change key to be entered into the bitting selector. A composite key is then instantly produced that will open the lock at the change key level. Each bitting increment is then tested in sequence for each chamber until the TMK value is determined for each position. This system is extremely compact and can allow the covert decoding of a cylinder within a very short period of time.

31_4.10.5 Obtaining Sample Change or Master Keys for the Extrapolation Process

In order to perform the extrapolation procedure, a change key is required. As detailed elsewhere in this text, there are a number of ways to secure this key, including:

- **Obtaining possession of an authorized key as an employee, agent, contractor or other legitimate status;**
- **Obtain a photograph or facsimile copy of the key and then generate a physical duplicate;**

- **Obtain a copy of the change key through the normal duplication process or by impression using clay, silicone, or other materials;**
- **Obtain the direct code from numbers stamped on the key;**
- **Obtain the code by compromise of the database where such information is contained;**
- **Obtain the code from the locksmith that set up the master key system;**
- **Obtain the code or a copy of the key from the manufacturer through authorized or unauthorized channels;**
- **Obtain the code for the key by visual inspection or by physically measuring it;**
- **Obtain the code for the key through shimming of the cylinder, discussed in previous sections;**
- **Impressioning the lock. This procedure may yield a change key, incidental master key, or TMK;**
- **Use of certain decoders that are produced by John Falle and others to determine bottom pin lengths for each chamber;**
- **Use of the Falle pin and cam pin lock decoder to determine the actual pin stack values for each chamber. This procedure would provide the codes for all lower pins segments. Test keys could then be generated with the same tool to derive the TMK, through a process of testing each combination against the target cylinder;**
- **Other methods that are summarized in chapter 28.**

31_4.10.6 Special Rules for Decoding Specific Locks

Certain locks will be extremely difficult to decode and extrapolate for the TMK. This results from the integration of secondary locking mechanisms that utilize independent systems that are not directly related to each other, or for which there is no constant. Even though traditional methods of defining master key systems (TPP, RC, PPP) are utilized for the generation of bitting codes, ancillary locking systems may yield information that is of no value in the decoding process.

31_4.10.6.1 Medeco Sidebar Systems

Detailed information regarding Medeco locks can be found elsewhere in this text. The company received the first patents for the sidebar locking concept based upon rotating tumblers,

both in cam lock and traditional pin tumbler configurations. Subsequent to the original designs, Medeco introduced its Biaxial system, and in 2003, the M3 enhancement. It expects to release the M3 upgrade and biaxial for cam locks in 2004. In the United States, Medeco has achieved the greatest market penetration as a high security lock manufacturer. Their locks are preferred in many applications within the public and private sectors because of the security that they provide against all forms of covert attack. Although certain of the mechanisms are subject to the more sophisticated forms of bypass, others are not. Our discussion will focus on methods to compromise master key systems that have relied upon Medeco hardware for security. Sophisticated tools and techniques have been discussed in earlier sections of this chapter with regard to methods of decoding and bypassing Medeco cylinders.

The author has always believed that the design philosophy that Medeco adopted for the implementation of the sidebar principle for pin tumbler locks was the most secure, as compared to techniques employed by other manufacturers. The integration of rotation and elevation within the locking component (pin tumbler) can make this mechanism extremely difficult to neutralize or decode. The Biaxial addition provided an extension of the original patent protection and offered the ability to implement extremely large master key systems without the problems of key interchange and insufficient differs for the definition of multiple keying levels.

The choice by Medeco not to split conventional pin tumbler locking technology (vertical movement across a shear line) with the rotation of the pin distinguishes the design from all others that have chosen to implement the sidebar as a secondary locking technique. Virtually every other manufacturer that utilizes the sidebar to secure the plug against rotation is limited to one arrangement, position, elevation or rotation pattern for all locks within a system (that have a common top level master key). This is not the case with the Medeco Biaxial and M3 designs, and therefore makes it unique with regard to the extrapolation process discussed in the preceding sections.

31_4.10.6.1.1 Medeco Cam Lock

The Medeco cam lock relies upon a single set of pins and does not have a traditional shear line. Rather, each tumbler has one or more bores that correspond to a protruding pin of the sidebar, as shown in **Figure 17-21A.** Master keying is accomplished by placing

multiple bores within each pin. The function of the key is to lift and rotate the tumbler in order to line up all bores so that the sidebar can retract into the plug. The M3 and biaxial schemes will be incorporated in 2004.

If a change key is obtained for any cam lock within a master key system then the TMK can be decoded by varying the elevation and rotation of each bitting position, using the change key as a constant. Even though the cam lock is a relatively low security mechanism in fact, it offers greater resistance against the extrapolation technique than does a conventional pin tumbler design because of the requirement to generate multiple permutations of bitting and rotation values for each chamber.

31_4.10.6.1.2 Medeco Original Pin Tumbler System

The original design of the Medeco pin tumbler lock provided for three rotation angles: left, center, and right. Within a master key system, the pattern of angles must be defined for **all** locks and cannot be altered, once established. Thus, all keys will bear the same angle pattern. It can be seen that once any key for any lock can be obtained, the information regarding the angle of rotation for each chamber is known. In order to defeat the original Medeco system, the same procedure is followed as for conventional locks, with the exception that the rotation pattern must be replicated for every test key. Although more time will be required to accomplish the extrapolation process, it will not prevent the successful decoding of the TMK. This is only true with respect to the difficulty of generating keys with sidebar codes. It is recommended that any master key system that relies upon the original Medeco design be evaluated as to the risk of compromise through the extrapolation technique. It is not a difficult matter to duplicate Medeco key bitting or angles, and so the threat is significant, depending upon the requisite security level of the facility. As discussed subsequently, use of the Biaxial or M3 cylinders will insure that a great deal more difficulty is encountered in compromising the TMK for those locks. Note that key blank distribution will continue to be restricted by Medeco after the expiration of applicable patents, so blanks may be difficult to obtain through normal channels.

31_4.10.6.1.3 Medeco Biaxial System

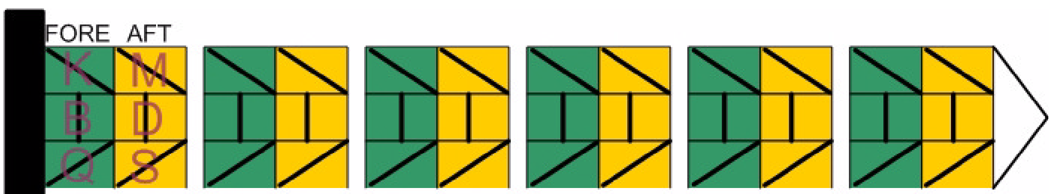
The Medeco Biaxial concept adds a layer of complexity and

security to the original design and also provides for many more differs for master key systems. The Biaxial and M3 will make the extrapolation of the TMK exceedingly difficult, but not impossible. A detailed discussion is presented here because of the prevalence of Biaxial cylinders in high security applications worldwide.

31_4.10.6.1.3.1 The Biaxial: An Overview

The Biaxial mechanism, as described in chapter 17, is a modification of the original pin tumbler design. It altered the location of the root of each tumbler position by creating an offset chisel point that rests be**fore** or **aft**er what would be the root center point in the original configuration. Although the lock functions in identical fashion, a total of 6^6 or 46,656 possible permutations of sidebar patterns were created. In the view of the author, the Biaxial is a lock that is extremely secure against the process of extrapolation, unlike most other mechanisms that employ a sidebar as a secondary locking system.

The original Medeco design, as well as those of other manufacturers, employ the sidebar as a totally separate locking system. However, unlike other designs, the rotation and elevation of the pin is integrated into the pin tumbler, rather than occurring as separate mechanical operations. Both Assa and Schlage, for example, utilize separate side millings on the key to interact with finger pins or side grooves on tumblers. In both examples, the side milling portion of the key can be separated from the bitting portion, thus allowing the lock to be picked. This is not possible with the Medeco designs.



The use of rotating pins is unique to Medeco and creates two parallel locking systems; one that is conventional and which relies upon the pin tumbler being raised to a shear line, and one that can be compared to a positional system that relies upon the rotation of each pin, and which can be varied throughout a system as graphically illustrated below. Although Emhart also introduced a rotating pin concept, it is interlocking and is of a different design.

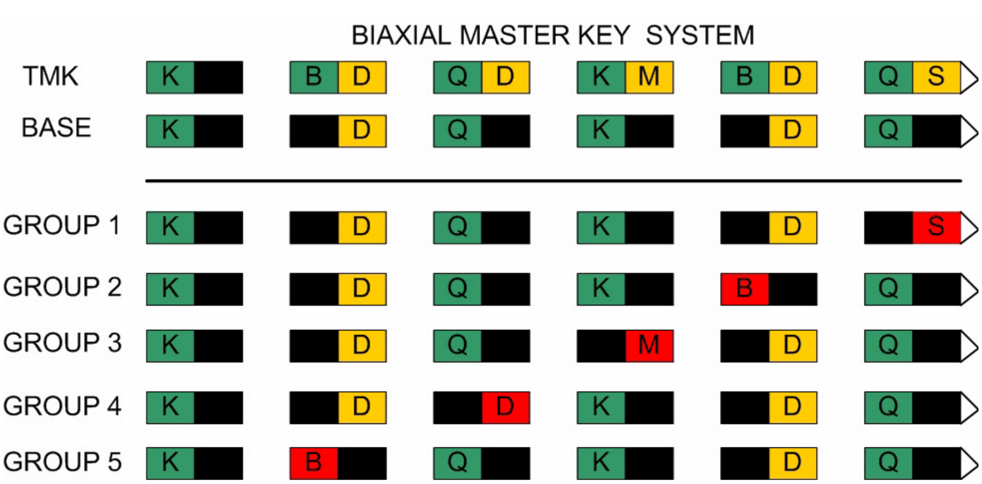
Security against the compromise of the TMK relies upon the ability to vary the sidebar patterns throughout a complex master key system. This feature can effectively prevent the use of a change key to probe the pin stack of each chamber. The Medeco Biaxial and the Assa V10 are the only known systems that offer the capability to alter sidebar combinations within one system,

although this option is rarely implemented.

31_4.10.6.1.3.2 Master Keying Theory for Biaxial Cylinders

The biaxial system allows for two possible tumbler positions (fore and aft) for each chamber that can be rotated twenty degrees from center to create three angles. In the original Medeco design, the angles were labeled as **R** (right) **C** (center) and **L** (left), denoting the orientation of each chisel point at the base of the tumbler. In the Biaxial, the base of the pin is formed by an offset chisel point that positions it be**fore** or **aft**er center; thus the positions are referred to as **fore** and **aft**, referenced to the shoulder of the key. To avoid confusion with earlier versions of the lock, the pins are designated with letters that denote whether they are fore or aft, as shown in the chart below.

MEDECO BIAXIAL ROTATION ANGLES



With respect to the pin stack, Biaxial locks are master keyed in the same manner as conventional cylinders. Bottom and master pins are utilized to create virtual shear lines based upon combinations that are generated by total position progression, rotating constant, or partial position progression schemes. It is the rotation angles and their integration with the dimension of each pin tumbler that distinguishes this system and makes it so secure against attack. A pattern of angles is first defined for the entire system. We shall refer to this as the "base pattern." It can be a combination of fore and aft positions and any one of three rotations for each chamber position. We then progress this pattern based upon the design of the system. The chart defines our hypothetical system, having five groups, each assigned their own sidebar pattern. The TMK, as shown in the graphic representation of a composite key, will open any lock in the system with any of the sidebar patterns shown in the chart.

MEDECO BIAXIAL MASTER KEY SYSTEM

MK GROUP	SIDEBAR PATTERN
BASE	K D Q K D Q
GROUP 1	K D Q K D **S**
GROUP 2	K D Q K **B** Q
GROUP 3	K D Q **M** D Q
GROUP 4	K D **D** K D Q
GROUP 5	K **B** Q K D Q
TMK	K D Q K D Q - B D M B S

It can be seen that each group of locks has a unique sidebar pattern. A key from group one, for example, can never operate a lock in group two, because the rotation angles would not allow the sidebar pins to mate with all pin tumblers. The unique property of the Biaxial design that allows the use of multiple sidebar patterns is the ability to **double cut** a key, or place a fore and aft cut in the same bitting position.

This feature replicates a positional master keying system and in effect allows multiple rotational patterns to be combined in one key. The TMK is actually a composite of the differences in rotation angles for each group of locks (shown in red), and also contains the base pattern from which each group is progressed. The TMK that will operate all locks in our example is shown below.

31_4.10.6.1.3.3 Decoding the Biaxial Master Key System

The conventional portion of the Biaxial lock can be decoded through the use of a change key. That is, the master pin value for each chamber can be determined through the normal extrapolation process. The bitting values will always remain constant throughout the Biaxial master key system, as with any other TPP or RC matrix. It is the rotational patterns that are varied and provide the system security.

The security of the Biaxial cylinder is based upon the following rules and design parameters, which affect the decoding process:

- **Rotation angles can be varied throughout a master key system;**
- **The position of cuts can be varied (fore or aft);**
- **Two separate locking systems are incorporated within one cylinder. Variance of the rotation angles can prevent accurate decoding of the TMK;**
- **All of the required data for any specific lock is not available and cannot be derived from another lock unless in the same group;**
- **There is no constant with regard to rotation patterns that can be utilized to probe the target cylinder as there is with the bitting values of the change key;**
- **Total position progression, rotating constant, or partial position progression is utilized to define the bitting values of each bottom and master pin, as with a conventional cylinder;**
- **Bitting values can be determined through the normal extrapolation process, as defined elsewhere in this section;**
- **A lock cannot be decoded for the TMK unless the bitting value, position, and rotation angle can be determined for the target lock;**
- **One "base" rotational pattern is established for the entire system which defines the fore or aft position and angle for each bitting position. This base pattern is then progressed or altered for each desired group or level of cylinders;**
- **The TMK is a composite of all rotational angles and positions that are used for every cylinder. In this regard, the rotational patterns can be viewed as a separate and distinct positional master key system;**
- **The rotation angle for any given fore or aft position cannot be varied once it is defined for a group of locks. For example, if a fore left angle (K) is utilized in the base pattern, it can never be altered for that position. That means that a B or Q cut can never appear in that location, but any aft angle could be used**

(M, D, S);

- **The TMK and intermediate master keys can be double cut so that they can operate cylinders that utilize either fore or aft cuts in the same bitting position;**
- **If the rotational patterns are varied between locks, then the sampled lock and target lock may not have the same patterns. In such a case, there is no way to derive pattern information for the target lock from any other cylinder, unless intelligence exists to indicate that the lock that is sampled has the same pattern;**
- **High tolerances are maintained for all components, including plug-shell interface and sidebar-pin interface;**
- **The "base" pattern code cannot be determined unless all locks within the system were to be analyzed through disassembly or physical decoding of all change keys;**
- **The progression pattern that alters the "base" code cannot be determined for any specific lock or groups of locks;**
- **Added security can be obtained if the bitting values as well as rotation angles and position are varied for different groups of locks. Normally, it would be assumed that the bitting values of both fore and aft cuts for any position would be the same. However, these may be varied within certain parameters. Thus, for example, a fore cut of 3 and an aft cut of 4 could be utilized in one position. This would make the decoding process infinitely more difficult;**

- **MACS for Biaxial is based upon an increment of .025" for six depths and is computed from bow to tip of the key. The system is single-step, with an 86 degree cutter:**
  - **if fore follows aft, MACS = 2**
  - **if fore to fore, or aft to aft, MACS = 3**
  - **if aft follows fore, MACS = 4**

- **Any angle can be utilized in any fore or aft position. No information will be available as to whether a specific position has been altered and if so, whether the angle for fore or aft has been changed; If an angle has been altered within a system, then the complement of that angle must be utilized. That is, two different fore (or aft) angles cannot be utilized within the same master key system if there is to be one TMK, because double cut keys can only have one fore and one aft angle for any one**

chamber;

- **From the change key, it is impossible to determine which positions and angles are different between the sample and target lock;**
- **If more than one bitting position is altered with respect to fore or aft cuts and angle, then decoding of any lock would require up to 3^6 permutations or 729 different angle patterns to be produced with the same bitting to determine the TMK for a specific cylinder;**
- **The TMK will be a composite of fore and aft angles for all cylinders;**
- **The TMK will contain the value of each fore an aft cut of the base pattern, and the progression of each position that is assigned to a specific group of locks. In order to derive the pattern for the target lock, the precise value of each change key position, or the three values of the opposite cut must be probed. This means, for example, that if the change key has a value of K (fore left) for the first cut position, then the TMK can only have the value of K or M, D, S (aft cuts) in that same position. The K will never be a B or Q anywhere in the system;**
- **During the extrapolation process as each lock is probed, positive locking will occur with respect to any pin whose angle or position is incorrect. Depending upon system progression, this may require that all possible permutations be tested against the sample lock;**

Intelligence as to how a specific manufacturer implements its master keying may provide information that will aid the decoding process. Methodology employed by Medeco can make extrapolation more complicated or easier. Certain patterns are more prevalent, especially in larger systmes. Likewise, the use of procedures that are not predictable will enhance the security of a system. It should be noted that sidebar patterns will rarely be varied within a master key system unless there are an extremely large number of locks. However, the author would recommend the implementation of varied sidebar codes in critical areas;

- **Double cut keys always use a MACS of 2. This may provide information with regard to depth cuts, but not to angle extrapolation;**
- **Added information for a target cylinder can be gained by impressioning to determine whether a fore or aft pin has been utilized in a specific position.**

An example will illustrate the difficulty in decoding a Biaxial cylinder. Let us assume that the change key and sample cylinder have a rotational pattern of **KDQKDS** and the target lock of **KBQKDQ.** It can be seen that the change key, in two positions (chambers 2 and 6) have different angles and fore/aft positions. Let us also assume that we have been able to derive the bitting values for the TMK from the sample cylinder. How do we produce the TMK for the target lock?

If we were to probe the sample lock in an attempt to derive all rotational values, we would have to generate a total of 729 keys, but still would not have the needed information. Why? Because the sample lock does not contain the same information as the target lock. Remember, this is a positional system and can be compared to the Sargent Keso, discussed elsewhere in this text. Different values appear in different locks but are not constant to all locks in the system. Therein lies the problem. There is no way to determine the values in the target lock (D and B, chamber 2, and S and Q, chamber 6) from the sample lock. In order to derive a key that would open the target lock, it would theoretically be necessary to run all 729 permutations, because there are two variables, and their position is unknown. The normal probing of one chamber at a time that is used to determine bitting values will not work in this instance, unless special procedures are employed.

If the lock was master keyed with different bitting values between the base pattern and target cylinder, then the process could be very difficult to achieve. That is, if the fore and aft cuts had different bitting, many more permutations would have to be generated to probe the cylinder. If the M3 system is implemented, even more security is achieved, as detailed below.

31_4.10.6.1.3.4 Decoding the Biaxial for Two Different Groups of Locks

This procedure assumes that each group of locks has a different sidebar code, as shown in the table in 31_4.10.6.1.3.2, and that only one rotational position is varied for each group. In this and the subsequent method of extrapolation, it is assumed that the conventional bitting has already been derived from the sample lock. The procedure will allow for the identification of two individual groups within a system (that of the sampled cylinder and a second cylinder, which may be the target lock). The identification of the second group can lead to the subsequent

identification of other groups in the system, and ultimately result in the derivation of the sidebar double-cut coding for the TMK. Note that this procedure will not provide the coding for the TMK unless unique angles for all groups are decoded. A change key must be utilized for this sequence, and contemplates double-cutting of the test keys to be done as the sample and target cylinders are probed. Subsequent probes can be carried out to determine the coding for the third, fourth, and fifth groups (and the TMK code). As will be described in a later section, there is a simpler approach to determine sidebar coding for a target lock that may only require a very few samples to be taken.

In the previous example, it was demonstrated that unknown rotational values in two positions require up to 729 theoretical permutations of the sidebar code to be run in order to identify the actual sidebar code of the TMK. In fact, this number can be reduced to a maximum of 135 iterations. In this procedure, pairs of sidebar complementary values are run against four constant chambers. Recall that for any position that is altered, the complement (fore or aft) of the value in the change key is changed, as shown in the table. Although there are 729 permutations of the sidebar code for use in the double-cut TMK application, we only need to find the value of the one that differs from the base code for the sample key and the target lock.

In order to identify two sidebar code groups, we utilize all combinations of complementary rotational values for two positions, against four constants (there are a total of six positions). In practice, all depths for the TMK and all angles as determined from the sample lock and it's change key are cut for every test key. The two complementary angles are then double cut and the key is tested. If this key does not work then the next pair of complementary angles is cut on the next test key and tested until one of the set of 135 complementary angles opens the lock. This requires that up to fifteen pairs of values must be tested, each requiring up to nine permutations (3^2).

IDENTIFICATION OF TWO GROUPS		
COMPLEMENTARY ANGLES VARIED	**CONSTANT FOR CHANGE KEY**	**PERMUTATIONS**
1+2	3456	**45 (3 x 3 x 5)**
1+3	2456	
1+4	2356	

1+5	2346	
1+6	2345	
2+3	1456	**36 (9 x 4)**
2+4	1356	
2+5	1346	
2+6	1345	
3+4	1256	**27 (9 x 3)**
3+5	1246	
3+6	1245	
4+5	1236	**18 (9 x 2)**
4+6	1235	
5+6	1234	**9 (1 x 9)**

If the tactical situation allows testing of these 135 keys in the target lock, then one of these keys will open the cylinder. If the tactical situation limits access to the target lock, then the above testing is done in a group two lock (a lock that does not open with the correct TMK depths and change key TMK angles).

With two positions identified, we can find the third rotational variable by testing a total of four positions. All depths for the TMK and all angles as determined from the sample lock and it's change key, and the two complementary angles found above are cut for every test key. A group three lock (a lock that does not open with this test key) is then tested. This requires up to twelve different keys to be generated (4 positions with three rotational values). The fourth position can be determined by testing up to three positions (9 total keys), and the fifth position, in like manner, will require up to six keys. The final position will require up to three keys to determine its coding. Thus, a total of 165 possible test keys may be required to determine the TMK coding for the system. Note that this procedure would require access to and identification of cylinders in each of the different sidebar code groups. In addition, it is assumed that there is only one rotation variable for each sidebar group, and that there are a total of six groups within the system.

31_4.10.6.1.3.5 Decoding the Biaxial with Impressioning Information

The most reliable and expedient means of compromising a Biaxial system, with the least number of permutations of test keys,

requires that additional intelligence be obtained about the target lock, especially if the **TMK** sidebar code is needed. If the sidebar code is different in the target lock, or if all group codes are required, then added information is needed to avoid the requirement of running up to 165 separate combinations.

Recall that the scheme that Medeco has employed to allow for multiple sidebar codes within one system requires that the variance between the base sidebar code and each group is premised upon the use of the complementary fore or aft cut for each position. This rule cannot be violated because the TMK is a composite of all individual rotation angles and positions. Thus, there can never be a different rotation value in the same position and with the same fore or aft orientation. For example, a system could never have in the first position of any key an **M** and **D** (aft cuts) or **K** and **B** (fore cuts) in any cylinder. The complement of such a cut can be used, but never the same one.

This rule allows a Biaxial cylinder to be easily decoded for a different sidebar code in a different group of locks, if additional information can be derived from the target lock. This also presupposes that there is only one variable for each sidebar code group. The procedure will become more complicated if two or more variables are utilized, and will require that more permutations be run. However, the ability to identify which positions must be progressed remains the same.

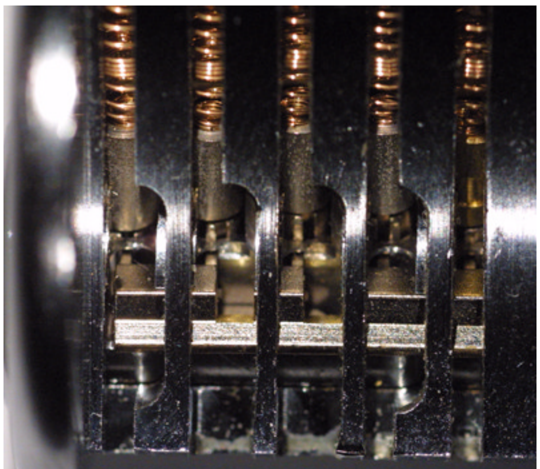
In the previous section (31_4.10.6.1.3.4) that described the decoding process to obtain two or more sidebar code groups, the procedure required up to 165 different keys to be generated to derive the information. The number of different iterations of sidebar codes is required because no information is available form the target lock with regard to its code, and none can be extrapolated from the change key that is utilized for probing, or from the sample lock.

However, if information as to the fore or aft orientation of each pin tumbler in the target lock can be observed, then the decoding process becomes quite simple and requires very few different combinations to be tested. This is based upon the fact that there will only be a variance in two positions of the six pin tumbler positions in the target lock, as compared to the sampled lock. These variances will provide the critical information that will indicate which positions and orientations to sample in order to derive the sidebar code permutations that must be tested, and eliminate unneeded permutations. The target lock as well as other

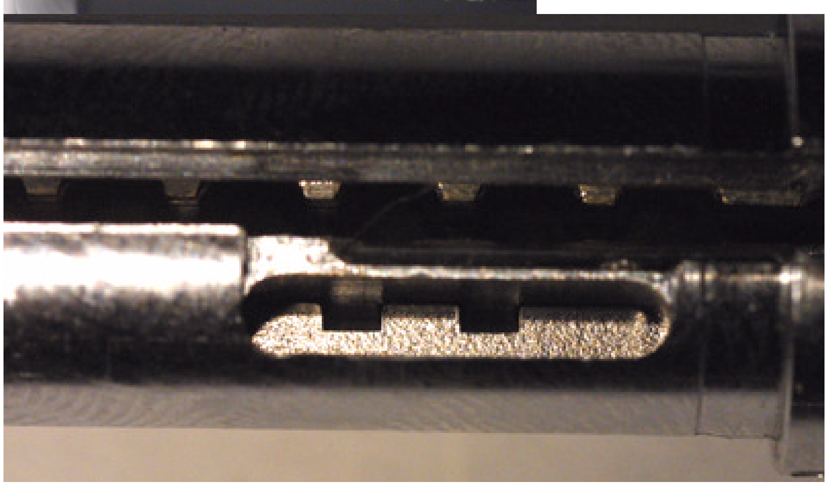
locks in other groups can then be probed in the same fashion as is done for the TMK conventional bitting values, using one position at a time.

Referring to the table in 31_4.10.6.1.3.2, let us assume that we are using a change key from group one, having a sidebar code of KDQKDS. We are probing a Group five cylinder that has a code of KBQKDQ. When we insert our test key into the target lock, there are two positions that will not match the code of that lock: 2 and 6. In order to successfully open the target lock, we must determine the values for 2 and 6, and how they differ from our sample change key. A critical examination of the table reveals that there will always be a variance of two positions between a sampled and target cylinder. If we are able to identify these two positions, then we can test a matrix of combinations until we find the correct one. The keys that are used for probing of the target cylinder are double cut with the original change key angle values and TMK depths and the probed complementary values.

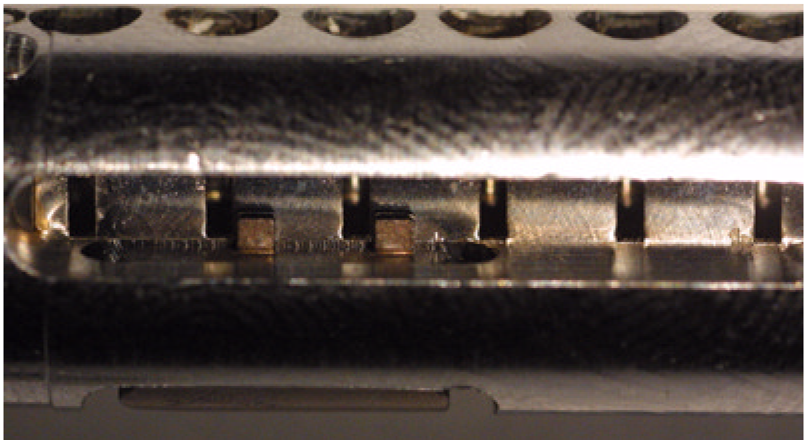
The required information can be obtained by overlaying a carbon film on a blank key, inserting it into the target cylinder, and causing each pin tumbler to mark the blank. From this, we can determine whether a fore or aft cut is employed. We then generate up to nine keys (three rotational values for two positions, or 3^2) based upon the two positions that indicate a variance from the original change key code. This will provide the sidebar code for the target lock. For each position that is progressed, we only use the fore or aft position that is the complement of that which appears on the change key for the sampled cylinder. This fact also allows us to double cut the test keys.



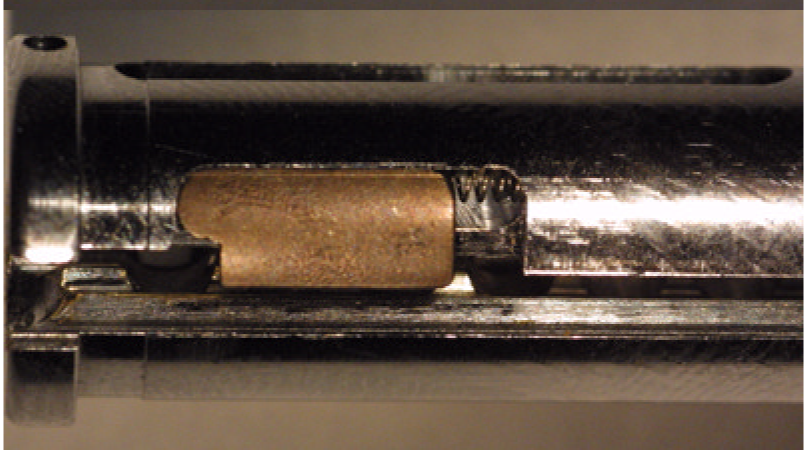
To deriver the sidebar code for other groups of locks, we utilize the same procedure to obtain information about another target. The number of blanks that are required to determine one additional sidebar group can range from one to three, depending upon luck and the particular sidebar code for the target. To obtain all sidebar codes for all groups within a system, we must run up to three permutations for each additional position to be probed. Generally, we would need to produce from six to twenty one blanks (nine to probe the first two positions, and twelve to identify the remaining four positions) and then take all of the information for each position and cut a composite TMK.



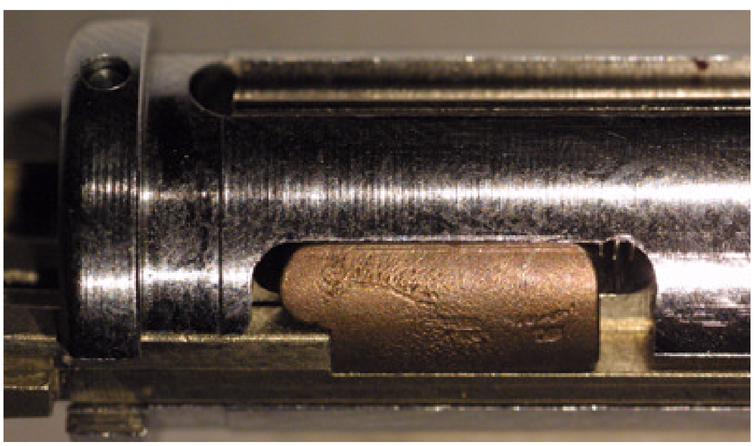
Although the method of generating multiple sidebar codes that has been chosen by Medeco will increase the security and theoretical available combinations of a master key system, unless more than



one variance of rotational values is assigned to each position, the system is relatively simple to decode.



31_4.10.6.1.4 Medeco M3 System



The Medeco M3 system was introduced in 2003 and is discussed more fully in **Chapter 17.** The M3 offers a third level of security against all forms of covert attack, but particularly with respect to extrapolation of the TMK. Although the information regarding the slider can be determined, its presence will make the decoding process more difficult. There is no backward compatibility between the M3, Biaxial, and original designs.

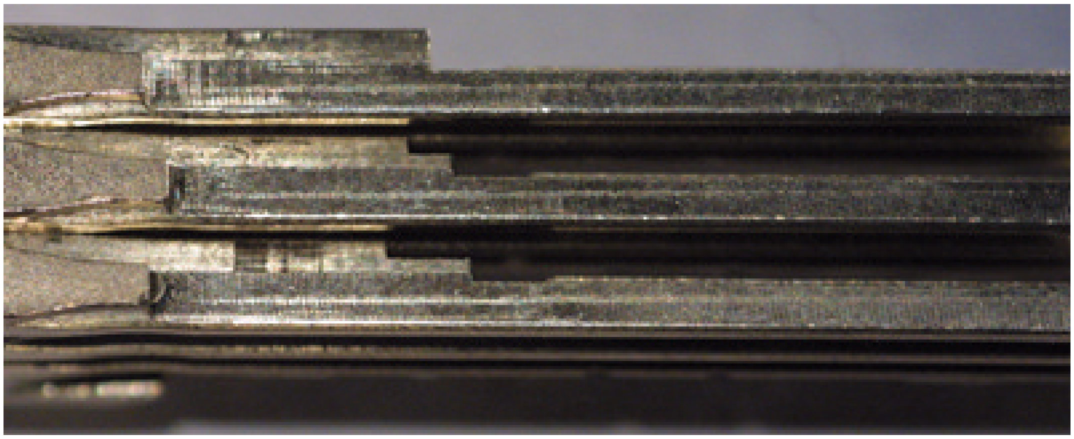


Figure LSS+3145. Sequence of photographs showing the operation of the Medeco M3 and the interaction of the slider with the side milling of the key. (Top left) shows the face of the cylinder with the edge of the slider visible. (Top right) shows the sidebar partially inserted into the plug. The two gates must mate with the slider, which has been removed from the plug but would occupy the space immediately above the sidebar in the photograph. (Middle left) shows the sidebar channel with the protruding locking tabs from the slider. Note the six channels for the sidebar pins and the relationship with the slider tabs. If the slider is not moved into its precise position to mate with the gates of the sidebar, the sidebar is blocked from entering the plug. (Middle right) shows the slider in the biased and locked position, with no key inserted into the keyway. The spring (right side of slider) will always force it to the front of the plug. (Bottom left) shows the interaction of a master key side milling with the MK slider. Note how the milling forces the slider backwards for proper alignment with the sidebar. (Bottom right) shows three different keys with side millings to mate with MK and CK sliders. The top key is for an MK slider.

31_4.10.6.1.4.1 Overview of the M3 Design

The M3 is a Biaxial cylinder with an added component. Called a slider, this moveable piece is controlled by side millings on the key that protrude into the keyway and make contact at one of two points. There are 27 slider permutations, based upon the position of the interface, and its control function. Sliders can allow or block keys from accessing cylinders that are designated for change keys or master key function. Thus, a change key can be coded so that it will never open any lock that is designated to be operated by a maser key only. Likewise, keys that are coded as master keys can be blocked from operating any cylinder that is set for change keys only. The third possibility allows a cylinder to be accessed by change keys or master keys. In such instance, the slider has two steps: one that makes contact with the change key milling, and one for the master key milling.

The slider is integrated with the sidebar and has two locking tabs that protrude. Corresponding gates in the sidebar must be aligned with these tabs in order that the sidebar can retract into the plug. Any misalignment between the sidebar and slider will result in a lockout. Tolerances are such that torque cannot be applied to the plug to bind the sidebar prior to the proper rotation pattern being set for all pins. However, a shim can be utilized to depress the slider as the lock is sampled.

The dimensions of a slider can be derived without difficulty. This results from the following design parameters of all sliders:

- **All sliders have a constant overall length;**
- **The locking tabs for all sliders are in the same position;**
- **The slider is accessible from the keyway and can be measured from the edge of the change key or master key step to the front of the cylinder.**

Even though the slider code can be derived, the information will not help in decoding the rotational pattern of the lock.

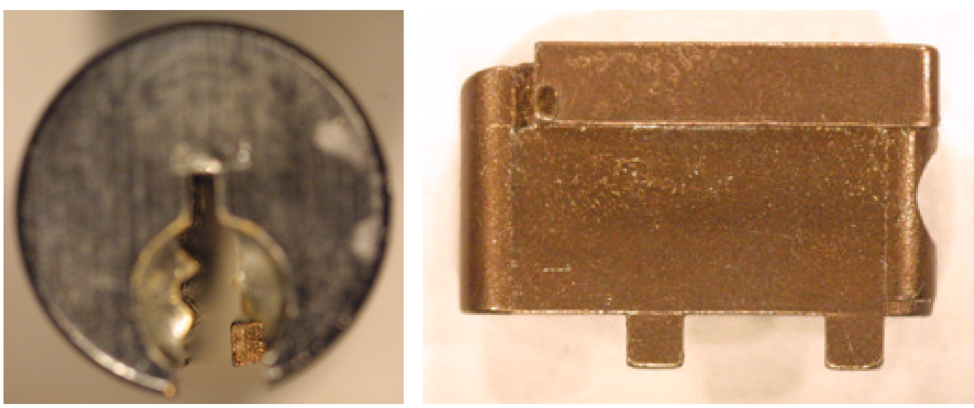

Figure LSS+3146 The Medeco M3. The slider moves along the keyway and is visible from outside of the plug.

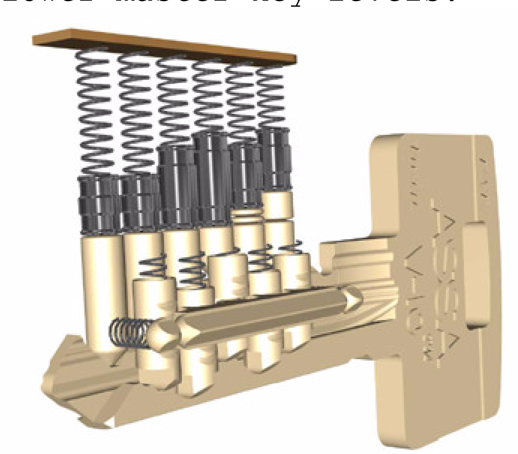
31_4.10.6.1.4.2 Decoding the M3 for the TMK

Decoding is more difficult in the M3 than in the Biaxial because of the slider component. The M3 cannot be opened unless the following occurs:

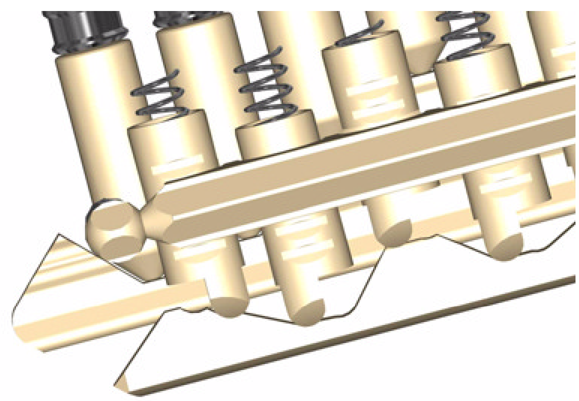
- **Proper bitting is determined;**
- **Proper rotation and fore or aft position of each pin tumbler is ascertained;**

- **Proper keyway is utilized;**
- **Proper slider code is determined, with regard to:**
    - **cylinder coding: change key only, master key only, or change and master key combination;**
    - **one of six possible positions.**

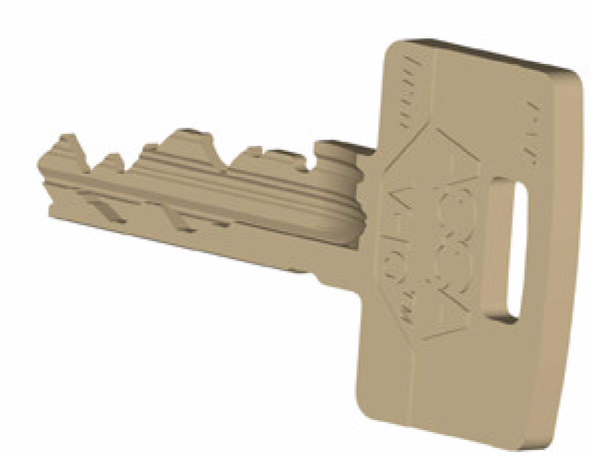
The security of the M3 with regard to extrapolation of the TMK results from:



- **Slider must be properly aligned with the sidebar in order to probe the lock;**
- **Difficulty in replicating blanks with side millings to make contact with the slider;**
- **Lack of information regarding the target lock and whether a CK, MK, or CK/MK slider is present;**
- **The slider provides a third parallel level of security; the proper bitting, rotation angle and position, and slider position must be correct before the lock can be probed or opened. Each of the three systems operate independently;**
- **Although a change key can be used to extrapolate the bitting values of the TMK, it will not provide sufficient information to derive the rotational patterns. A key with side millings that restrict its use to cylinders designated for change keys only can still be used to decode the bitting for the TMK. However, the change key blank, if replicated, would not open a lock that is coded only for master key operation.**
- **Blanks cannot be altered to operate different slider codes. Thus, a CK only blank cannot be made to operate the slider in a MK only lock;**
- **The slider code must be determined for the target lock before any probing can occur;**
- **If the slider code is not determined and replicated for the target lock, then that lock can never be decoded and opened, even with the correct bitting and rotational pattern;**
- **Unless the slider is manually manipulated in the target lock for each sample, there are 27 possible permutations that must be generated in order to probe the sidebar for the correct angle and position for each chamber;**



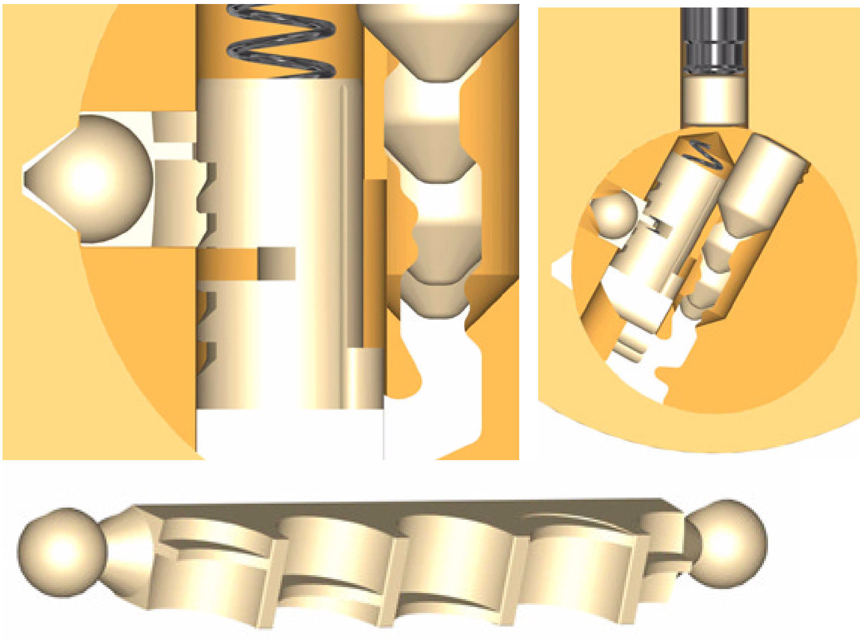
Although Medeco introduced the M3 primarily to extend the patent protection of the Biaxial design, the addition of a third security layer makes the process of extrapolating the TMK more

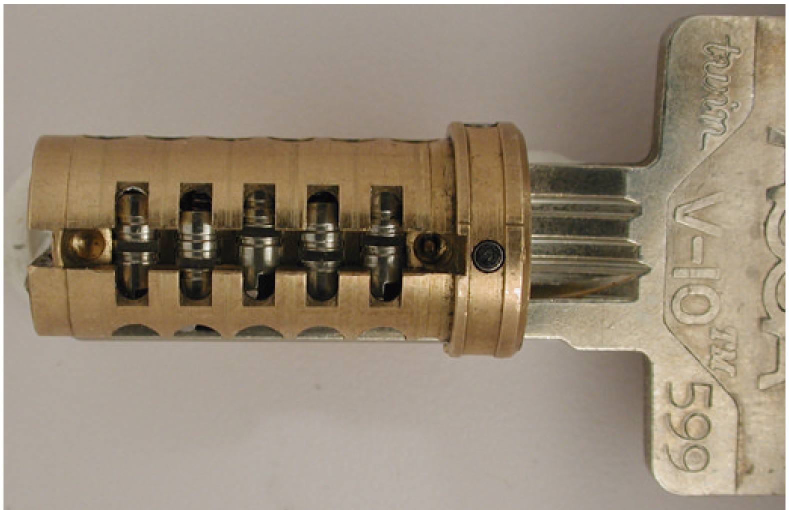


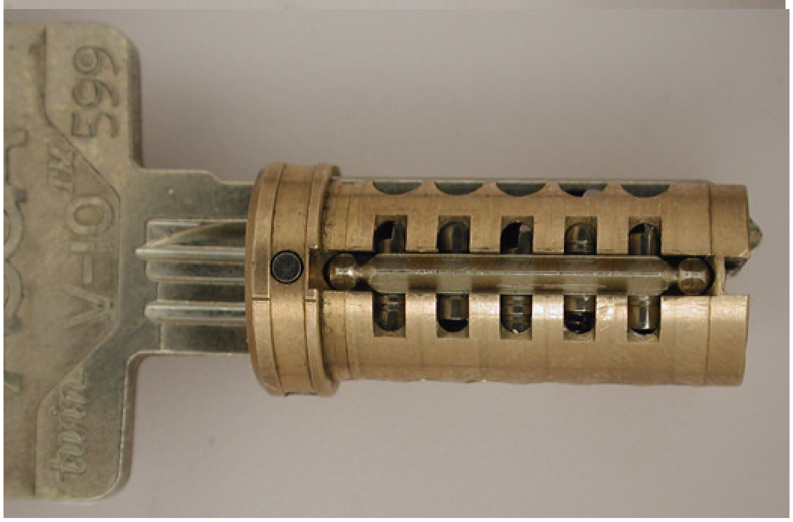
difficult and time consuming, and will insure a high level of security for any master key system.

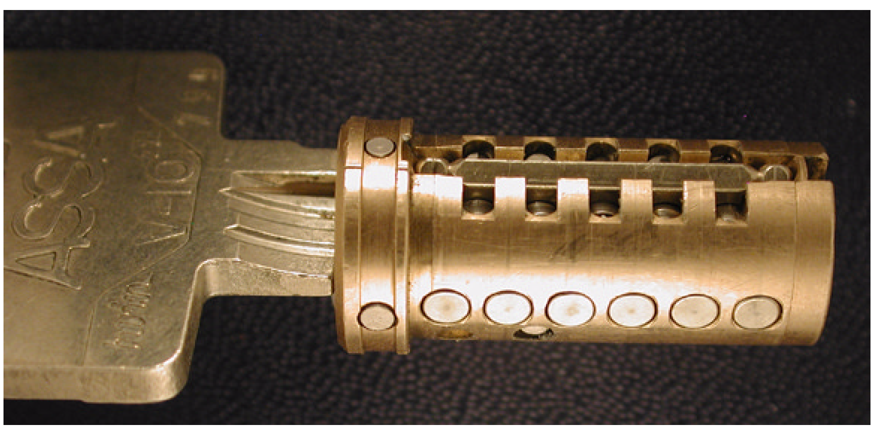
31_4.10.6.2 Assa 7000 V10 Sidebar System

Assa has designed the V10 system to provide for increased master keying flexibility and useable differs without compromising security. These systems are employed within extremely large installations, where hundreds of thousands of cylinders must be keyed to multiple keying levels. The Assa V10 and Medeco Biaxial can deter the compromise of a master key system through the extrapolation of the TMK. While other sidebar systems may make picking and decoding extremely difficult, they do not adequately address the problem of extrapolation. Virtually every sidebar lock (other than Assa and Medeco) is limited to one sidebar code that is shared by the TMK and all cylinders that are keyed to lower master key levels.









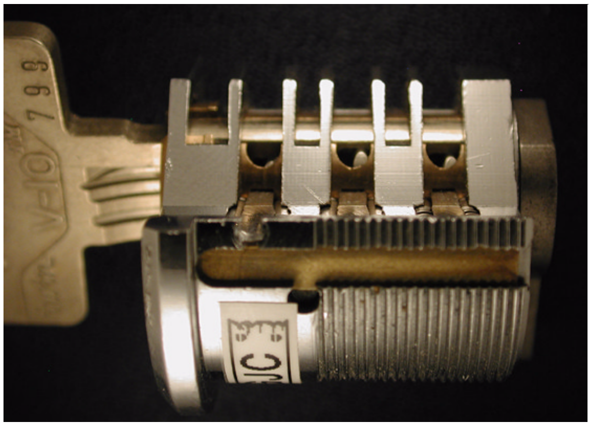


Figure LSS+3151 The Assa V10 system utilizes a sidebar with a fixed code for individual groups of locks or for all locks within a system, depending upon the security level. Note that there are different depth increments on the sidebar that correspond with finger pins that make contact with the side milling of the key. Courtesy of Assa.

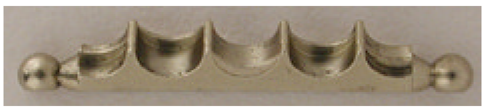
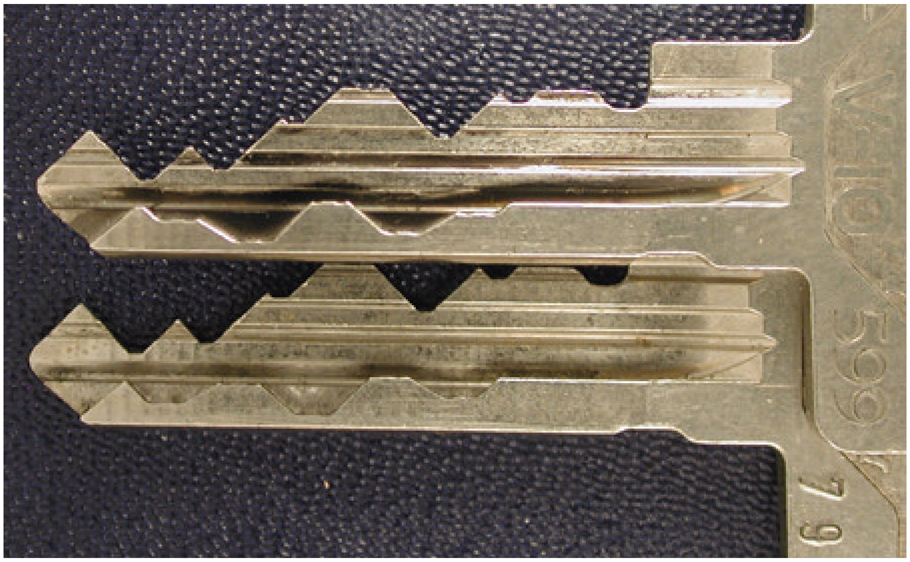
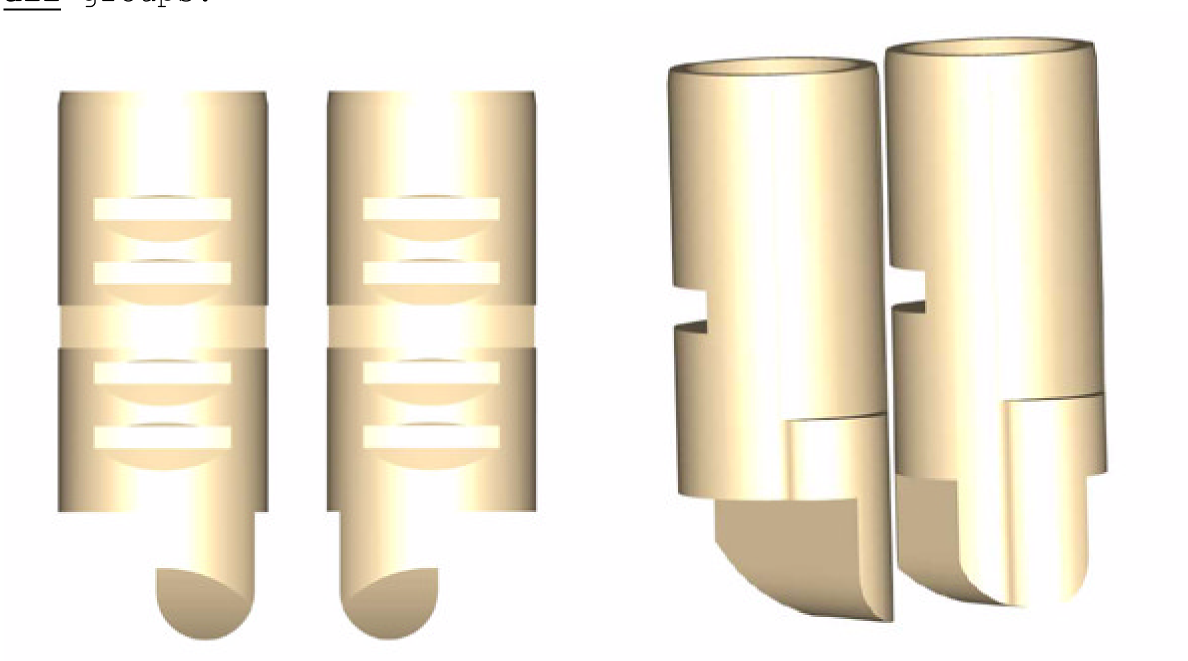


The Assa 7000 series V10 sidebar lock allows variations of one sidebar code, or multiple sidebar codes to be utilized in one master key system, much like the Medeco Biaxial or M3. Assa only utilizes this design in large master key systems that require the highest of security. Few systems exist in the United States. The lock is mainly used in Europe but with limited implementation. In many respects, the approach that Assa has taken is similar to that of Medeco in the way that they provide for the use of more than one sidebar pattern under the control of one top level master key. The photographs show the relationship between the gates in each individual finger pin and the sidebar fence that mates with its corresponding pin. The photograph of the cylinder face shows the finger pins in the keyway (lower left). A comparison of the bitting of two different sidebar codes for the same key demonstrates the capability for multiple sidebar codes under one TMK.



SSA
ASSA
V-10

Assa offers two subsystems of multiplexed sidebar codes to increase the security and number of differs within a master key environment. In one system, Assa **simulates** different codes for each group of locks, although in actuality, there is one common code for all locks. In the higher security series, there are actually different physical sidebar codes for each group of locks. Each approach will be examined in this section, because like Medeco, Assa can provide a serious obstacle to the extrapolation of the TMK.



31_4.10.6.2.1 Overview of the Assa Multiplex Systems

Within a traditional sidebar master key system such as the original Medeco cylinder, a Biaxial cylinder where multiple sidebar codes are not employed, a Schlage Primus system, or even other Assa systems **not** utilizing multiplexing, security is based upon the secondary locking action of the sidebar. With regard to master keying, no additional security is provided to protect against the derivation of the top level master key. Sectional keyways, Everest undercut, and other schemes have been implemented, but none offers any protection against extrapolation. The Assa sidebar code scheme is an integral part of the keyway design and a form of virtual keyway subset that provides positive locking when the wrong key is inserted. In some respects, Medeco achieves a similar but higher security result with their M3 slider.

The Assa V10 utilizes a fixed sidebar for secondary locking. As

shown in the photograph above, the sidebar has the capability of five different depths in five positions, or 3,125 (5^5) theoretical permutations. This assumes that the sidebar can be reversed within a system. There are actually two physical sidebar code possibilities if the reverse image is also utilized. Assa reports that there are actually 1402 useable sidebar differs for each orientation within a cylinder.

There are two primary levels of multiplexing of sidebar codes within the Assa V10 series of lock. These two levels can also be combined to form a third hybrid system. Each relies upon a scheme of double cutting of sidebar millings to raise finger pins that interact with the fixed sidebar code. The finger pins for both systems utilize left and right orientations that correspond with side bitting on the key. A matrix of left and right pin positions is selected for each group of locks. As shown in the chart below, there are a total of 32 (2^5) possible permutations of left-right combinations. A unique code is selected for each group, as shown in the example. All of the keys for each group have identical side millings, based upon this selection. The TMK is double-cut so that it can accommodate the sidebar codes for **all** groups.

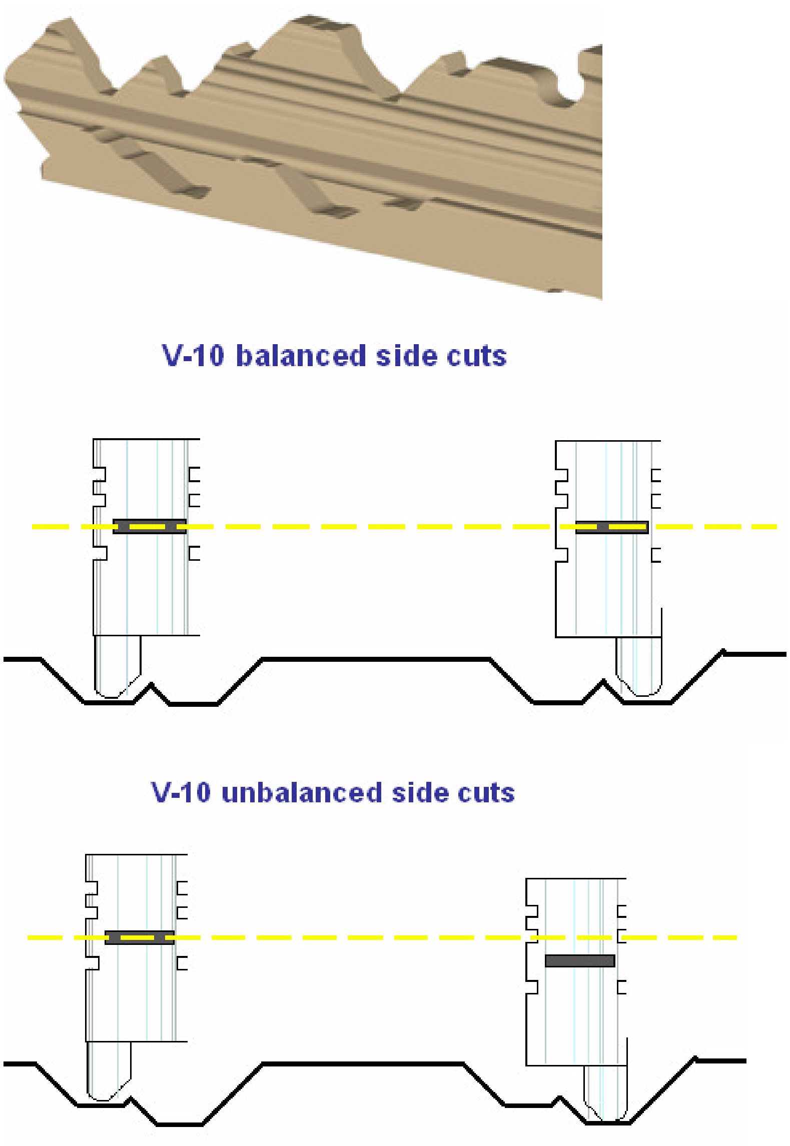


Figure LSS+3152 The Assa V10 utilizes finger pins that provide for a left or right contact point for each bitting position of the side millings on the key. Pins can be balanced or unbalanced with respect to left and right contact and the position of their gates.

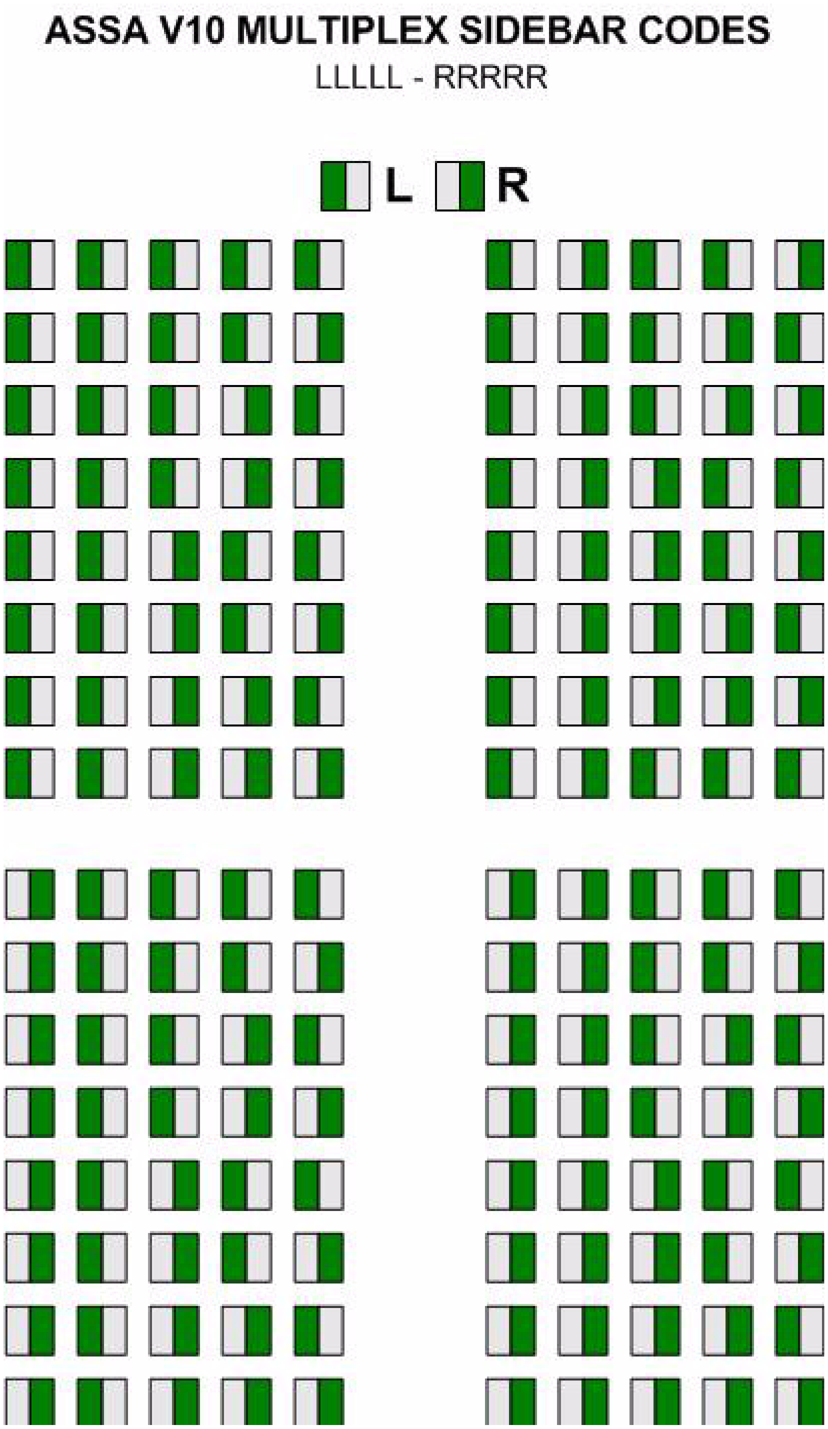

Figure LSS+3153 A total of 32 different sidebar code patterns are available in the Assa V10. These are derived through a matrix of all possible left and right finger pin combinations for five bitting positions on the key. Green indicates the active contact point between finger pin and side milling.

In the first level, which Assa refers to as **"blocking,"** they utilize variations of **one** sidebar code for all locks within the system. Two positions (out of a possible five) on the sidebar milling of each key are double-cut to correspond with the correct assigned group. In all other groups, either the left or right cut will be wrong and will improperly lift a left or right finger pin, thereby blocking rotation of the plug. The scheme, in many ways, resembles the reverse of a warded lock. It will be recalled that wards block entrance of all but the correct key. However, if the material is removed from a key (skeleton key), then it can pass all of the wards. Similarly, double-cutting of side millings performs much the same function, but in reverse. It is an example of positive locking, in that pins are acted upon by the key to prevent retraction of the sidebar and block rotation.

In the higher security **"multiplex"** level, individual sidebar codes are utilized for each group of locks. Double-cutting of two positions on a key is employed and the system can be difficult to decode for the actual sidebar code for a given group unless certain information is known. Much less information can be derived from a single change key, and for the TMK, unless certain procedures are followed. In a hybrid, both multiplexing and blocking are employed.

31_4.10.6.2.1.1 Comparison: Medeco Biaxial and Assa V10

In the author's view, the only way to protect a master key system from compromise through the extrapolation of the TMK is to provide for multiple sidebar codes under one top level master key, and prevent any information from being derived about differences in groups of cylinders. This premise assumes that the manufacturer in fact utilizes more than one sidebar code within the system. This can be an effective security measure if the sampled cylinder has a different code than that of the target lock. In such event, even though the conventional bitting information has been derived, it will not allow other groups of locks (that utilize different sidebar codes) from being opened without certain expertise. Assa and Medeco have adopted different design philosophies in an attempt to accomplish the same result. In the case of Medeco, it may be required to generate up to 729 different sidebar code permutations in order to determine the correct rotation pattern for the target lock. In actuality, this number may be far less. Within the Assa system, fewer permutations may be required to derive the sidebar code. In part, this will depend upon whether Assa employed the lower security

blocking method, or higher security multiplexing of sidebar coding.

Medeco, in their Biaxial and M3, utilize left and right (fore and aft) oriented pin tumblers to achieve multiple coding of rotation patterns. A variance in pattern can occur within any position; thus there are 3^6 or 729 possible combinations that can appear within one system. The TMK is double cut to accommodate all fore-aft permutations. The only real restriction in system design is that fore or aft rotation values cannot be different for a specific position in different groups of cylinders. Recall that Medeco combines rotation angles and pin tumbler depth increments, whereas Assa separates these functions through the use of independent side millings. The difference can be critical to the security of a system for several reasons:

- Sidebar millings within Assa (and other locks) can be replicated separately from conventional bitting values, thus potentially making the extrapolation process simpler by allowing the reuse of the sidebar portion of the key during the probing or picking of a cylinder;

- It may be easier to derive the sidebar codes for groups of locks or an entire system when the sidebar millings are separated from the standard pin tumbler pin stack;

- Assa sidebar information can be read from keys and locks as a result of the physical design of the system.

Assa also uses double cut bitting to generate multiple sidebar codes. However, the approach is slightly different than Medeco. In the lower security level, called **blocking**, Assa actually varies the side bitting for each **group** of cylinders and their keys. These codes are all derived from one "base code" sidebar bitting pattern. In this scheme, two side milling positions are set up for ***either*** left or right contact between the key and finger pins. The Left-Right pattern establishes a form of virtual keyway subset for each group of locks; a key with the wrong Left-Right code will positively lock a cylinder that does not match that code.

The higher security level system is called **multiplexing**. This scheme provides for a different physical sidebar code for each group of cylinders. Variances of each sidebar code is selected, and Left-Right combinations of finger pins are employed to block

or allow access to a specific cylinder. It is more difficult to determine the sidebar code for the entire system when different physical sidebars are utilized within different keying groups, although such information can be extrapolated.

The material presented in this section provide an insight into the Medeco and Assa design philosophy, and demonstrate the following:

- **Each system offers enhanced security over conventional master keying techniques;**
- **Each provides an increased number of differs for master key systems;**
- **Each provides greater resistance against an attack by extrapolation;**
- **Assa has more theoretical differs than does the Medeco Biaxial, but may be easier to reverse engineer and obtain vital system information;**
- **Medeco routinely implements multiple sidebar coding within large systems; Assa does not.**

31_4.10.6.2.2 Basic Rules for Both Assa Systems

Certain rules apply with regard to allowable bitting combinations, establishment of groups, and the interaction of keys within each group. Common parameters are applicable to both levels of multiplexing, while others relate only to systems that incorporate unique sidebar codes for each group of locks.

Basic Definitions

Assa (and the author) have established certain basic definitions for all multiplex master keyed systems.

Profile: Design of the key and cylinder to accomplish access control;

Side codes: Secondary bitting that is cut into the side of the key blade. The term is referred to in this section as sidebar code;

Keyway: A composite of the keyway and side code;

Base Sidebar Code (author definition): This is the physical sidebar code, based upon five depths and five positions, that is employed within a specific lock;

Position: The slot or place that is occupied by one set of left and right sidebar millings in each of five locations for the finger pins;

Contact Points: The orientation of the finger pins, indicating whether they make contact with the left or right hand side of the milling position.

Design rules that apply to all cylinders and both multiplexing schemes

- **All permutations of sidebar codes must be checked for cross-keying issues. Assa refers to these as "ghost codes";**
- **There are no MACS restrictions for side millings;**
- **One of thirty-two multiplex codes of Left-Right cuts will be utilized for each group of locks;**
- **Normally, only two sidebar positions will be multiplexed, although this number can be expanded to four for larger systems;**
- **A variance of one depth increment between left and right cuts is allowed for any one position;**
- **In all positions that are not multiplexed, the left contact point should be utilized. This design parameter allows the bitting values to be easily decoded;**
- **In positions that are not multiplexed, double cut side bittings are utilized but both left and right values are the same. In certain cases, one of these cuts can be a false value;**
- **Multiplex positions are usually constant throughout the entire system. That is, if positions one and two are utilized in one lock, they will be utilized in all locks;**

Blocking Rules

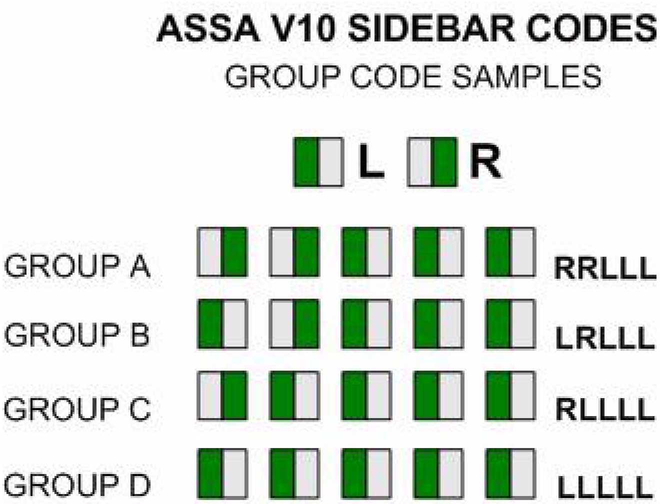
- **One physical sidebar code is utilized for all locks;**
- **Depth combinations for side millings can utilize any value so long as there is only one depth increment difference. Thus, 1-2, 2-3, 3-4, and 4-5 are all acceptable;**
- **A lock can be disassembled and the sidebar code derived for all locks within the system;**
- **Blocking provides a higher level of security than conventional**

master key systems where one sidebar code is utilized. In such systems, there is security against picking, but not against extrapolation. In the Assa system, enhanced security is provided because of the positive locking that occurs if the wrong key is inserted into the cylinder.

- **The sidebar code is divided into five positions, with two cuts in every position (left and right);**
- **The designation for the two cuts within a position are left and right. They are coded by holding the key so that the bow is to the right. Position 1 is closest to the tip of the key;**
- **There are a total of five depth increments for each sidebar cut. These are read in ascending order, from the base of the key blade (1) to the top of the blade (5);**
- **Every cut can be at one of five different heights;**
- **For any one position, cuts can be balanced or unbalanced. This means that a cut can be equal to, one increment higher, or one increment lower than the other, as shown in figure LSS+3152;**
- **Within most systems, only two positions are multiplexed, thus creating four code groups;**
- **The two multiplex cuts can be in any of five positions, although they are usually set so the sidebar can be reversed within the cylinder;**
- **The sidebar code is written as follows: LR LR LR LR LR, so that both left and right positions are designated. In our blocking sample, the base sidebar code is 31524. The blocking code for Group D is 32 12 5 2 4. In this example, the multiplex code is LLLLL. The right cut in positions one and two (3<u>2</u> 1<u>2</u>) would block entry of other keys not associated with Group D. Thus, a key that was double-cut with 32 12 in the first two positions could open all locks within Group D, but in no other groups, because the Right cuts would raise side pins in Groups A,B,C to positive lock the plug. <u>Bold underlined</u> positions indicate blocking or the non-contact position of the finger pin;**
- **Even numbers are selected for blocking codes;**
- **There are three available side milling depth increments that are available for active codes (1-3-5);**

The multiplex positions are changed for every possible permutation, for a total of four different available codes;

- **Left or right cuts are utilized in each multiplex position;**
- **Once an active cut (L-R and depth value) is established for a specific position, no other active cut can be utilized for that position anywhere in the system;**



Multiplexing Rules

- **Physically different sidebar codes are utilized for each group of locks;**
- **A matrix of multiplex codes is established to allow one top level master key to pass all codes in all locks;**
- **A "1" depth increment is not normally utilized, due to structural weakness of the key;**
- **Each sidebar code can differ by one cut in any position that is multiplexed.**

31_4.10.6.2.3 Blocking Method

The blocking method of multiplexing utilizes one physical sidebar code for all locks within a system, and is relatively simple to decode. In the diagram below, four groups have been established as an example. The Left-Right codes are **RRLLL**, **LRLLL**, **RLLLL**, and **LLLLL.** These designations represent the location of the finger pins within each bitting position on the key. As shown, a left pin will make contact with the left bitting, and the right pin will be raised by the bitting on the right side of the cut position. In our example, **Group B** has a sidebar code of LRLLL. This translates to the first, third, fourth and fifth finger pins making contact with the left hand side of the bitting for each position; the second pin makes contact with the right. The base sidebar code for every lock within our example is 31524. This means that if a key is cut with this sidebar bitting code, it will open the lock (assuming the conventional bitting has also been properly cut). The use of double-cuts relates to the creation of virtual sub-keyways. By establishing a matrix of patterns, Assa is able to block the use of keys that do not have corresponding left or right cuts in different groups of locks.

A total of four permutations are created for each pair of depths. Thus, if depths 2-3 is utilized for the sidebar code 23524, then 2_3_, 2_ _3, _2 3_, and _2 _3 would be available.

Figure LSS+3154 Four groups have been established, based upon a sidebar code of 31524. Each group has a different matrix for the first two positions.

The first two positions of each side milling are double cut, yielding 2^2 or four combinations. The possible permutations for the first cut is a value of 2 or 3; for the second cut are 1 or 2. A matrix of all combinations yields: **23 21(349) 32 21 23 12 32 12.** We selected Group **B,** which means that the Left-Right matrix is **LRLLL.** This requires that the first position has an active left finger pin, the second position an active right pin. Positions three, four, and five all have Left pins, pursuant to the general rules applicable to all locks. In like manner, different patterns have been established for Groups **A, C, D.** It

can be seen that in each case, the Left-Right pattern is different. If a key with the pattern that is utilized in Group **A** tries to enter Group **B**, it would be blocked in the first position. An examination of each group will demonstrate that its code would positively block the sidebar in every other group.

23 11 55 22 44
32 11 55 22 44

Figure LSS+3155 This diagram represents the relationship between groups and keys. Note that the sidebar matrix for each key will work in two groups of locks. Green indicates active contact between finger pin and bitting. Black denotes double cutting in the same position, and is the master key code. Grey represents blocking.

The relationship between the side milling on keys and groups is shown in the diagram above. It can be seen that only one multiplex position causes blocking. The other four positions represent the TMK code. Thus, **"E"** coded keys will work in groups A and B. That is because the second bitting position is the same as these two groups. It is different for **C** and **D**, however, and no key assigned to **E** would work in these two groups. It is also clear that an analysis of one change key from **E**, for example, would yield four of five bitting codes for the TMK. This results from the fact that there is only one true sidebar code for every lock in this system. Thus, if a key is cut for **33 11 55 22 44**, it will open every lock. It would only require two permutations to determine the correct code. If the key **"E"** were utilized as the sample, then it would be required to make keys with the code **33 11 55 22 44** and **33 22 55 22 44**. In other words, the only double-cut position is 2 on key **E**. Thus, we know that the master key code must be one of the two permutations (1 or 2) in the second position.

Decoding Rules

- **All five depth increments may be utilized;**
- **Any position can be multiplexed;**
- **If there is only one position that is double cut for different values, then the system is of the blocking type;**
- **Within a given group of locks, there will be two positions that are multiplexed. For each specific group, there will be only one corresponding position on a key that will have varying left and right cuts;**
- **For any key, only one of the two positions will vary from the TMK multiplex value; the other position will have its left or right cut set to block rotation. Thus, only one active cut within the two multiplex positions on the key is different than the TMK value;**
- **Any position that is double cut and has the same depth increment for left and right has the same value as the TMK;**
- **Only one bitting position will be different than the TMK;**

31_4.10.6.2.4 Multiplex Method for Higher Security

The **multiplex** method of deriving sidebar codes relies upon the use of different sidebar combinations for each group of locks. This system is more secure than the blocking technique because it is more difficult to determine the particular coding of the sidebar from a specific key bitting. In addition, two variables are introduced into each set of sidebar codes at the key level, rather than just the one in the lower security system. In the example, four different base codes are utilized: 55524, 45524, 54524, and 44524. Significantly more combinations can be generated in this scheme with no key interchange potential between groups of locks. One TMK can be designed to open all locks within all groups, as shown in the diagram.

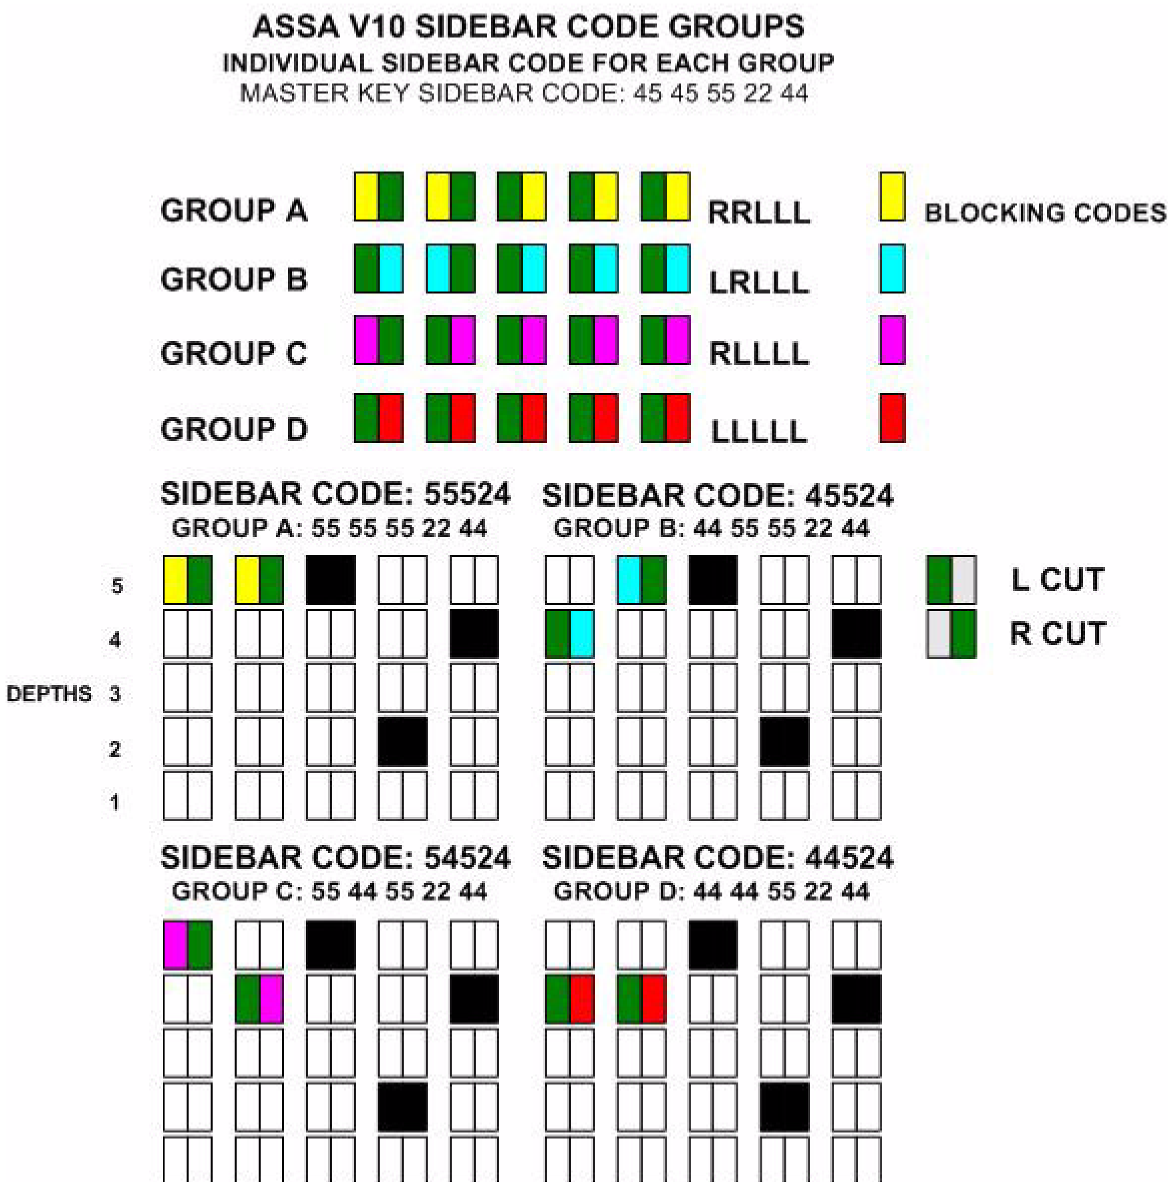

Figure LSS+3156 Sidebar codes for the higher security multiplex system utilize different physical sidebars in each group of lock. Note that the codes for the groups in this illustration are: Group A 55524, Group B 45524, Group C 54524, and Group D 44524.

As with the blocking system, Left-Right code patterns are selected and assigned to multiplex codes for each group. The same four combinations have been chosen for this example. Note that two of five positions are utilized for each group, based upon the Left-Right pattern. A total of four primary progressions are available for each group of two depths. If pairs 2-3 and 4-5 are utilized, then there are 32 possible permutations that can be

applied to a Left-Right matrix. In our example, the following codes would be available to assign to groups:

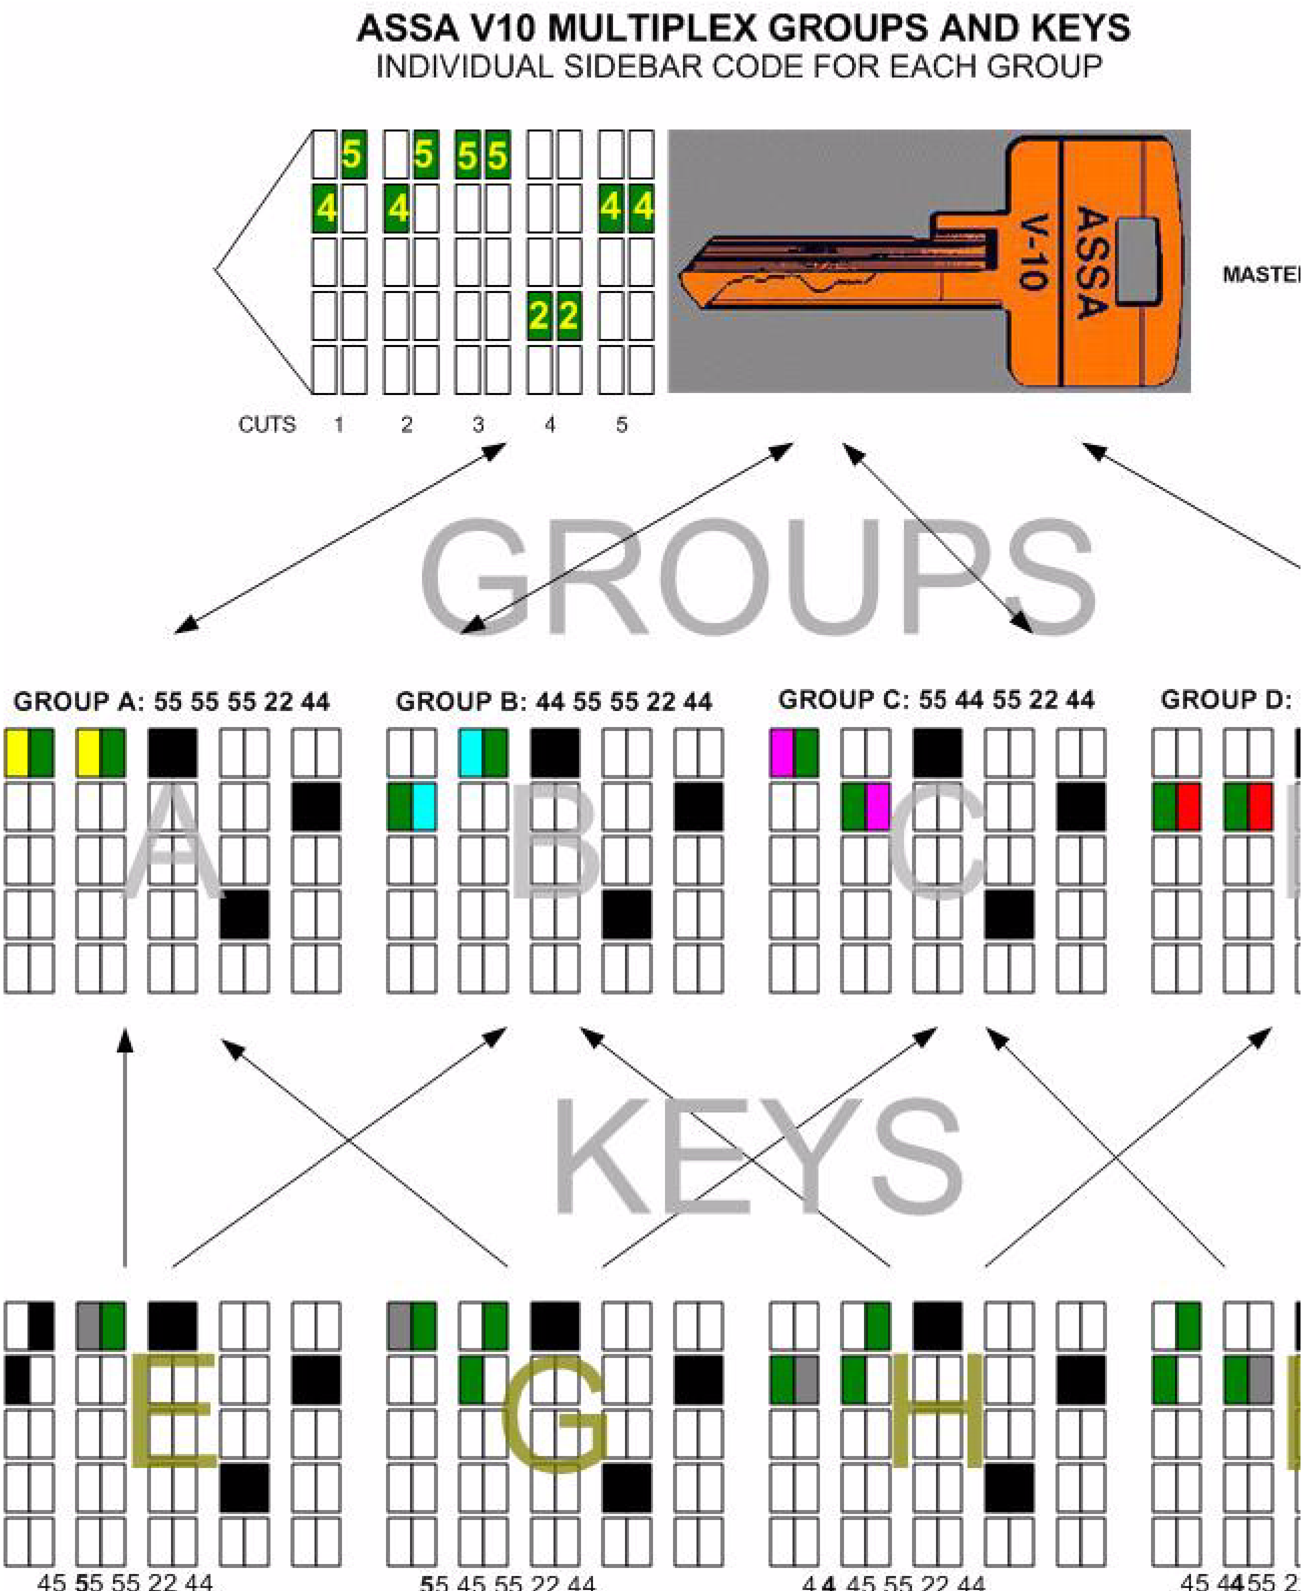
ASSA V10 MULTIPLEX CODES						
SIDEBAR CODE PAIR 2-3						
All combinations for depth increments 2-3: 22, 23, 32, 33						
COMBINATION	POSITION 1	POSITION 2	SIDEBAR CODE	COMBINATION	POSITION 1	POSI
22	2_	2_	2_ 2_ 55 22 44	32	3_	2_
	2_	_2	2_ _2 55 22 44		3_	_2
	_2	2_	_2 2_ 55 22 44		_3	2_
	_2	_2	_2 _2 55 22 44		_3	_2
23	2_	3_	2_ 3_ 55 22 44	33	3_	3_
	2_	_3	2_ _3 55 22 44		3_	_3
	_2	3_	_2 3_ 55 22 44		_3	3_
	_2	_3	_2 _3 55 22 44		_3	_3

ASSA V10 MULTIPLEX CODES						
SIDEBAR CODE PAIR 4-5						
All combinations for depth increments 4-5: 55, 54, 45, 44						
COMBINATION	POSITION 1	POSITION 2	SIDEBAR CODE	COMBINATION	POSITION 1	POSI
55	5_	5_	5_ 5_ 55 22 44	45	4_	5_
	5_	_5	5_ _5 55 22 44		4_	_5
	_5	5_	_5 5_ 55 22 44		_4	5_
	_5	_5	_5 _5 55 22 44		_4	_5
54	5_	4_	5_ 4_ 55 22 44	44	4_	4_
	5_	_4	5_ _4 55 22 44		4_	_4
	_5	4_	_5 4_ 55 22 44		_4	4_
	_5	_4	_5 _4 55 22 44		4_	_4

Figure LSS+3157 These tables show all possible combinations that can be generated with the four available side milling depths if pairs 2-3 and 4-5 are utilized. The colors indicate those multiplex codes that are used in the example for Groups A, B, C, and D. An underscore_ indicates the inactive left or right bitting.

It can be seen that four codes were chosen at random from the available pool of all multiplex combinations: **_5(350) _5 55 22 44, _5 5_ 55 22 44, 4_ _5 55 22 44,** and **4_ 4_ 55 22 44.** Each pair of digits represents the left and right bitting for each sidebar position. How they are applied with regard to which is the active

contact point and which is the blocking side is determined by the L-R matrix which also provides a total of 32 Left-Right combinations. In the same fashion as the lower security blocking technique, multiplexing provides a matrix of active left and right finger pins. It can be seen that the keys are double-cut in one position for both the active and non-active position. If an **"E"** key whose code is assigned to cylinder Group **A** and **B** attempts to unlock a cylinder in Group **C**, the plug would be positively blocked from rotation because _5 in position two on **E** would not match the code of _4 in Group **C**. Thus, the sidebar would be blocked and could not retract into the plug. A comparison of every blocking position in each key with each of the codes for each group illustrates how each group has a different matrix of left and right finger pin positions in the two multiplexed positions. The system is designed so that only the keys with the correct double cuts can operate locks within a matching group.



ASSA V10 MULTIPLEX GROUPS AND KEYS
INDIVIDUAL SIDEBAR CODE FOR EACH GROUP

55 45 55 22 44
4 4 45 55 22 44
45 4455 2

Figure LSS+3158 The interaction of keys and groups within a multiplex system differs from that of a blocking system, in that there are variations in both multiplex positions for each key. Numbers in bold underline indicate non-active combinations.

The diagram above shows the relationship between keys and groups and their multiplexed bitting patterns. Each key has two positions that are double cut, to correspond with their respective groups. Green designates the active portion of the bitting (left or right). The **"H"** key, for example, is coded to access Groups **B** and **D.** Note that there is one double cut position (2). In position 1, the active side is Left. Position 2 is double cut as a 45. Corresponding finger pins are shown in **B** and **D.** In the first position in Group **B,** 4 Left matches key **H.** Likewise, in the first position of Group **D,** key **H** again matches 4 Left. In the second position, Group **B,** 5 Right is active. In Group **D,** however, 4 Left is the active pin. Each pattern is unique to a group and key, and none will conflict with any other, so long as the active finger pins are in the correct position. If not, they will be blocked.

31_4.10.6.2.4.1 Decoding Multiplex Systems

The starting point in this process is to understand that every cylinder has a fixed sidebar that is made up of five individual depths and five positions, as with all Assa sidebar systems. Rather than having finger pins that make contact with the center of the bitting increment of the key, multiplex finger pins can make contact on the **left** or **right** portion of the side milling, but not both. There can only be one finger pin for each position, and thus, only one side (left or right) of the side milling is active. Sidebars cannot be double-cut; only keys can be so configured. The geometry of the finger pin is such that there is only room for one pin per position. Thus, it is physically impossible to have both a left and right pin in one position within one lock.

In the blocking method described earlier, double-cuts were employed for certain side milling positions to create a form of virtual keyway. The Left-Right combination of millings must mate with the active left or right finger pin, otherwise positive locking occurs. In the multiplex scheme, blocking is not the primary objective. Rather, two multiplex positions are utilized for each key. These must mate with the appropriate finger pin orientation.

When cylinders are multiplexed, a unique sidebar code is established for each group of locks. These codes, however, must all be related to each other in order that one top level master key can contain a matrix of all left and right bitting positions for each sidebar code. In order for this to occur, there can be a maximum deviation of one depth increment between left and right bittings. This variance allows sidebar codes to be altered to provide different unique codes that do not create key interchange. As with the Medeco Biaxial scheme, Assa utilizes a matrix of left and right active positions between all of the locks to accomplish this result.

A total of four permutations for each pair of depths is available, and a total of sixteen permutations are thus created for all possibilities when two depths are matrixed together. Thus, for example, if depths 2 and 3 are combined for the first two positions of the sidebar code, the primary pairing is 22, 23, 32, 33. In order to expand this to sixteen unique sidebar codes, Assa uses a two digit notation system for each position. If the base sidebar code is 33524, it would be written as 33 33 55 22 44. Let us assume that the multiplexed positions are 1 and 2. The chart in Figure LSS+3157 shows the four different codes that are created. If all four pairs are utilized, then there are sixteen unique sidebar codes that would be available.

In our example, one top level master key can incorporate the attributes of four different sidebar codes. This is accomplished by utilizing each left and right cut for each of the multiplexed positions, and insuring that they do not overlap. As with the Medeco Biaxial, there can only be one depth value that is utilized in any left and right location for each position. This means that groups of locks can be keyed so that, for example, Group **A** utilizes 3_ and Group **B** _3 in the first position, and _3 and 3_ in the second position. However, there can never be a condition that allows 3_ and 2_ to occur simultaneously in the first position. So, it is simply a requirement that a matrix of non-recurring depths be established that do not overlap in the same position and same Left-Right orientation. The TMK is a composite of all left and right positions that have been established for each group of cylinders.

Like the Medeco Biaxial, a great deal of information can be derived from an Assa cylinder if one change key is available that is associated with the top level master key. This information can be utilized to reverse engineer a system, and in some cases, may provide the complete bitting values of the TMK.

Multiplex systems can be decoded to determine a number of critical factors. Some information can be derived from the lock itself, and some data from a change key. Some information can be extrapolated from an examination of both the lock and key.

Information from the lock (and key):

- **The individual sidebar code for a specific cylinder and group of cylinders;**
- **All of the probable sidebar code groups for the entire system;**
- **The L-R matrix that is utilized for a specific group of cylinders;**
- **The active left or right pin for each position;**
- **TMK code;**

Information from the key:

- **Whether the system is of the blocking or multiplex type;**
- **The individual orientation of each finger pin (left or right) for each position;**
- **The multiplex positions that are utilized within the system;**
- **Both of the depth values that are utilized for multiplexing for each position;**
- **The values of each sidebar bitting and how it relates to the TMK;**
- **Whether a +1 or -1 depth offset is utilized for each multiplex position;**
- **The depth of four of five positions that are common to the TMK;**
- **From the double-cut position(s), both values that are used in the TMK can be determined, and in what order. In Figure LSS+3158, the TMK is 45 45 5 2 4. The value of 4+5 in each multiplexed position provides critical information that both a 4 and 5 depth is utilized in the TMK, and in which position;**

Information that cannot be derived solely from the key:

- **The position of the TMK value of the position that is double-cut, but we do know that it is one of two values (left or right);**
- **Whether the Left or Right side of each position is active;**

There are a number of rules associated with the multiplexed system which must be understood in order to derive the TMK values.

Decoding Rules

- **The same rules apply that were defined for the blocking method;**
- **The system utilizes more sidebar codes than in the blocking method;**
- **If two positions that are multiplexed are constant throughout a system, then the TMK can be derived from the change key;**
- **The system can provide a higher level of security;**
- **Depth increments 1,2,3,4,5 are valid for multiplexing;**
- **Any positions can be multiplexed;**
- **In a multiplex system (in contrast to blocking), one side of each position is not active;**
- **Any number of positions can be multiplexed. This depends upon the size of the system;**
- **The TMK must be a composite of all multiplexed positions;**
- **Two depth combinations per position are available (1-2, 2-3, 3-4, and 4-5);**
- **The determination of the sidebar code for one group will yield information about sidebar codes for other groups with regard to those positions that are double-cut for the same depth increment. These positions would be constant throughout the system;**
- **A position that is double-cut and has a left and right depth increment that is different may constitute a TMK value, or only one of the two cuts may be valid for the TMK;**
- **If there are two positions that have different left and right double-cuts, the system is the high security multiplex type that utilizes individual sidebar codes for each group of locks;**
- **Within a given group of locks, there will be two positions that are multiplexed. For each specific group, there will be two corresponding positions on a key that will have varying left and right cuts. For any key, only one of the two positions will vary from the TMK multiplex value; the other position will have its left or right cut set to block rotation. Thus, only one active cut within the two multiplex positions on the key is different than the TMK value;**
- **For any position that is double cut and having different depths for Left and Right, all permutations of multiplexed positions are**

utilized, thus there are four derived codes;

- **Generally, only two positions are multiplexed;**
- **The codes for left and right cuts for any position will only vary by one;**
- **A "1" cut is not utilized, as a general rule;**
- **Any position where both left and right cuts are the same will be part of the TMK;**
- **In any position where left and right cuts are different, only one side will be active;**
- **If two positions are multiplexed, then four different keys may be required to be generated to determine the TMK multiplex values;**
- **The same two positions will always be multiplexed within a specific group;**
- **Usually, the same two positions that are multiplexed will be constant throughout an entire system. However, this is not required. In such case, two positions for Group A could be different than for Group B, making extrapolation significantly more difficult because more permutations of sidebar codes would need to be generated;**
- **Generally, only those positions that have two different cuts must be varied when probing a lock in order to determine all permutations that may contain the TMK sidebar code;**

Decoding a multiplexed lock, based upon the rules cited above, can be fairly direct if both a change key and cylinder are available. The process to extrapolate the conventional bitting pattern of the TMK is identical with any other master key. The problem is to determine the sidebar coding for the target lock if it is different than that of the probed cylinder. This can be done is several ways, detailed in the following discussion. There are two critical issues to consider with regard to sidebar coding: **decoding of the target lock**, and **decoding of all locks** within the system. This analysis is based upon information that is obtained from the key as well as the lock, and depends upon whether the blocking or multiplex scheme has been employed.

- **Determine if blocking or multiplexing is employed;**
- **Determine which two positions are multiplexed;**
- **Determine if there are one or two positions that are double cut;**
- **Determine the value of double cut positions for left and right contact, and whether the same or different values are utilized;**

- **Determine the individual sidebar code for the probed lock. This can be accomplished by first examining the key for all positions that are not double cut. Each of these positions provide direct information about the sidebar code of the TMK;**
- **The positions that are double cut and have two different values will yield critical information: the Left-Right sequence that is used in the TMK, and the values that are utilized in the TMK. One of the two contact points for each double cut position will be utilized to formulate the sidebar code of the probed lock. Remember that all values of double cut bittings must be utilized in the TMK, because the TMK is a composite of all Left-Right values for every key in every group. From the change key, we can learn the depths of all of the side millings. This will provide the needed information with regard to the TMK;**

The orientation of each finger pin (left or right) for each position can be determined through the use of the key, by impressioning. Smoking the change key to produce a carbon residue, then placing pressure on the side millings should yield a left or right contact for each finger pin. This will provide critical information as to the code for the specific lock, and the ability to extrapolate probable codes for the other three groups of locks. Once the orientation of each finger pin is determined, the lock and entire system is vulnerable. Remember, the sidebar code has five depths and five positions. Each depth either has a left or right orientation, but there can only be one orientation per position. Thus, once we know the depth increment and orientation, we know the sidebar code.

Let us assume that we find that the key has a code of **45 55 55 22 44**. This reveals the following information:

- **The TMK must have a value of 45 for its first position**
- **The first position is multiplexed;**
- **Probably the second position is also multiplexed, but this information is only speculative;**
- **The second, third, fourth, and fifth positions are all common to the TMK;**
- **The actual sidebar code for this cylinder is either 45524 or 55524;**

Because depth values can be varied by +- 1 increment, the codes for the other three groups within the system are likely to be 54524, 45524, and 44524, assuming that only the first two

positions are multiplexed. The issue becomes more complicated if other positions are utilized in the process. This possibility is discussed below.

At this point, we know at least three (and possibly four) of five of the Right-Left orientations for finger pins, and the depth values for those pins that are associated with the TMK composite sidebar code. We need to determine the remaining finger pin orientations that can exist in other groups of locks, and which are not present in the probed lock. This can become a bit more complicated in the multiplexed lock because each group of cylinders has their own sidebar code. There are several issues with regard to how the sidebar codes are multiplexed:

- **Two positions are constant throughout the entire system;**
- **Positions are varied throughout the system;**
- **More than two positions are utilized for multiplexing;**
- **All positions on the key are double-cut, making the initial determination of multiplexed • Positions more difficult until the Left-Right contact position is determined.**

If the multiplexed positions are constant throughout the entire system, the process becomes much simpler, and the TMK can be extrapolated from the sample change key. In this event, permutations of each position that is double-cut and has the same depth values must be run. We know that depths can only be varied by one increment. So, in our example, 45 55 22 44, we can be fairly certain that the first position (45) is multiplexed. If we make the assumption that the second position is also multiplexed and constant thorughout the system, then it must have a value of 55, 54, 45, 44 for the TMK. This requires three permutations to be tested against the target lock. The TMK then would have a value of 45 55 524, 45 54 524, **45 45 524**, or 45 44 524. In our example, the actual code is **45 45 524**.

If positions are varied throughout the system, then we must run the known position (the first in our example, 45) against the remaining four positions to determine the sidebar code, based upon knowledge of the Left-Right contact of each finger pin. We know that the combination of our sampled lock is 45 _5 5_ 2_ 4_. Remember that there can be no multiple use of a contact point for any given position; thus we only need test the **complement** of the location of the finger pins in our sampled lock. This greatly reduces the number of permutations that must be run.

This will require a total of five permutations to be tested. In such case, the following combinations would be run:

45 + **45** 55 22 44
45 + 55 **54** 22 44
45 + 55 55 **23** 44
45 + 55 55 22 **45**
45 + 55 55 22 **43**

If the Left-Right orientation for each position cannot be determined, then we must utilize the information available from the key only. In such a case, there would be a total of 20 permutations (four variances for each of five positions) that must be run. This would again require that we change one position against the other four. We would run **1**2345, 1**2**345, 12**3**45, 123**4**5, 1234**5**. The underlined position would be altered with a total of four permutations each. Thus, in our example, the first permutation would require that the following four sidebar combinations be tested in the first position: **55, 54, 45, 44.**

Finally, if the only information we have is from the key, we do not know the Left-Right orientation of each finger pin, and we believe that multiplexed positions are varied throughout the system, (but that there are only two positions that are multiplexed at any one time), then there are total of 3^5, or 243 permutations that must be run in order to be certain that we have the combination for the TMK. This number is derived from a variance of one depth above and below those that are utilized on the sample key. Note that we are not concerned that there are a total of four available depths that can be utilized in the multiplex system (1 is not available). We only require that the actual depth for each position, with a variance of 1 above and below. Thus, in our example wherein the second position is our code of **45 55 55 22 44,** the differs would be **55, 54, 45.** Note that **44**, however, is not a valid permutation, because it would require that we utilize a different value in the same position, which is not possible.

31_4.10.6.3 InstaKey Programmable Cylinder

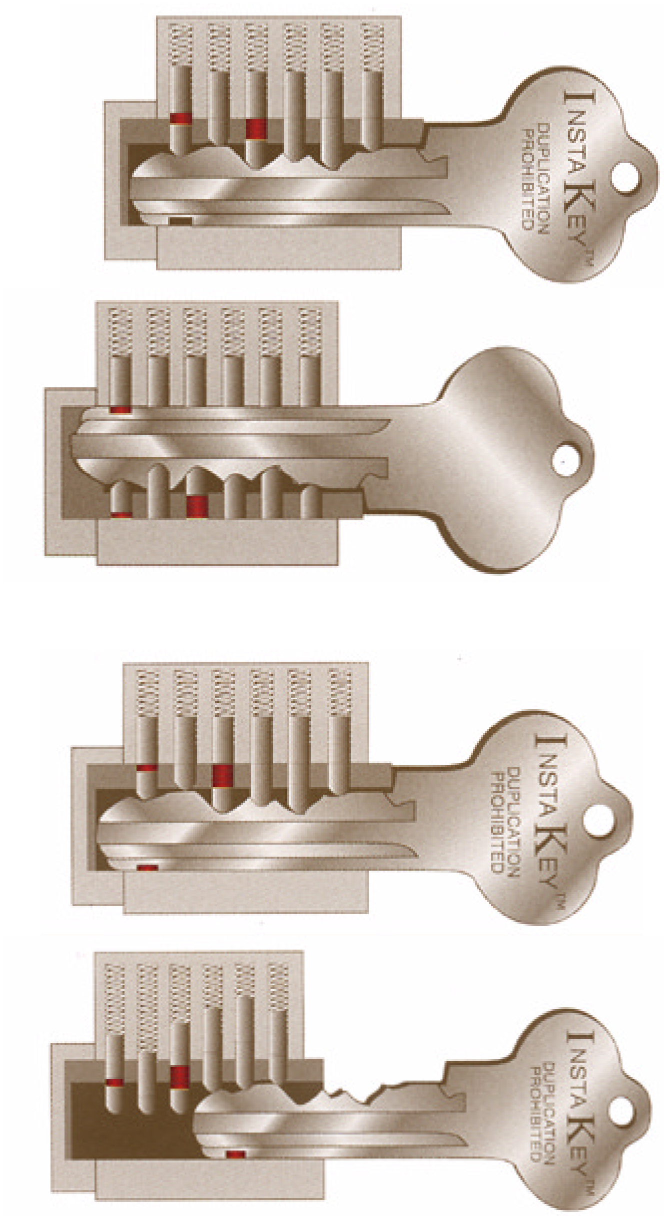

Figure LSS+3147 Instakey system allows for instant reprogramming of a cylinder, up to twelve times. In the programming sequence, the step key is first inserted for the specific chamber and pin stack that is to be altered.The key is turned, causing the next pin segment to be sliced. The key is then rotated back to home position. At this point, the sliced pin segment is carried in the notch at the base of the blade. Upon removal of the key, the .025" segment will drop out of the lock.

The Instakey programmable cylinder is utilized in many large facilities as well as by Medeco Bi-axial customers. The lock can present security and decoding issues if encountered in the

extrapolation process. See **chapter 22** for a detailed discussion of this technology. It is possible to sever one or more programmable pin segments within each chamber while probing a pin stack, which can lead to false positive indications of the depth of the TMK. Only three chambers are utilized for reprogramming, but they can be in any position. Little torque is required to slice a pin, and it does not need to be removed from the lock to cause problems. Generally, the Instakey name will appear on the face of a cylinder if the technology is employed, so caution is advised when working on these cylinders.

31_4.10.6.3.1 Security Issues Regarding Instakey

There are a number of security issues with regard to Instakey cylinders that relate specifically to the extrapolation process. These are summarized below.

Severing of programmable pin: Little torque is required to slice one or more segments within a pin stack.

False positive: If a programmable pin is sliced within a pin stack, then another shear line is created. This can be decoded as the top level master key. The problem becomes compounded if every depth is probed, because up to four additional shear lines may be created.

Key interchange: If a lock is sampled for the TMK and pin segments are sliced, then serious key interchange, incidental master keys creation, and cross keying issues will be the result.

Pick resistance: The pick resistance of a cylinder will be reduced if multiple shear lines are created.

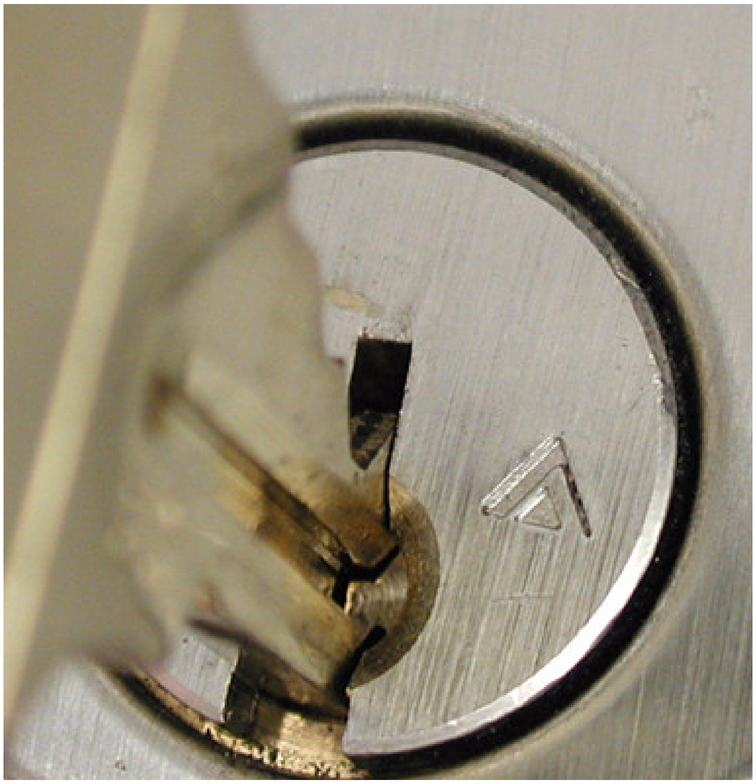
Covert operation discovery: If a covert operation to decode a lock is undertaken and pins are inadvertantly severed, then there would be evidence of tampering with the lock by unauthorized individuals.

31_4.10.6.4 Schlage Everest

The Schlage Everest is a popular cylinder for use in master key systems where increased security against key duplication is required. Operatives may encounter different Everest keyways, and

would have difficulty extrapolating master keys within these systems without the capability of replicating blanks and accessing the check-pin. Thus, information regarding bypass of these cylinders is presented in this section. This lock is also utilized as an example of the capabilities of the Easy entrie profile milling machine in simulating blanks for restricted keyways or special designs that would make access to blank keys difficult.

This mechanism employs a unique patented keyway that incorporates an undercut area that must mate with a corresponding channel along the longitudinal section of the key wards. This blank is only available from Schlage, but may be simulated with the Easy entrie profile milling machine, or through modification of other non-patented blanks. See the detailed description of the procedure for bypassing the undercut portion of the keyway in **Chapter 8**.



The reader is cautioned that replication of the exact Schlage profile and integrated undercut channel constitutes an infringement of their patent. The reader should consult with legal counsel prior to producing exact replicas of keys for this or any other patented cylinder.

As described in **chapter 8**, a digital image of the keyway of any Everest cylinder may be imported into the PC software of the Easy entrie. It will allow a key to be produced that ignores the undercut. The profile of the key, once obtained, can be stored for later generation for a specific keyway. When the proper blank is cut with the correct bitting, the Peterson ET-1 can be utilized to lift the check-pin. See **chapter 29** for an explanation of picking of this lock. The photographs show a key that has been produced for the Everest cylinder. Note the Peterson ET-1 that is inserted within the undercut next to the key to allow rotation of the plug. To produce this blank, the author, while using the draw mode within the Easy entrie software, actually created a profile that ignored the channel, normally present on OEM Schlage blanks. The undercut portion of the keyway is bypassed so that a precise indent is created to allow its passage by the key warding.

Figure LSS+3148 The Schlage Everest cylinder utilizes a patented check-pin system and undercut keyway. A blank has been produced with the Easy entrie profile milling machine that effectively eliminates the requirement that a corresponding channel on the key must pass the undercut in the keyway. Compare

the Easy entrie blank with the OEM Schlage Everest blank on the right. The channel has been removed during the "drawing" portion of the profile creation process. A blank for the cylinder (top) was produced entirely from a digital image of the keyway, shown below. Once the finished blank was cut on a standard key machine, it is inserted into the keyway together with the Peterson ET-1 tyne to raise the check-pin. The lock is opened without any difficulty, as if operated with a factory original key.

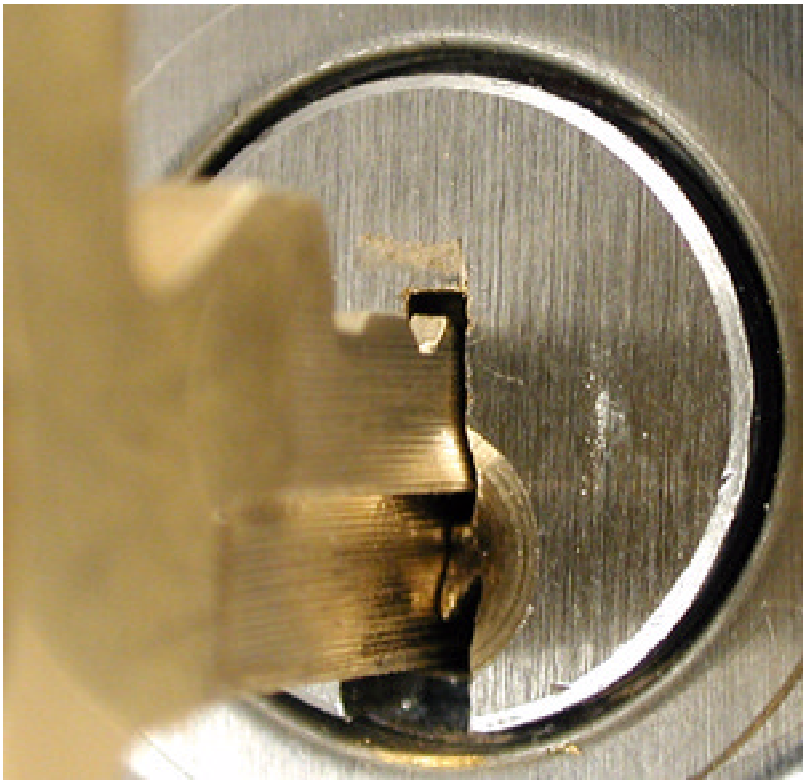


Figure LSS+3149 The Schlage Everest keyway, showing the patented undercut design. This feature normally requires the integration of a corresponding channel along the side of the key. However, the system can be bypassed by specially milling a blank and inserting a tyne into the undercut to raise the check-pin. A factory original blank is inserted into the cylinder (left). Note the undercut and how it must ride in the channel. The simulated profile (left) is created with an indent to physically bypass the undercut.

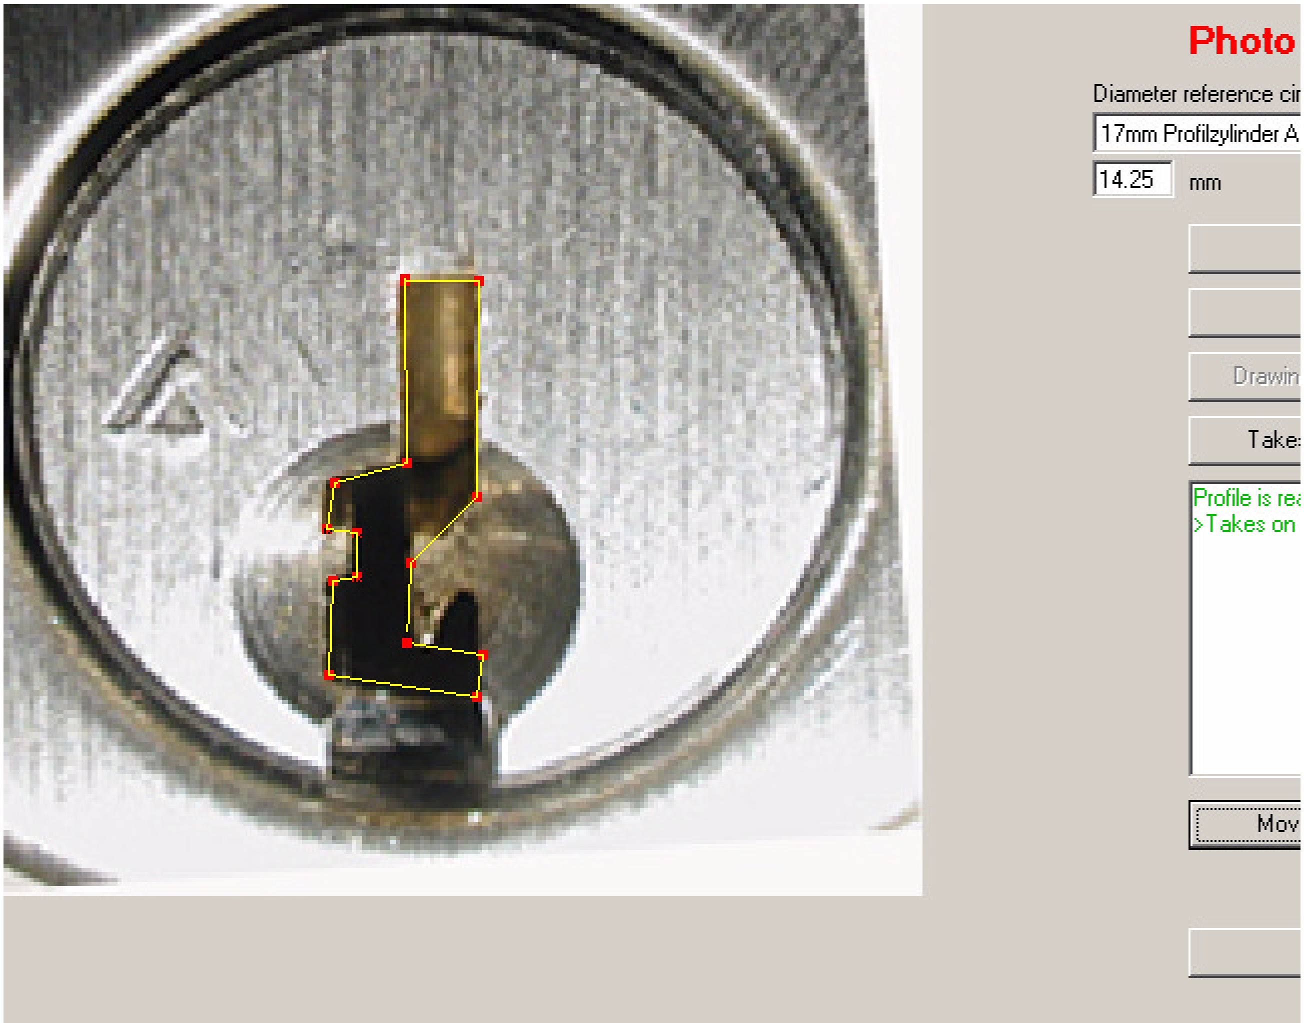

Figure LSS+3150 The Easy entrie is capable of simulating restricted profiles for the Schlage Everest and other conventional locks. Note how the keyway is "drawn" to bypass the undercut portion for the check-pin. This menu, from the special PC software, allows a profile to be created that will bypass the ward pattern of most keyways.

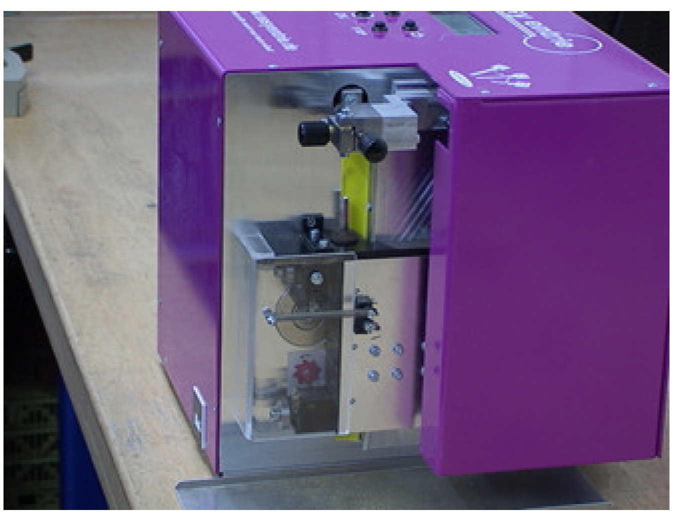
31_4.10.7 Obtaining Blanks for Target Locks



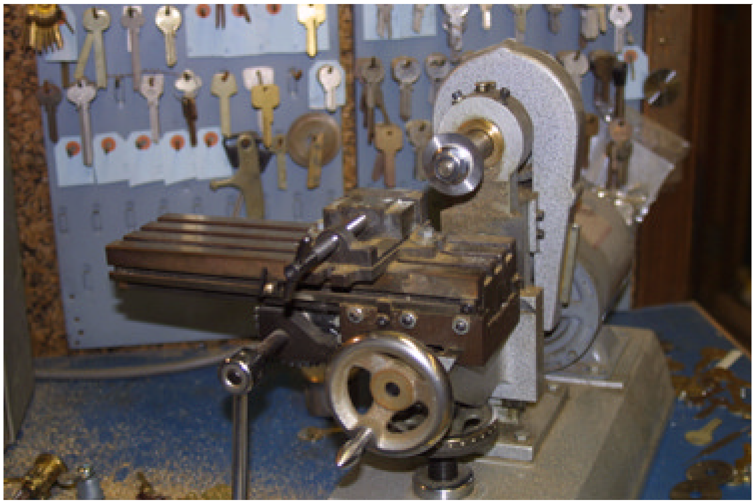
The extrapolation process requires the operative to be in possession of a sufficient number of blank keys to allow sampling of each chamber in order to ascertain the depth of each lower pin segment. This process may become more complicated under certain conditions:

- **Restricted blanks are utilized that are unavailable through normal channels;**

Only a bitted change key is available for the target lock;

- **A manufacturer or keyway cannot be readily identified, or no intelligence is available about the lock. Typically in this scenario, a target cylinder is identified that must be decoded. Blanks are only available from the manufacturer, and are not accessible to the operative on-site;**
- **There is no source for blanks to fit the particular keyway;**
- **Sectional keyways may be employed that are not readily available;**
- **A sufficient number of blanks cannot be obtained;**
- **Foreign locks may be involved for which blanks are not available or cannot be obtained within the required timeframe;**
- **Special blanks are utilized that contain unique sidebar millings, protrusions, or other obstructions that will prevent their use within the target keyway;**
- **Patented or legally protected(351) profiles are only available from the manufacturer;**

The production of blanks may require the use of profile milling machines that are described in **chapter 8.** The use of the Easy entrie machine will be discussed in the context of the compromise of master key systems in this section because of its suitability for such purpose. Additionally, the capabilities of other types of cutters may also be required if secondary mechanisms are employed, such as sliders, protrusions, detents, steel bearings, side millings or other physical obstructions which must be replicated.



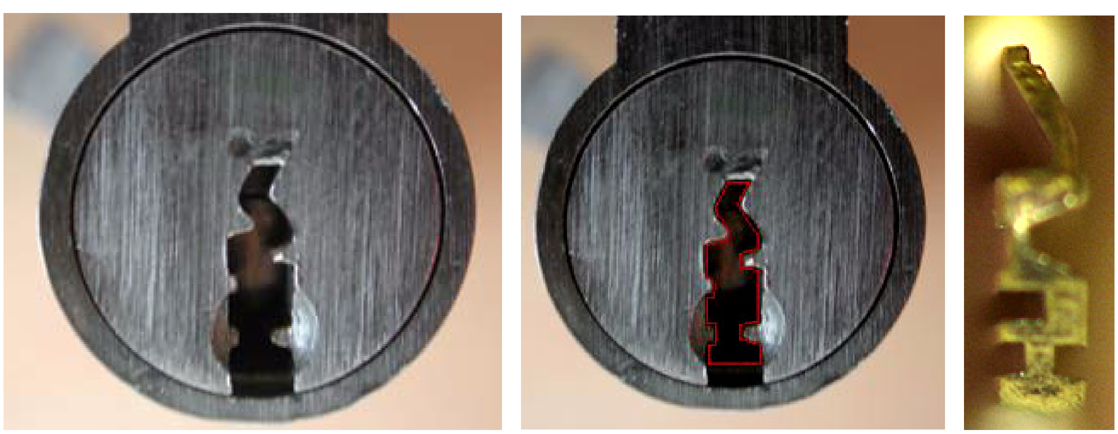


Figure LSS+3144 The Easy entrie and Keyway King profile milling machines can be utilized to generate or create blanks, even for restricted keyways.

The Easy entrie profile milling machine can allow the generation of blank keys from a variety of sources:

- **Sample of blank key;**
- **Sample of a cut key;**
- **Digital image of keyway;**
- **Digital image of end-view of the profile of a key obtained from a blank or cut key;**
- **Impression of a keyway;**
- **Feeler sample of a source key, from which a silicone impression is produced and photographed;**

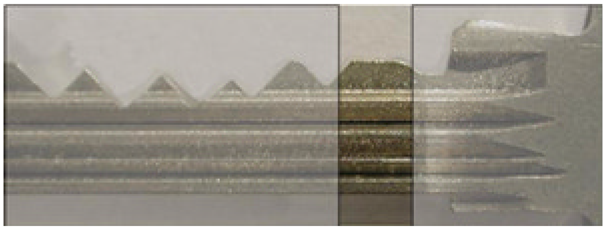

Figure LSS+3143 The Easy entrie profile milling machine can reproduce blanks from a variety of sources. In the photographs, a keyway from a European profile lock is shown, with the pattern traced in the software provided with the Easy entrie. A blank can also be generated from a photograph of the tip of the key. From a cut key, a section can be measured that provides a sample of the complete bitting surface. Any portion of the cut key can be measured to produce the blank. In the photograph (right) the portion of the key that shows the first cut from the shoulder is utilized to produce a blank.

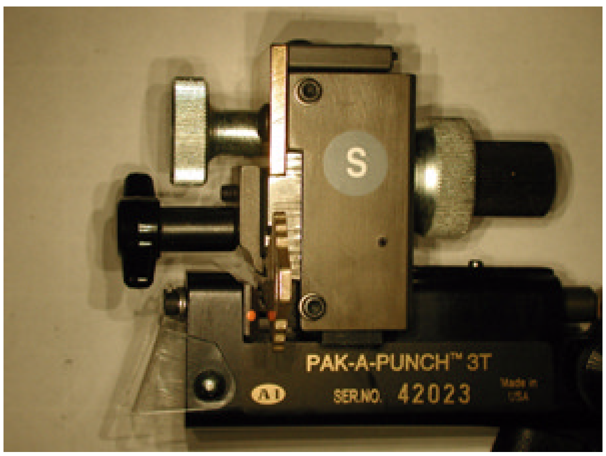
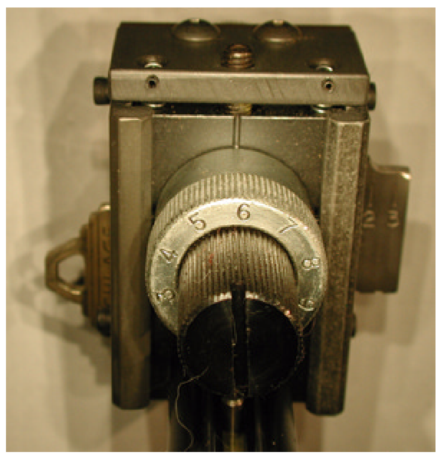


The Keyway King, distributed by DiMark Manufacturing, requires a great deal more skill to generate a blank but has the capability for precise milling of different sections of the key. The Keyway King is a milling machine that allows cutting on three axis, as shown in the accompanying video in **Chapter 8.** Unlike the Easy entrie, the Keyway King has no capability to automatically generate a blank from a source key, nor can it replicate a profile from a photograph. The advantage that the Keyway King provides is the ability to utilize many different cutting wheels to create different profiles. The Easy entrie cannot accomplish this because it measures a very small portion of the longitudinal cross section of the key and then replicates that measurement across its entire surface. If side millings or other unique configurations must be reproduced, then other specialized cutters can be utilized in conjunction with the Easy entrie to accomplish the task, so long as the millings are consistent across the entire surface of the key. The DiMark product has no computer interface capability, and thus does not have the capability of accurately repeating a process where multiple blanks must be created for the same profile. However, individual actions can be repeated with the same milling setup. In other words, several blanks can be milled in sequence for one particular cut before the settings are changed.



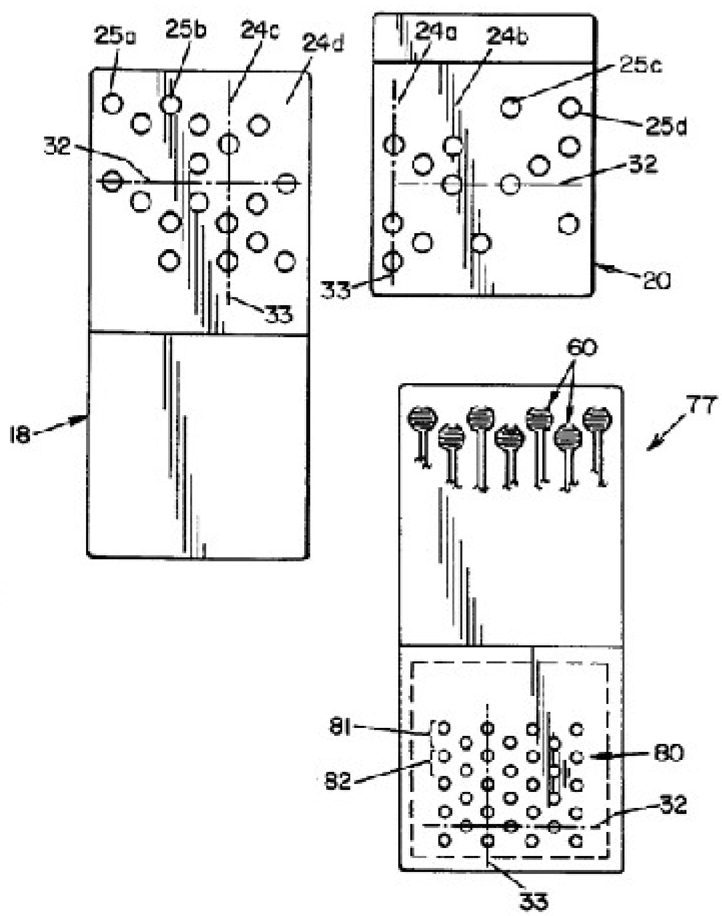
31_4.10.8 Cutting Keys During the Extrapolation Process

Operations may require that system keys be cut in the field for the target lock. In such an instance, there are a number of different alternatives available for key cutters. Two of the most versatile portable devices are the **Pack-A-Punch** and the **HPC 1200**

Punch.

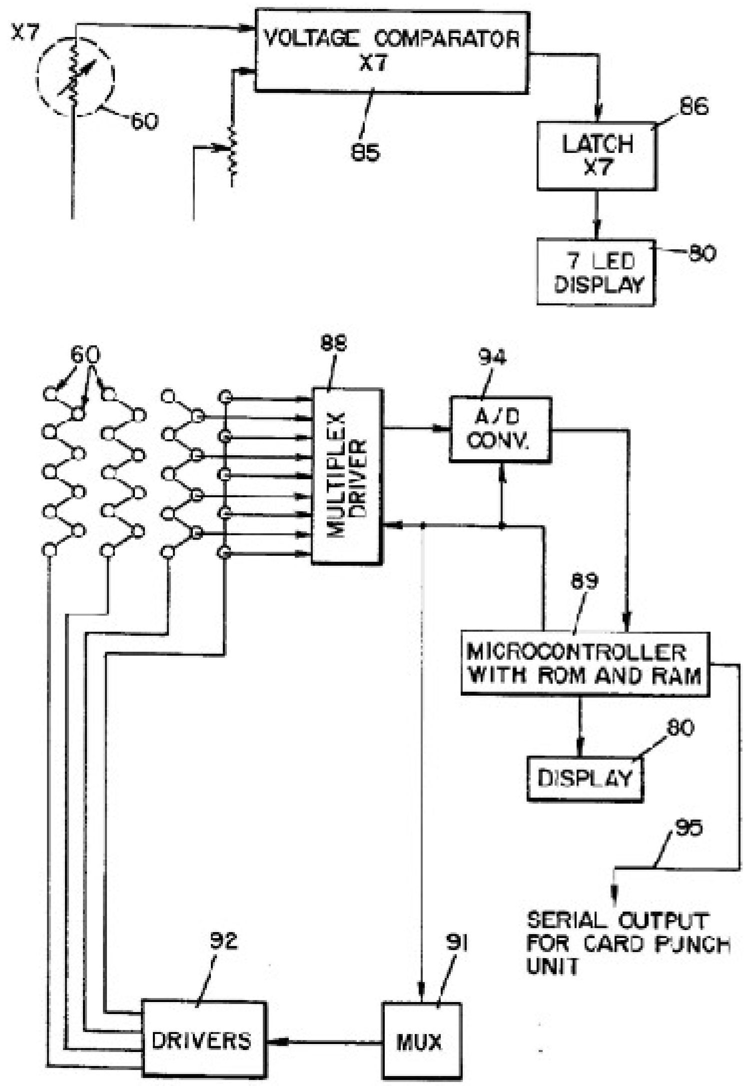
The Pack-A-Punch is available for certain manufacturers and keyways as well as for most automotive locks. The tool can be carried in a jacket pocket and is completely self contained. Different dies are utilized for specific manufacturers. A key blank is inserted into the tool and then advanced and cut for each space. The bitting depth can be rapidly selected with a knob that denotes each depth increment, and the punch then makes the cut. The key is moved laterally across the punch; each position is shown on the right or left side of the cutter. If the Pack-A-Punch is utilized in conjunction with the Easy entrie machine, care must be taken to properly index the special blank because there is no bottom shoulder stop, which is required for the key to be properly referenced to the cutting die.

31_5.0 Electronic Sensing, Measurement, and Capture of Position, Pressure, Polarity, or Presence of Components or Data



Depending upon the design of the lock, there are several tools and techniques that can be used to sense, measure, and capture the position, pressure, polarity, or presence of active locking components or internally stored data. Primary techniques to provide information about active locking elements include:

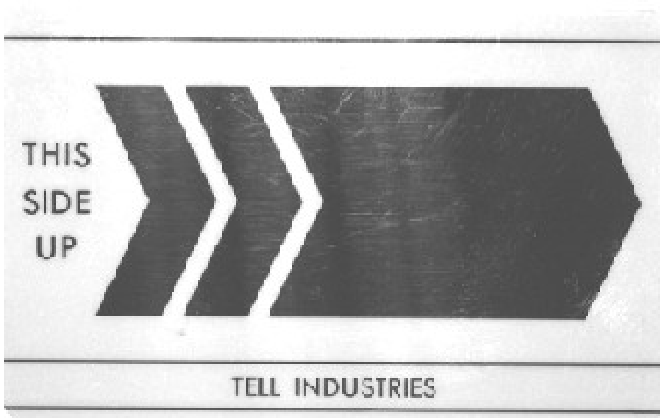
- **Pressure-sensitive resistive materials;**



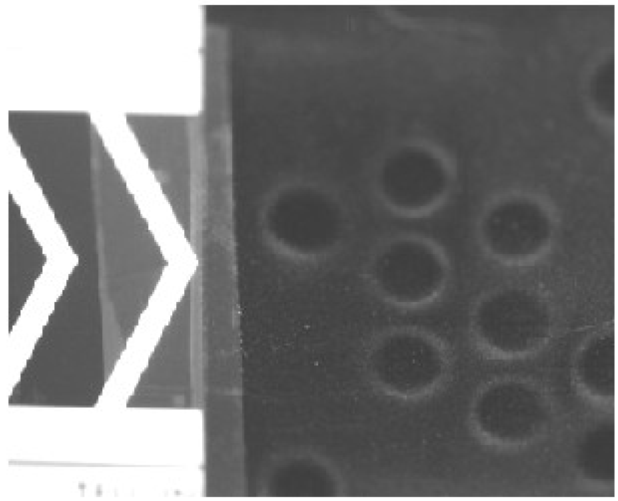
- **Hall-effect sensor for magnetic locks;**
- **Reading the lock;**
- **Decoding the information contained in a code source;**
- **Infrared decoders;**
- **RF decoders;**
- **Vibration at resonant frequency of active locking component.**

31_5.1 Conductive Ink Decoding Systems

The author received a patent in 1994 (**5355701(352)**) for a conductive ink resistor decoding device, used with Ving pin tumbler card locks. This system could sense the position and relative pressure of a pin tumbler within a pin tumbler array.



A matrix of conductive resistors matching the spacing of each pin chamber is produced on a plastic card that is interfaced to a small computer and light-emitting diode array. When the card is inserted into the lock, the pressure of each pin is sensed through a change in resistance. The display provides an instant picture of the combination of pins from which a key can be generated.



31_5.2 Magnetic Signature Capture

Some magnetic key, card, and disc locks are susceptible to decoding, with different materials and techniques. These devices

rely upon two distinct and different principles to provide security: one is based upon the physical law that like poles of a magnet will repel; the other utilizes tiny magnetized particles to store information.

A variety of materials and devices are used for decoding magnetic information. The 3M Company produces a magnetic-sensitive fluid that is encapsulated in a plastic carrier. Other manufacturers offer fluids containing iron oxide and magnetic sprays. Fine magnetic particles found in copier toner may also be used to read the location of magnetic spots. They are deposited over the target area, then the particles can be lifted with cellophane tape. NCR invented a magnetic paper that could be used in the same manner as the 3M material, except that it would retain the image after removal from the magnetic field.

31_5.2.1 Magnetic Pins or Rotating Discs

In one type of arrangement, magnetic pins or rotating discs are positioned to create a shear line, either directly or through the use of a sidebar. The pins or discs are repulsed from or attracted to a break point based upon the coding of a key or card having corresponding magnets or magnetic spots. The Evva and Miwa locks utilize these principles and were described in Chapter 19. In order to decode these devices, the position and polarity of the magnets must be determined (see patent (**4229959(353)**). The Ikon and Evva mechanisms are extremely difficult to decode due to the use of rotating discs and gates. Analysis of information from these locks will yield no useable indication of the location of any of the gates.

Hall-effect sensors contained within a tiny integrated circuit may be inserted into a magnetic array to provide information as to location and polarity of each magnet. So also, magnetic film, spray, or carbon particles can accomplish the same result. The author developed a sophisticated technique for capturing information as to the number, position, and polarity of magnets within a card lock at the request of a government agency. This technique is briefly described below.

The process involves the insertion of sensing material into the lock for about one second in order to record the presence of magnetic fields and the signature of the key or card. The material is withdrawn and read with a film that visually indicates where magnetic spots are located. Then, a sensitive Hall-effect probe is utilized to determine the polarity of each magnetized spot.

31_5.2.2 Magnetic Stripe Technology

In another type of lock, a magnetic stripe is incorporated onto the surface of a plastic card. Information is encoded onto this ferrous material to provide data to the microprocessor within the lock. It is the same technology as utilized in the credit card industry. Generally, up to 240 bits of information is written on the stripe in the form of magnetic flux reversals. ISO standard 4909 provides an international reference for encoding data and sets card size, thickness, and schemes for writing the information. Generally, three separate tracks can be created and written. In the case of credit cards, tracks one and two are utilized for account information. Track three is reserved for ATM transactions where new information must be written to the card in order to reflect the latest transaction. Lock manufacturers similarly encode these channels.

The encoding of cards is a simple process requiring a record head much like those found in tape recorders. These heads can be purchased at many electronics stores; the circuitry to encode magnetic tracks is relatively simple to construct. Card locks using magnetic stripe technology can be compromised by decoding and duplicating the data on the card or by reading the corresponding information contained in memory within the lock. Inexpensive card readers can be constructed or purchased that are capable of deciphering the data on most magnetic tracks. Likewise, it is reported that Weigand systems can be duplicated and compromised by reading the position of wires within a card

and simulating the data stream created by wire segments.

31_5.2.3 Solid-State Memory

Many of the electronic locks contain removable memory circuits that can be decoded with an EPROM (erasable programmable read-only memory), or EEPROM (electrically erasable programmable read-only memory) reader. A logic analyzer or storage oscilloscope can be used to examine the data contents of memory that remains active and in place on the printed circuit board.

It is also possible to determine the location within a memory device of passwords unique to a lock or lock system. Once the information is derived, it can be used to create a key, card, or other device to bypass the lock. The author conducted one investigation involving an Israeli safe used in thousands of hotel rooms in Las Vegas, Nevada. The 24-byte code that comprised the security bypass card for all of the safes in the hotel was compromised in less than ten minutes. A card was then encoded using a laptop computer that would open any safe in the hotel.

31_5.3 Infrared Decoders

Some locks utilize infrared as a transmission medium for the transfer of data between an encoding device and a receiver. Resembling a television remote control encoder, they head of the key has an IR transmitter built into it that transmits the data to the lock. In certain cases, the data stream between transmitter and receiver can be intercepted and decoded. Once this information is captured, it can be analyzed quickly and reproduced.

31_5.4 Radio Frequency (RF) Decoders

Many automobiles, security, and access control systems utilize RF as the mode to transfer information between user and the lock. These are quite easy to intercept, decode, and simulate because they use common frequencies and the encoding scheme can be fairly standard.

31_5.5 Other Decoding Systems

Many other types of electronic systems can be intercepted, measured, and decoded. Anti-theft systems in stores and

libraries, for example, generally rely upon the creation of a harmonic frequency through the introduction of RF into a tuned circuit sensor that is contained in the item to be protected. These systems can be compromised in many ways.

VATS decoders that measure the resistance of the pellet contained within the head of certain automotive keys require nothing more than an ohm meter to determine its resistance. Some proximity detectors may also be subject to compromise by planting a sensor near the receiver to determine the characteristics of the card or other device.

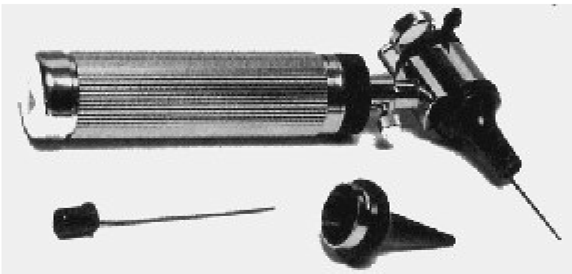
31_5.6 Resonant Frequency of Active Locking Component

In certain locks, it may be possible to determine the precise characteristics of an active locking component by the introduction of audio frequencies. Such energy can cause a pin tumbler or fence to vibrate at a specific frequency, which can then be correlated to the length of the pin or position of the fence (in a combination lock).

31_6.0 Optical Viewing

Internal components may be observed and decoded through the use of a variety of precision optical technologies. The three primary devices for acquiring images from the surface or inside of locks and safes are the **otoscope**, **ophthalmoscope**, and **borescope**.

These instruments can provide sharp, high-resolution images that can be viewed, photographed, or observed with a video monitor. Color and monochrome video camera heads are easily attached to facilitate decoding. Borescopes utilize relay lenses, or fiber optic links, to transmit images from sensors measuring as little as .3 mm. Charge coupled device (CCD) cameras are also available that may be inserted directly into the lock to provide a video image of internal components.



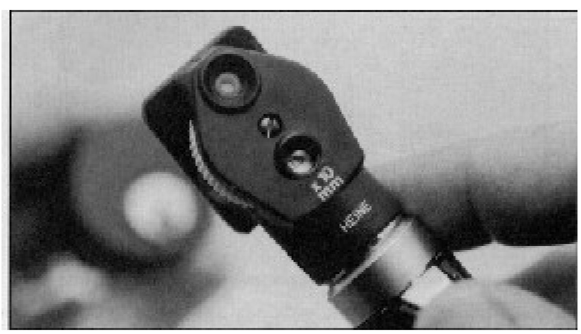
Otoscopes and ophthalmoscopes are inexpensive and simple in design as compared to borescopes. They provide for the surface viewing and magnification of components and allow for the adjustment of diopters and focus to compensate for individual visual acuity. Several factors will dictate which device is best suited to provide optimum imaging. These include:

- **Diameter of the aperture through which the view is to be made;**
- **Distance from the entry point to the active locking component;**
- **Clearance dimensions within the lock or safe;**
- **Required resolution;**
- **Viewing angle;**
- **Magnification requirements;**
- **Illumination requirements;**
- **Capability of video link;**
- **Digital capture requirements.**

Many locks can be decoded by viewing their wards, levers, wafers, pin tumblers, or wheel packs. Extrapolations can then be made from such observations. The information is then converted to code data resulting in the production of a key or derivation of the combination. Optical viewing devices are also used for conducting non-destructive forensic examinations. This section will describe the most common optical tools and their use. For detailed information including the decoding of safe locks, see **LSS+/^{x} CD/ROM.**

31_6.1 Otoscope

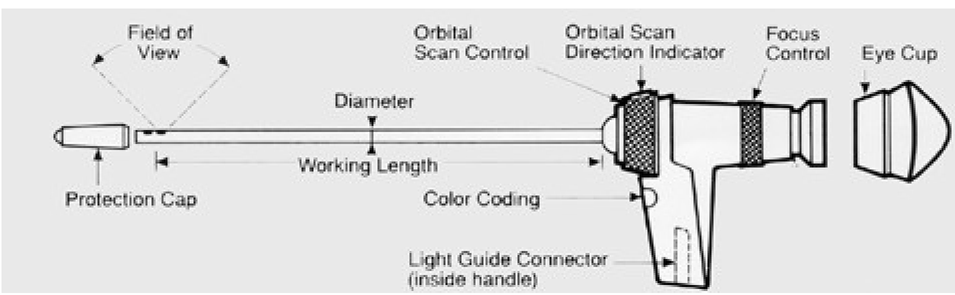
An otoscope is the least sophisticated optical viewing device. Typically, these are battery-operated magnifying and illuminating instruments designed specifically for small or difficult-to-view areas. The otoscope generally is provided with a magnifying lens, specula, and pin depressors to manipulate tumblers inside the lock. In 1963, a patent was granted to Rubens (**3087050(354)**) for a combination otoscope, light source, and pick holder.



An otoscope head can be used with a borescope lens array. In this case, the otoscope provides a magnified view at a set distance from the lens. Any object that is outside of the depth of field will be out of focus. Generally, an auxiliary lens can be inserted for viewing objects farther away.

31_6.2 Ophthalmoscope

The ophthalmoscope is a necessary instrument in the fields of ophthalmology and optometry and is used to view the interior portion of the eye. It is equally useful for looking inside of locks.



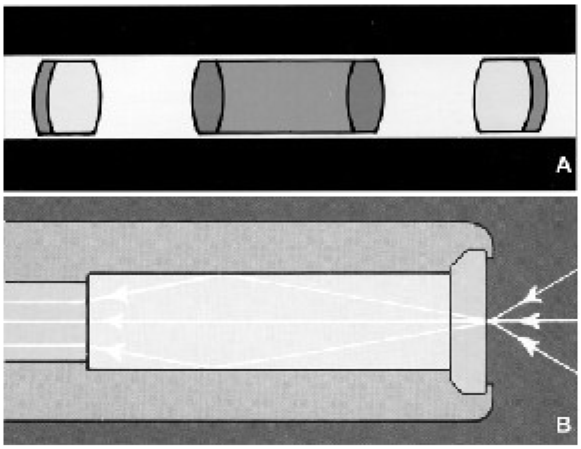
The device allows surface viewing and magnification of objects within a field of view of 5 mm to 250 mm, or approximately 32". Diopter adjustment is generally available. Usually a series of lenses may be selected for different focal lengths.

31_6.3 Borescope

Discussion of endoscope and borescope. Courtesy of Hans Mejlshede.

The borescope is the most sophisticated and expensive optical device available for lock and safe work and is an essential tool for the professional safe technician. Olympus is the leading supplier of relay lens and fiber optic viewing systems in the world. There are two types of borescopes: **rigid** and **flexible**. Each has certain characteristics and restrictions. Video and photographic attachments can be linked to the eyepiece of most borescopes to provide real-time images. This is especially valuable to the safe technician. Illumination of the target is provided by incandescent lighting, or transmitted via fiber optics from a portable light source.

Borescopes generally offer a very wide depth of field so that the target is always in focus. Angled views of up to 90° can be achieved, as can rotation of the target image. Illumination can be precisely adjusted for optimum contrast.



31_6.3.1 Rigid Borescope

A rigid borescope resembles a telescope in design. The imaging system relies upon three primary components: **objective, relay, and ocular.** The distal tip incorporates an objective lens that transmits an image onto the relay lens system. Different prisms can be used to provide varying directions of view. The image system is comprised of lenses and prisms. It will not tolerate any bending, which can prove a disadvantage in certain applications. The image resolution in the rigid scope is far superior to flexible units. The relay system, encapsulated within a long tube, transmits the image created at the objective to the ocular viewing lens and eyepiece. The images are actually relayed or recreated as they encounter each lens and prism. Auxiliary prisms are sometimes used to correct image orientation as they reach the eyepiece.

31_6.3.1.1 Lens Systems

There are three common lens systems used for relaying images: **thin lens relay, hybrid rod and thin lens relay, and selfoc/grin relay system.**

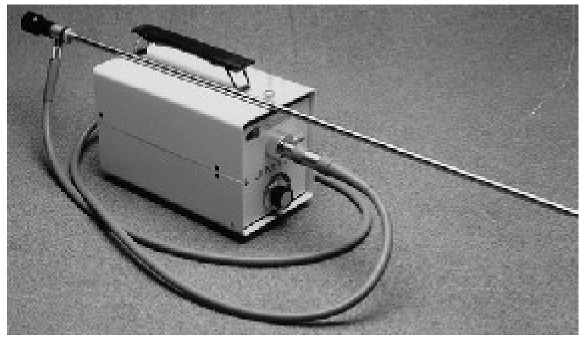
Thin Lens Relay

The convex thin lens is the simplest form of image relay and provides the greatest light loss or absorption during transmission. The system is comprised of a series of convex lenses that simply acquire and retransmit images down the chain.

Hybrid Rod and Thin Lens Relay System

This is a more sophisticated system and utilizes the convex lens in combination with cylindrical "rod lenses" with specially ground ends, for more efficient light transmission. The increased amount of glass provides greater resolution.

Selfoc System

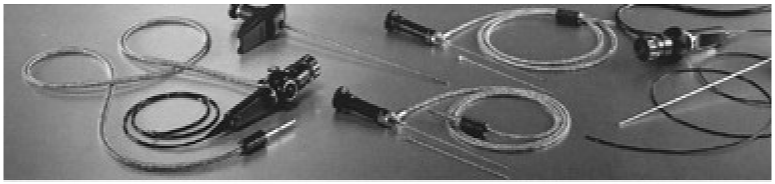


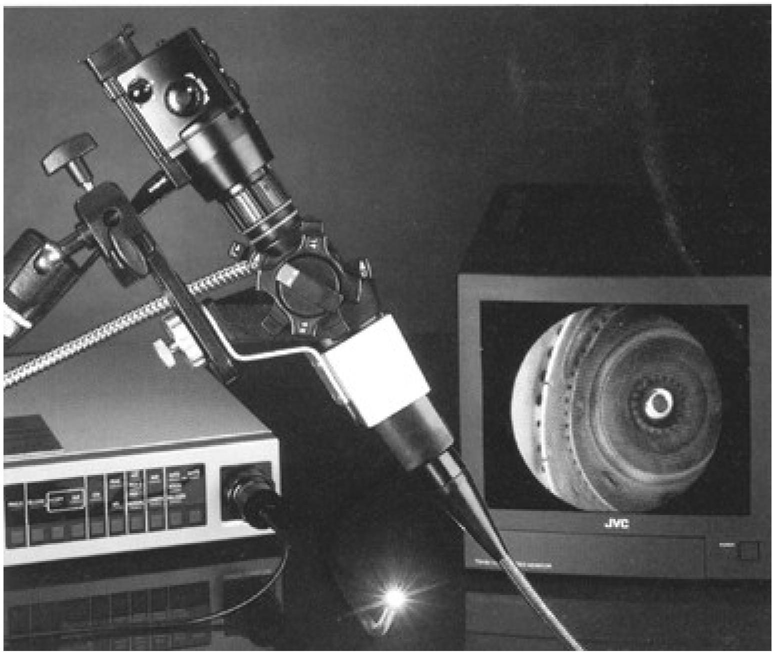
The Selfoc system is used on 1.2, 1.7, and 2.7 mm diameter borescopes. In this configuration, a glass rod forms one continuous cylinder. This is the most expensive system and is quite fragile.

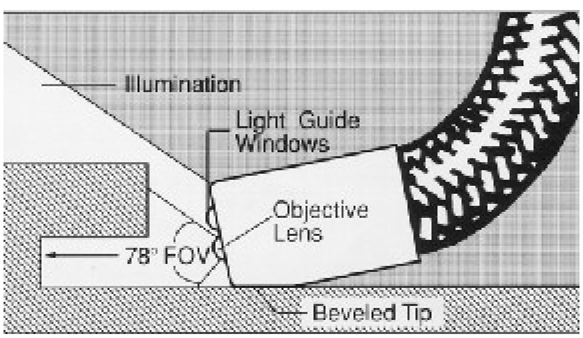
31_6.3.1.2 Lenses and Image Quality

Image distortion depends upon the quality of the lenses within the optical instrument. Compound lenses are generally used in the more expensive borescopes for sharper definition. Two primary forms of image distortion result from the use of simple spherical

lenses: **chromatic** and **spherical**. Chromatic distortion refers to the characteristic of a lens that refracts light at different angles, depending upon wavelength. Short wavelengths (violet) are bent more; the longer ones (red) less. The result is color fringing within the image.





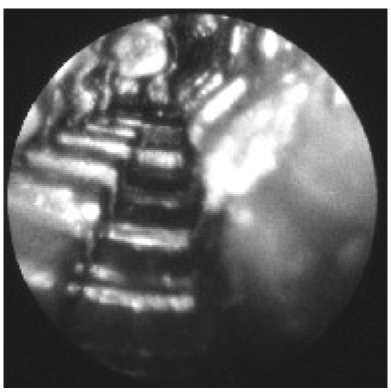


Spherical distortion occurs because the lens surface itself is shaped as a sphere rather than parabolic. This results in the lack of a single focusing point. In such cases, light rays are refracted to different degrees depending upon the point where they enter the lens, other than at the axis. To correct these errors, compound lenses are utilized. They consist of both concave and convex elements that have different refractive indexes. They cancel distortion without altering the transmission properties of the lens.

31_6.3.2 Flexible Borescope

Differing from a rigid borescope (where images are relayed by lens elements contained in the array), a flexible fiber optic guide is used to transmit images in this configuration. The resolution is not nearly as good in these systems, but allows viewing of targets in difficult locations up to ninety feet away. The tip can be controlled to observe different areas of the target. The Olympus series of flexible scopes can be used for covert operations that require the capture of images through walls, ceilings, and under doors.

31_6.3.3 Lighting Sources



Incandescent lamps or fiber optic routing of light is used to illuminate the area or object being viewed. Optical fibers are preferred because they can provide lighting with high output that is adjustable and remote from the probe. A separate light-generating source is interfaced in the borescope, usually with a fiber optic pack that surrounds the tip of the probe. Halogen lights are often used to provide brilliant white illumination.

31_6.3.4 Using a Borescope for Decoding and Opening Locks

Borescopes have excellent resolution and can be used to observe active elements within a lock. The dimension, location, coding, and alignment of such components can be observed and calculated. Decoding of wafer, lever, and combination locks can be accomplished using regular and micro-borescopes. Micro-borescopes can penetrate pin tumbler and other locks that have keyways with ward clearance of .5 mm or more.

31_6.3.4.1 Decoding Wafer Locks Using Borescopes

Although it is technical overkill, most wafer locks can be decoded with a borescope. It will be remembered that the **overall** outer dimensions of most wafers do not vary. Differs are created by the relative vertical position of the void area within each wafer (where the key enters). The amount of bitting material that is present between the top of the open area and the top or bottom edge of the wafer determines the depth code.

Exploded view.

With an understanding of this principle, it is a simple matter to observe each tumbler and the relative position of the internal open areas, with respect to the top or bottom edge of each wafer. Since there are generally no more than six depths, the coding is simple to calculate. In the case of some General Motors sidebar locks, the depth code is imprinted on the face of each wafer, as well.

31_6.3.4.2 Decoding and Manipulating Lever

Locks Using Borescopes

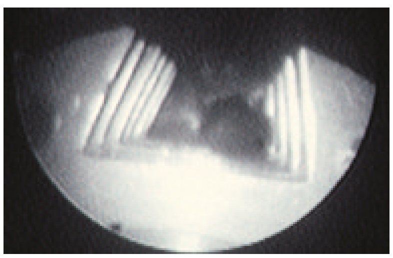
Using two primary techniques, lever locks may be decoded, analyzed, and opened with a borescope. In addition, the number of levers, their characteristics, and any special security enhancements can often be determined.

31_6.3.4.2.1 Observing Fence-Gate Relationship

The levers can be individually manipulated by picking while observing the position of each gate and fence. In this instance, a viewing hole is often present through which the probe can be inserted. Otherwise, a hole can be drilled to accomplish the same purpose. Once a direct view is available at the point where the fence enters the gate of each lever, it is a simple matter to lift the levers for proper alignment.

31_6.3.4.2.2 Extrapolating Information from Bellies of Levers

The bellies can be viewed and analyzed for contact marks that occur where the bitting surface of the key interacts to lift each lever. Once decoded, the depth of each lever can be extrapolated and then transferred to a key. In locks where bellies are not uniform, the width of the interaction mark will be different, based upon the amount of lift required to bring the fence and gate into alignment. The ability to decode a lever depends in part upon how much the lock is used and the resultant wear. If very pronounced, then the width of the marks will be noticeably different for each depth.



Uniform bellies, as are present in the Chubb 3G110, can be a great deal more difficult to decode. This is because the width and placement of the marking will change. A detailed knowledge of each lock is required to successfully decode these mechanisms. Tryout keys can also be used with lever locks having fewer differs because of the lack of tolerance. In England for example, many locksmiths carry sets of keys that will open all lever locks within the country.

31_6.3.4.3 Penetration of Safes and Vaults with Borescopes

There are many ways to effect an opening of a safe or vault. Other than manipulation, drilling is the primary technique. Once

the decision to drill has been made, the craftsman must decide where to drill and for what purpose. The primary reason to drill **any** lock is to gain access to the wheel or lever pack and to observe the interaction of the gate and fence. When a view of this interaction is achieved, moving the components into alignment can open the lock. This presumes that relockers have not been fired.

Critical components may be viewed by drilling anywhere that allows the wheel pack, levers, relockers, or active locking components to be observed. The borescope is generally the preferred instrument, where components are inaccessible to other forms of optical aids or surface viewing. They may probe into remote areas up to 30″ away and are ideal for safes, vaults, and lever locks.

Although covered in later chapters regarding safe penetration techniques, a brief description of the drilling process as relates to the use of a borescope will be presented here.

A small hole, generally between ¼″ to ½″ is made into the body of the safe at one of several preferred locations. A drill point template is generally required, as the placement of the hole must be quite precise to obtain the proper view. There are complicating factors to this process relating to the use of security glass attached to relockers and the penetration of barrier materials. Special compounds are also employed to frustrate penetration. These are discussed in **Chapter 5.** Barrier material, generally having a Rockwell hardness rating of up to 90, is usually positioned so as to cover the lock. This makes drilling more difficult and time consuming.

A pane of Herculite glass is generally placed in front of critical locking components in high-security safes in order to protect against penetration by drilling. The theory is that if the drill point touches the Herculite, the glass will shatter, releasing tensioned relockers. There are methods to circumvent glass that are discussed in later chapters. One other problem

involving the use of Herculite deserves mention. In some older safes, manufacturers had a practice of painting the glass. This technique was discontinued when it was discovered that the paint acted as a cohesive material to hold the panel together after penetration.

Notwithstanding the difficulties that may be encountered, a borescope requires that a small hole be precisely positioned to provide a view of the wheel pack or levers and their interaction with the fence. In the case of combination locks, a hole may be made anywhere within a 360° field around the wheel pack, so long as the outer edge of each wheel can be observed. Lever locks require more precision to provide a direct view of the point where the fence enters the gates.

To open a combination lock with a borescope, the probe is inserted and each wheel is rotated until the gate is observed. The **relative position** of the wheel is correlated to the number that is indexed on the dial. Each wheel is rotated, in the left-right-left or right-left-right sequence as if the combination were being dialed. All wheels must be aligned so that the fence **would** retract if the wheels were properly positioned with respect to the drop in position of the fence. Once this occurs, it is a simple matter to extrapolate the difference between the observed and actual drop in point.

The observation of the wheel pack can be achieved from the front, side, or back of the lock. Often, a hole is drilled at the rear of the safe; the change-key hole at the back of the lock is used as the viewing aperture. Security glass may be avoided by drilling a scope hole at the edge of the door in front of the glass.

31_7.0 Obtaining Key Codes Using Photographic Techniques

A target key, if available, can be photographed with high-resolution film that is indexed for precise measurement. From the print, it can be reproduced and decoded. If keys are visible for a few seconds, they can also be photographed through covert means. The author has successfully utilized the Tessina (Swiss) 35 mm double-lens-reflex handheld camera for this function, as well as standard format 35 mm with long lenses. Video is more difficult to obtain useable images due to the relatively low (30 dpi) resolution. Target keys can also be

overlaid on photographic paper and briefly exposed to light to obtain a 1:1 contact print. They can also be reproduced on a copy machine.

31_7.1 Photographic Techniques

The code information of keys can be derived through three primary photographic techniques: **covert**, **macro**, and **exposure overlay**.

31_7.1.1 Covert Photography

Keys sometimes can be photographed covertly if the proper circumstances either exist or can be created. Depending upon the following factors, covert photographs may be taken of target keys that are carried, worn, or left open to view.

Covert photography is used where direct access to the target key is not possible. For example, the master key carried by a maid in a hotel may need to be obtained. A series of photographs may be shot as she walks down the hall. The pictures may then be examined and the size of the key correlated with a known sample. One case that the author reviewed involved the surreptitious capture of the master code for a VingCard lock by hotel burglars in Europe. The thieves were able to photograph a VingCard plastic key and determine the matrix of holes that comprised the system master key. It will be recalled that these plastic cards have a series of holes punched randomly. It is a very simple matter to correlate the photograph with the generation of an actual card. In this particular case, thieves were able to compromise a number of hotels in Belgium and Holland before being caught.

Factors that will affect the acquisition of an image:

- **Size, design, and intricacy of the key;**
- **Type of locking system and complexity;**
- **Whether certain aspects of the bitting is not visible, such as sidebar data on an ASSA key that can only be viewed from one surface;**
- **Design of the bitting surface: ramps and valleys, square-cut, or dimple;**
- **Differences or spacing between each cut;**
- **Difference between the depth of each tumbler position;**

- **Angle and perspective of view;**
- **Contrast of bitting surface;**
- **Distance from the camera;**
- **Lens, focal length, and iris opening;**
- **Image capture format: film, video, radioactive imaging;**
- **Film format: size, DIN, resolution in lines per millimeter;**
- **color, monochrome, or infrared;**
- **Lighting;**
- **Reflection of light from the key;**
- **Background surface and color and the contrast thus created.**

31_7.1.2 Macro Photography

A macro photograph can be taken of the key with a precision ruler, providing a 1:1 guide for printing the image. It is then a simple matter to enlarge the photograph or extrapolate the depth of each cut.

31_7.1.3 Exposure Overlay

A very simple means to obtain a precise 1:1 image of a target key is to contact overlay the key on a piece of photograph paper or film in the dark, then briefly expose it to light. The image may be retained for a long period within a dark container and developed later. The resulting image may be translated to a hard metal blank.

31_8.0 Pressure-Responsive Materials

Pressure-responsive materials may be utilized for producing a direct impression of a target key or for decoding the active elements. Electronic and pressure-sensitive resistive materials can also be used to decode a lock.

31_8.1 Duplication of Keys

Target keys may be physically copied through the use of pressure-responsive materials. These include plasticine, clay, modeling clay (Fimo is recommended), metal foil, silicone material, soap, or even human skin. They may all be utilized to

obtain an impression of a key for later duplication. In an emergency, a key can be firmly depressed against the soft skin of the wrist. This will leave an impression that can then be dusted with talc and lifted with cellophane tape.

31_8.2 Decoding Active Components with Pressure-Responsive Materials

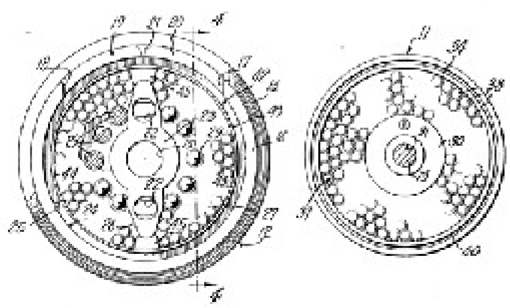
As detailed in **Chapter 26**, many materials may be used to decode the position and dimensions of active locking components within a warded, wafer, disc, lever, and pin tumbler mechanism. The proper and effective use of plasticine, carbon, wax, cellophane, metal foil, clay, and carbon paper rely upon basic impressioning theory, detailed in **Chapter 30.** Each of these materials is used to produce an imprint in order to obtain an image of the key or to extrapolate its measurements.

31_8.2.1 Newton Plasticine System

Martin Newton (UK) has developed a plasticine impressioning and decoding system for lever locks. A collection of several different keys is provided within a kit. Each is cut to lift one lever within the lever pack, allowing decoding. A special blank is also provided, upon which plasticine is overlaid. Once coated with the material, the blank is inserted into the lock and turned against the levers. The depth of each belly is defined as an impression, allowing a key to be generated (see **Chapter 30).**

Plasticine reading kits are available for the following locks:

- **Union 5-lever Black, Yellow, and BS3621**
- **Ingersoll M50**
- **Yale Titan and PM550**
- **ERA Invincible 5-lever, Viscount 5-lever, and Endurance 5-lever**
- **Securefast 5-lever**
- **Chubb Upgrader 5-lever**
- **Gibbons 5-lever**
- **Squire Defiant padlock**



31_8.2.2 Falle Metal Foil System

The Falle metal foil impressioning and decoding system utilizes a

thin layer of metal to define the position and length of each pin tumbler. This technique is quite effective and can result in a precise image of the key that can then be decoded. See **Chapter 30** for a detailed description of this system.

31_9.0 Radiographic Imaging

Computers have changed conventional methods of radiographic imaging. Now, both radiography and radioscopy may be utilized for bypass and covert entry. X-ray, gamma ray, and other radiation technology have been successfully used by Russian, American, and other foreign intelligence agencies to determine the position of the wheel pack within a combination lock and to examine pin tumblers in a cylinder. Several patents have been issued for techniques to prevent the gathering of such information, generally through the use of lead masks.

Traditional x-ray methods utilize photographic film for the detection and recording of images. The electronic version, radioscopy, uses x-ray sensitive detectors to produce an image on a CRT or liquid crystal display. Radioscopy is a relatively new procedure and is used in industry for non-destructive testing. Standardization efforts began in 1988 by the ASTM, and the use of the technique is expected to increase. Presently, the primary users of radioscopy are industry, medicine, and aerospace. As equipment becomes more sophisticated, the application for covert entry will expand.

The technique can allow the examination of almost any object, including electronic components, ceramics, composites, plastics, and other non-metallic materials. Radioscopy can save cost, time, and labor, and eliminates the need for films and chemicals. It is obviously a more environmentally friendly process. One of the most important benefits of the imaging process is the ability to manipulate the photographed part or component, using

sophisticated software. It is possible to obtain different views and perspective when using such programs.

Once the data is collected in digital format, the results can be processed for detailed enhancement and analysis. Most importantly, radioscopy can provide a real-time examination of active locking components. There are now portable x-ray units produced by SAIC and others that can be used to derive real-time information about a lock, explosive, or other mechanical device. The second generation of these devices provides an enhanced image, displayed on a liquid crystal array or computer CRT.

There are inherent difficulties involved in the use of such technology. These relate to the fact that radiography relies upon a **difference** in the density and composition of metals or other materials in order to provide useable images. Minimal changes in density mean that it is impossible to distinguish between different components. Effectiveness is limited by many factors. These include:

- **Thickness, density, and composition of the outer surface that protects the lock;**
- **Composition of the individual locking components;**
- **Difference in composition and density of protective surfaces, barrier materials, and other enclosures in comparison to the active locking components to be measured;**
- **Ability to obtain an image based upon the position of the lock and the enclosure. This relates to the distance between the target and radiation source, as well as the capability of placing the lock within the focal length of the instrumentation.**

Typically, the use of x-ray to determine the position of each gate in a combination lock requires that the dial cover be removed. Film or a detector array is placed in front of the

wheel pack, and a gamma source is located at the rear of the safe. In practice, a small hole is drilled and radiation is directed through the hole to shadow the wheels by moving the area of exposure. Shadowing can be compared to the use of a borescope or focused light beam that is swept across the active locking components.

Two critical difficulties can be encountered with shadowing. If polymer components are utilized as an obscurant, such as delrin or nylon, the image will be almost impossible to read. Additionally, the use of protective hard plate may block the radiation source. Even if polymer wheels or other patented techniques are not in use, a great deal of skill is required to interpret the image information. It is reported that the Russians have been able to read a delrin wheel pack through digitization and enhancement techniques. Ultrasound and florescent penetrants have also been successfully utilized for covert entry.

31_10.0 Interception of Information Transfer

The newest lock technology involves the transmission, receipt, and validation of a data stream between key and lock. Described elsewhere in this text, these locks utilize keys containing passive transducers that receive, modulate, and echo data back to the host. The technology is now popular in automobiles, access control systems, and certain high-security programmable locks. Depending upon design, shielding, and environment, such data may be intercepted and decoded. Chubb, Medeco, Ford Motor Company, and many others are utilizing this technology.

Other systems utilize both infrared and radio frequency energy to transmit code information to validate the user. RF is easily detected several feet away; IR poses more of a problem. Interception is dependent upon frequency, ambient light, transmission angle, and power. IR systems are in use by Abloy, Marlok, and others.

Proximity sensors that are incorporated within access control and anti-theft inventory systems use passive devices that modulate or modify data and radiate it back to a source. They may also utilize schemes that repeat signals at overtones or multiples of original frequencies. This information can be captured, decoded, and simulated.

32_1.0 Introduction

This chapter surveys methods of destructive entry for locks, enclosures, and premises. Penetration of safes and vaults is covered in **Chapter 35**. The manipulation of safes is detailed in **Chapter 36** as are the methods of covert entry. Integral to our discussion is the characteristics of materials under stress as detailed in **Chapter 5**. The chemistry and physics of metallurgy will determine how a security device can be compromised by force. The focus of this chapter is premised upon the use of tools and techniques by two disparate classes of users: authorized, and criminal. Tools employed by government security services, military units, and rescue services are described. Unfortunately, professional criminals utilize many of the same devices in the business of burglary and espionage.

Whereas the more sophisticated thefts are covert in nature, almost ninety percent of all burglaries are based upon forced-entry. Although this statistic would seem to indicate that the amateur and semi-professional burglar resort to the more basic forms of forced-entry to steal his goods, this is not necessarily the case. There are certain distinctions between the different types of burglars. Generally, they can be described as belonging to one of three categories: amateur, semi-professional, and professional. The semi-pro steals regularly and targets residences and businesses that are easily compromised. The professionals earn their living from thefts. They are knowledgeable about locks and security systems, safes and vaults, and other security hardware. More important to our discussion, the professional can afford the latest tools and technologies. Opportunities are created with such implements. He will look for property of substantial value and assess the difficulty and risks involved.

Destructive entry shall refer to any process that causes any

damage or indication of compromise of a security system, container, or device. Covert and surreptitious entry can be considered the opposite of destructive entry. The United States government in Federal Specification AA-F-358G, issued March 7, 1989, defines **Covert entry** as “a method of entry which would leave evidence, but would not be detectable by a user during normal use, but would be detectable during inspection by a qualified person.” **Surreptitious entry** was further defined as “a method of entry, such as lock manipulation or radiological attack on the combination lock, which would not be detectable during normal use, or during inspection by a qualified person.”

A discussion of covert entry by Harry Sher

A discussion of GSA containers and covert entry, by Harry Sher

A discussion of surreptitious entry and government containers, by Harry Sher

There are many methods by which a lock and anything to which it is attached can be forcibly compromised. Today, a variety of tools, both off-the-shelf and custom, can be utilized to effect entry. This chapter will describe the more specialized tools and techniques rather than to reiterate common attacks. Destructive entry procedures, for our discussion, will be classified in terms of **tools** and their use, the **application of energy**, and **devices** subject to attack. Application of energy means the use of some form of force, energy, or temperature to directly or indirectly displace, distort, bend, break, shear, twist, expand, compress, contract, or move the critical component of a security system, to allow compromise or bypass. **Tools** shall refer to any implement that is employed to effect the compromise of a security system or device. This includes locks, barrier material, enclosures, or perimeter protection. **Devices subject to attack** shall refer to locks, barrier material, enclosures or other thing that protect or secures an entry, area, or enclosure.

32_2.0 Application of Energy or Force

The application of energy to effect the compromise of a security device is dependent upon the design of that device and surrounding materials. It is axiomatic that energy is applied in order to reverse, distort, break, or bypass the fundamental mechanical configuration that makes such designs secure. Materials utilized in locks, safes, and security devices are designed to withstand many different kinds of stresses that can

result in the alteration of molecular structure. Most testing procedures reproduce the stresses associated with different forms of attack and measure a material's resistance to such forces. ASTM, ISO, UL, BSI, and other standards organizations have developed extensive criteria and protocols for such testing. International regimes for certifying locks, security devices, and materials are defined in **Chapter 37**.

32_2.1 Specific Forces

Tools are utilized as the vehicle to deliver and focus energy upon a specific target. The fundamental forms of force and stress, applied through direct or indirect means, include:

- **Shearing, cutting, and chopping requires the application of pressure to the material between two edges, much like a scissors. Drilling is included within the definition. Example: padlock shackles may be cut when two shearing blades are positioned within a tensile loading device having a compression load capability;**

- **Tension, stretching, or pulling. This technique requires that the component be stressed past its tensile strength. In the case of cylinders, the plug is forcibly withdrawn. Padlocks are especially vulnerable to forms of attack that create such stress;**

- **Torsion or twisting generally requires that a blade type tool be inserted into the keyway until the lock opens;**

- **Opposing forces applied simultaneously include Prying, Bending Ripping, and Wedging;**

- **Compression requires pressure to be applied to a material in order to weaken or sever it;**

- **Breaking will cause an alteration or fracturing of a material through the application of temperature or some sort of force;**

- **Impact or blows, including dropping. Explosives or shock is applied to the device. The weight of the security device can also be exploited when dropped on its face or sides;**
- **Temperature extremes can be utilized to alter the molecular structure of a material. High temperatures can be generated by a thermic lance, torch, electric arc welder, lasers, and chemicals. Super-cooling agents such as freon and liquid nitrogen are utilized to freeze materials;**
- **Acids and other chemicals can be applied to virtually any material to dissolve, disintegrate, or destroy the molecular structure.**

32_2.2 The Results of the Application of Force

Force and energy are applied to a material to secure a specific change in structure. This will be dependent upon the mechanical design of the security device, metallurgy, and security rating. The desired result will ultimately include one or more alterations:

- **Displacement of components;**
- **Vaporization, disintegration, burning, or melting;**
- **Shattering, brittleness, or loss of temper;**
- **Breaking;**
- **Movement of components;**
- **Distortion, warping, bending, or alteration;**
- **Expansion;**
- **Change in molecular structure.**

32_2.2.1 Displacement of Components

Locks may be attacked in an effort to displace internal components. For example, a pin tumbler mechanism may be drilled at shear line in order to move and destroy pins so that the plug is free to rotate.

32_2.2.2 Vaporization, Burning, or Melting

Heat can be utilized to melt, soften, or vaporize barrier materials. Torches and thermic lances will generate sufficient temperatures to destroy the molecular structure of any material.

32_2.2.3 Shattering, Brittleness, or Loss of Temper

Extreme heat and cold can be utilized to alter the properties of a given material in order to cause brittleness or loss of temper. If a metal is superheated then rapidly cooled, it can be fractured or shattered. A common technique when penetrating hardplate is to drill until the material is red-hot, then repeatedly strike the metal with a sharp punch to break or fracture the surface. This provides a place for the tip of the drill bit to engage.

A similar procedure was utilized to forcibly enter the old cannonball safe. The circumference of the door was superheated around the outer groove. Cold water was then poured on the hot metal, which would cause it to harden. A special hatchet was then pushed into the channel. Repeated blows to the hatchet would be struck with a heavy hammer as it was moved completely around the door until it broke open.

32_2.2.4 Breaking

Creating sufficient stress on barrier or supporting materials to cause fracture may break critical components.

32_2.2.5 Movement of Components

Active locking components may be physically moved by certain procedures involving the application of energy or force.

32_2.2.6 Distortion, Warping, Bending, or Alteration

Distorting, warping, bending, or altering the mechanical configuration of active components may compromise locks or security devices. Perhaps the simplest example is the spreading of an aluminum door frame in order to provide clearance between the strike and strike plate.

32_2.2.7 Expansion

The expansion of materials may provide sufficient clearance to access active locking elements and to bypass their proper operation.

32_2.2.8 Change in Molecular Structure

A change in molecular structure can sufficiently weaken the barrier material so that it no longer presents an obstacle to bypass. Chemicals, heat, cold, electric charge, and induced energy may all effect such a change.

32_3.0 Tools

LSS201: Forced entry tools produced by Sigma. Courtesy of Ian Bauchop.

The definition of a "tool", in the context of destructive or forced-entry, is often elusive because many common implements can be used for such purposes. Burglars are quite adaptable and inventive in such regard. Our discussion shall examine and survey those tools that have been designed to apply different kinds of force described in the previous section. There are many tools specifically produced for locksmiths, military, and law enforcement in order to effect a forced-entry. Others, which are commercially available to the consumer, may be readily adapted to such tasks.

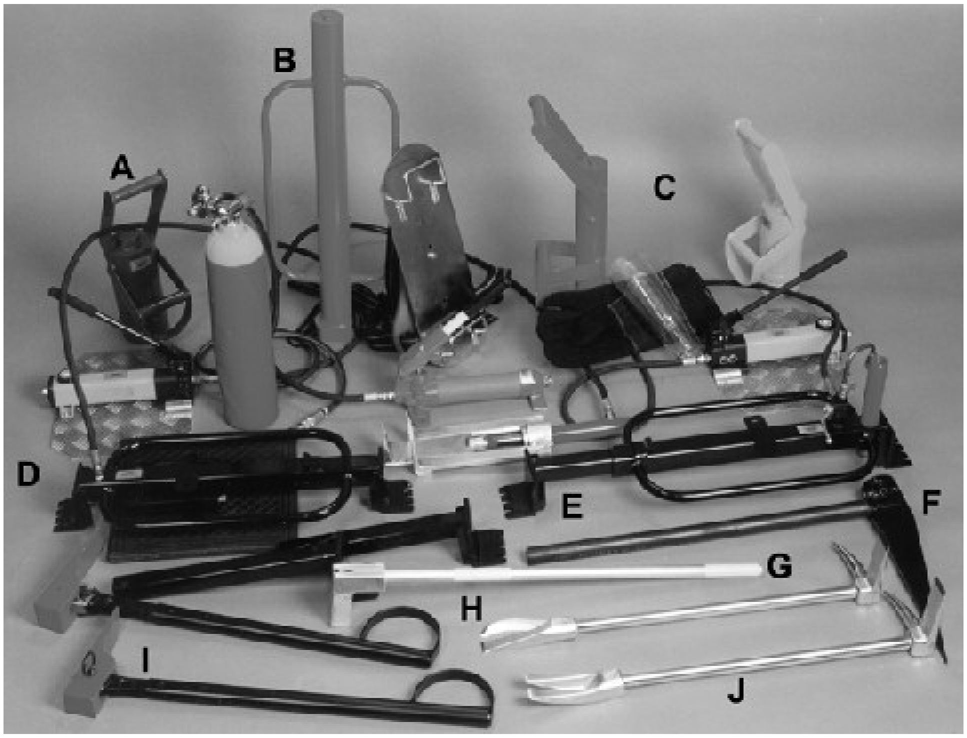

Figure LSS+3224 A sigma forced entry team shows the technique for breaching a door.

Many tools are utilized to forcibly enter or bypass a lock or security device. The more common of these include:

- **Bolt cutters;**
- **Channel-lock pliers;**
- **Chisel;**
- **Crowbar;**
- **Cylinder wrench;**
- **Disc cutters;**
- **Drill-rigs, including vacuum, magnetic, and snap-on;**
- **Drills;**
- **Drills made or coated with carbon, chromium, tungsten, and carbides;**
- **Duckbill tool;**
- **Grinding wheels and grinders;**
- **Hole-saws;**
- **Jamb-spreader;**
- **Jimmies in various lengths;**
- **K-Tool;**
- **Laser-cutter;**
- **Levers;**
- **Nail-puller;**
- **Piercer;**
- **Pry bar;**
- **Punches, ice pick, chisel, awl;**
- **Pulling-tools, including slam-hammers, dent pullers, and nose-pullers;**
- **Sledgehammer and dead-hammer;**
- **Wedges;**
- **Wrenches, including plumbers wrench.**

A destructive entry tool or device will act upon materials in different ways, depending upon its design and the resultant concentration of energy. The following discussion will detail the various methods that a tool or process employs to compromise the security of a device or enclosure.

Figure LSS+3231, an attack on a file cabinet safe with a variety of tools.

32_3.1 Shearing or Cutting

One of the favored modes of entry is to shear or cut the barrier or protective material. Shearing and cutting of materials can be accomplished in many ways to include:

- **Drilling**
-

- Cutting
- Sawing
- Filing
- Grinding

Tools that are capable of shearing or cutting generally require the application of pressure between two edges, simulating the action of a scissors. Drills are included within the definition because they perform their task by cutting.

32_3.1.1 Drilling

Drilling is probably the quickest and most effective way to compromise a security device. A thorough explanation of how a drill cuts metal is presented in **Chapter 5**. The use of drills to penetrate barrier materials in safes is described in **Chapter 35.** A drill is an extremely complex cutting device that requires precision design in order to work properly. They are engineered

to cut various materials based upon hardness rating. In order to penetrate hardplate and specially designed barriers, drills must be capable of operating at extremely high temperatures and pressure. They are made from or contain carbon steel, cobalt, chromium, tungsten, and diamond. Historically, locks, locking devices, and related mechanisms have been protected from drilling by the use of various barrier materials and other techniques. These include:

- **Layers or laminations of steel plates, or iron laced with hard studs to snap drill tips;**
- **Free-rotating hardened discs;**
- **Case-hardened plate;**
- **Insertion of beryllium and copper plates to act as a heat sink. Drilling is frustrated because heat must be generated at the drill tip in order to penetrate hard metals. Heat sinks quickly draw high temperatures away.**

The first drills that were capable of penetrating dense materials were invented at the end of the nineteenth century and were designed to function when red-hot. Since their introduction, a tremendous amount of engineering has produced improvements in metallurgy, speed, pressures, operating temperatures, and ability to cut different materials.

The **core drill** was popular for a brief period and was used in both the construction industry and by safe technicians. It was originally designed to make large holes through concrete. The drill bit was actually a tube, measuring from one to nine inches in diameter, with diamond or carbon chips embedded around the rim. The water or air-cooled tube was attached to an electric drill motor and operated at high speeds. Standard **high-speed drills** tipped with special materials are utilized to make precise holes in safes and lever locks. They are equally useful in the neutralization of pin tumbler locks, by creating a new shear line or allowing removal of the plug.

32_3.1.1.1 Drilling Pin Tumbler Cylinders

Situations dictate that a cylinder must be drilled when picking or impressioning is not possible. Several techniques are available for compromising a cylinder by drilling.

32_3.1.1.1.1 Rotary Pick

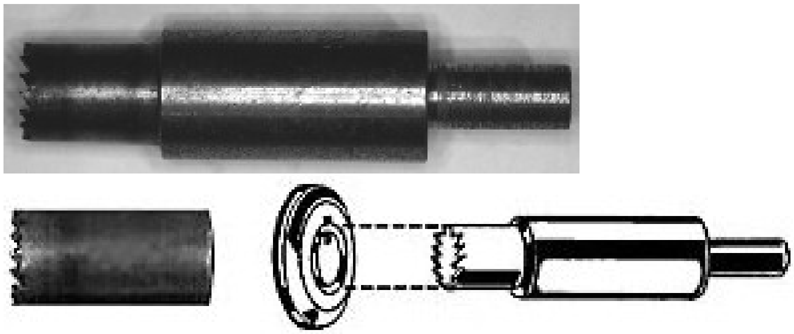

Figure LSS+3243 HPC produces a hole saw specifically designed for cylinders and axial locks.

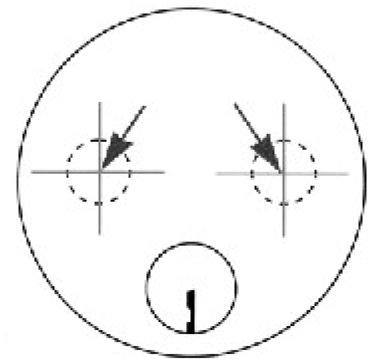

Figure LSS+3232 (ISP 35-3529)
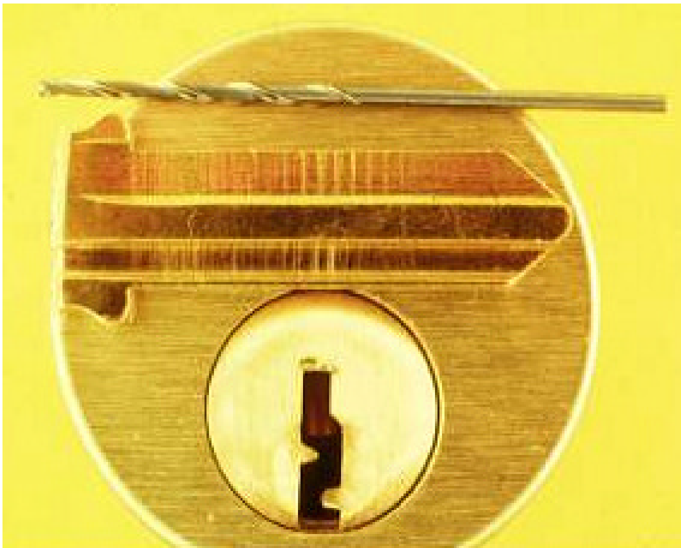
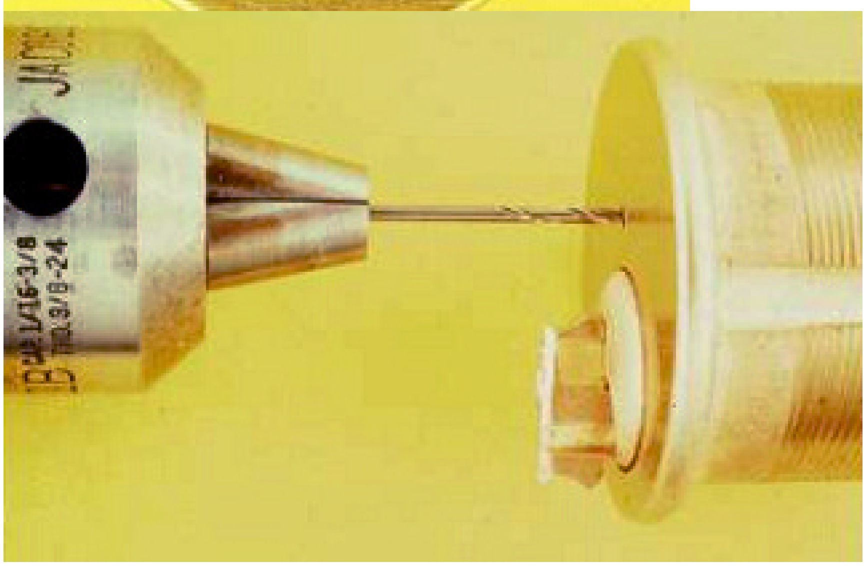
A hole saw can be used to ream out the entire plug.

Referred to as a rotary pick, a large drill bit can destroy an entire plug. The drill is almost the same diameter as the plug and is utilized as a reamer to remove all metal that blocks rotation of the cam.

32_3.1.1.1.2 Retaining Screws



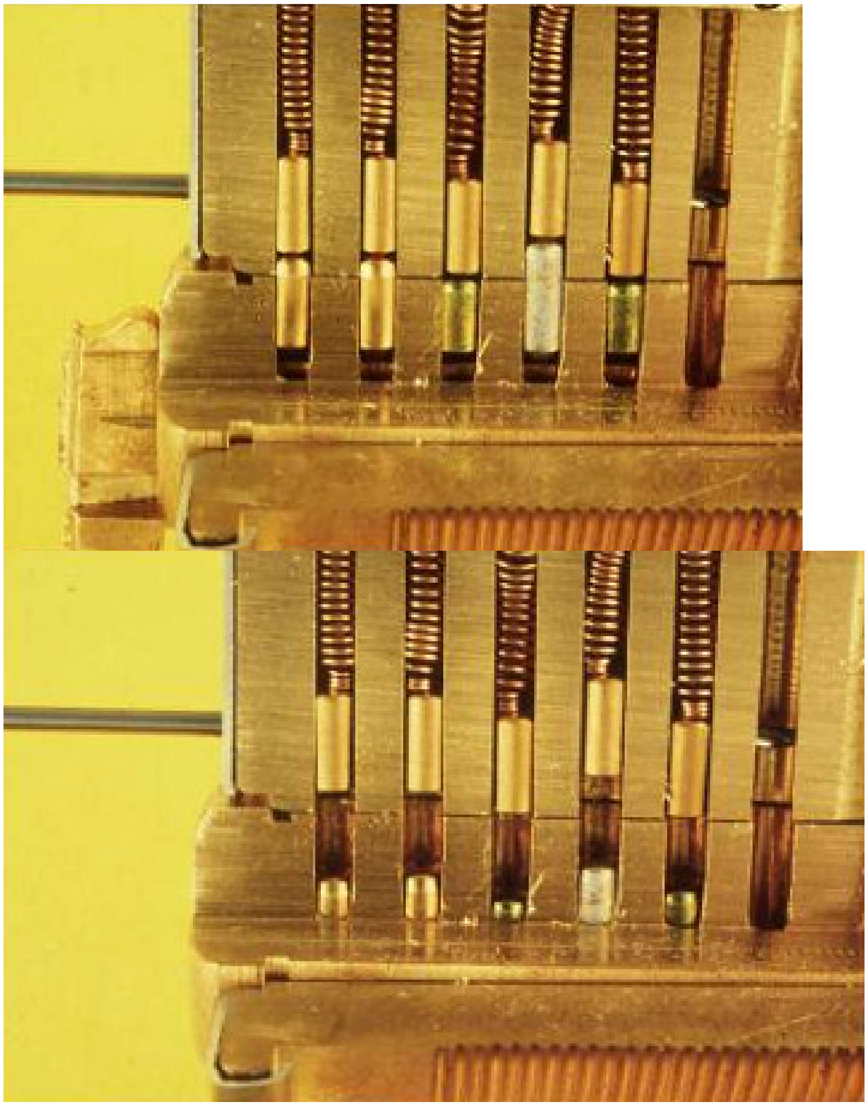
Cylinder drilling jigs are available that are designed to fit over a fully inserted key blank. The retaining screws on rim cylinders can be drilled; the cylinder is simply rotated counterclockwise and removed. Holes can also be made above and below some cylinders to allow manipulation of the bolt works.

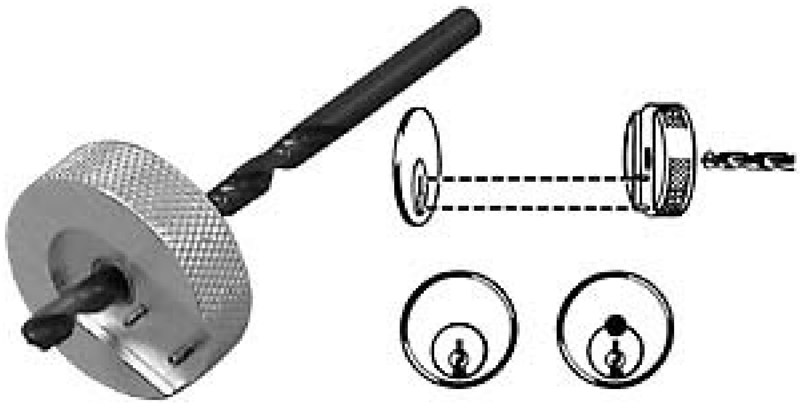


32_3.1.1.1.3 Shear Line

There are three primary means for drilling a cylinder in order to effect bypass.
Using a 3/16” or smaller bit, the face of the cylinder is penetrated immediately below the top of the plug. The bit is placed above the centerline of the keyway, as shown in the photograph below and even with the circumference of the plug to create a new shear line. The bit must be run across all pin chambers.

Another variation of this procedures requires that a key blank be inserted prior to drilling in order to engage all of the lower pins, and raise them to their highest point in the plug. This will engage all of the driver pins, placing them above the plug, or at shear line. A drill is then inserted just above shear line, which will create a new break point, by virtue of splitting each of the drivers. Once the cylinder has been penetrated and all pins have been cut, the key is removed. The plug is then rotated.





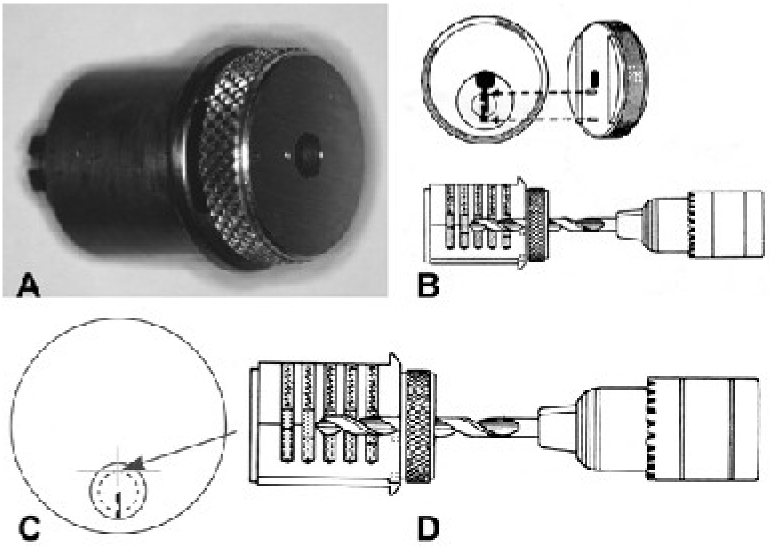


Figure LSS+3244 A blank key is inserted prior to drilling in order to raise all drivers to a position at or above shear line. Then a drill bit is run across all chambers. The blank is removed and the pins allowed to fall into the lower chamber, The plug can then be turned. Courtesy of Medeco.

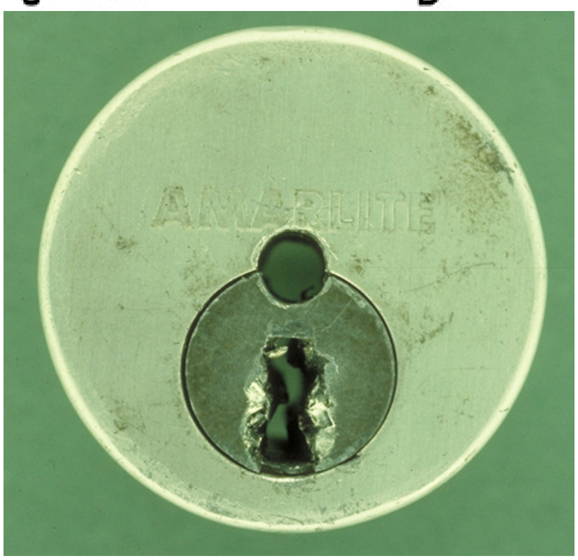
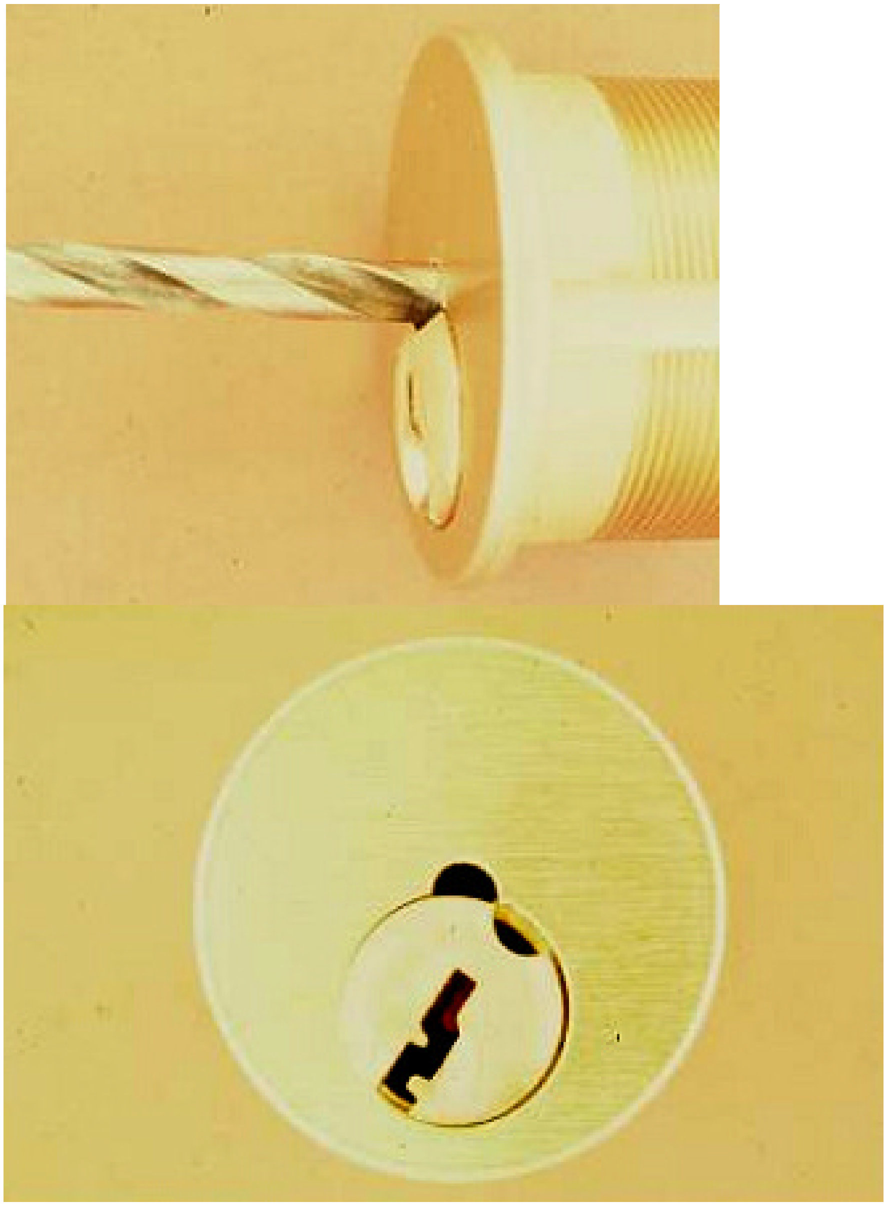


Another technique requires a very fine hole to be drilled precisely at shear line, just to the first pin chamber. A shim is inserted and fed through each break point between pins, as they are raised with a pick. This is the exact reverse procedure that is described elsewhere in this text for shimming open a lock from the rear of the plug.

A
B
C
D



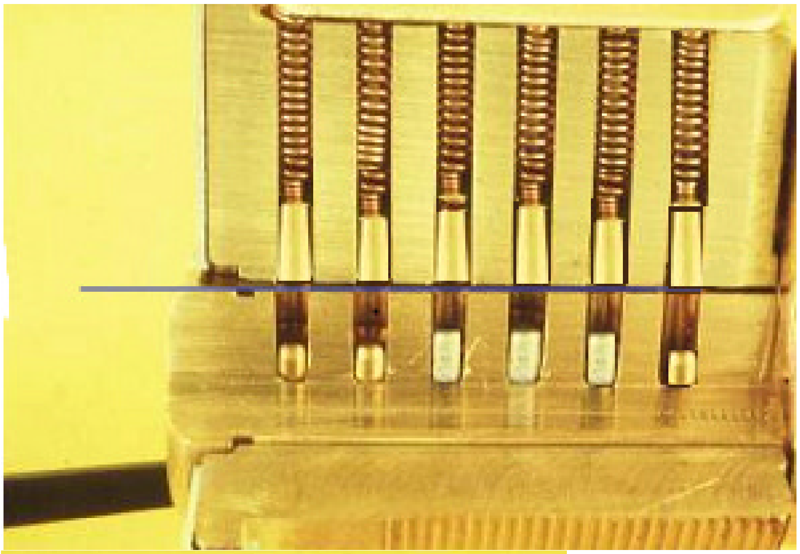


Figure LSS+3245 A lock can be drilled to create a new shear line. Courtesy of Medeco.

Figure LSS+3233 (ISP 33-3529 center, 34-3529 right). A new shear line is created by drilling the plug. A shim is inserted through a small hole drilled at shear line to the first pin chamber. The blue line indicates the shim, showing how the drivers are split from the lower pins, thereby allowing the plug to rotate. In such attacks, the hole may be repaired and an examination of the internal plug may be required. A pick (shown lower left) is utilized to raise each of the pins from front to back.

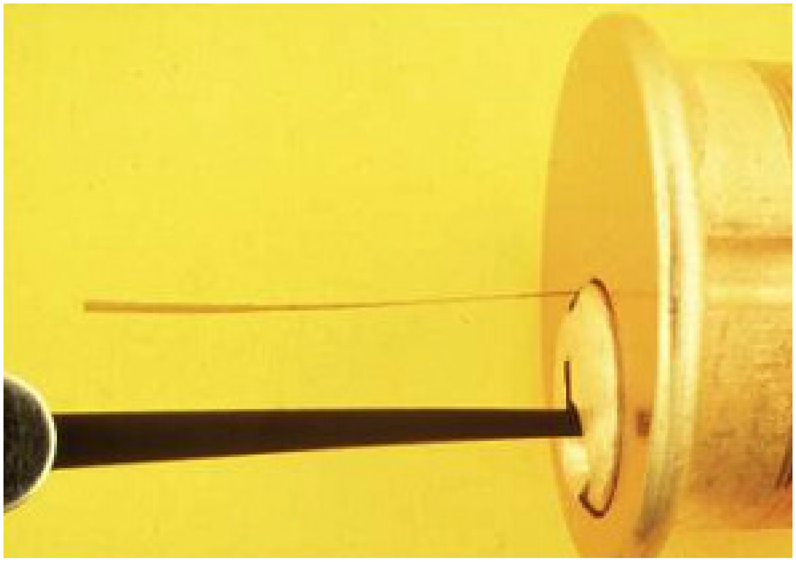

Figure LSS+3246 A lock can be drilled and then shimmed. Courtesy of Medeco.

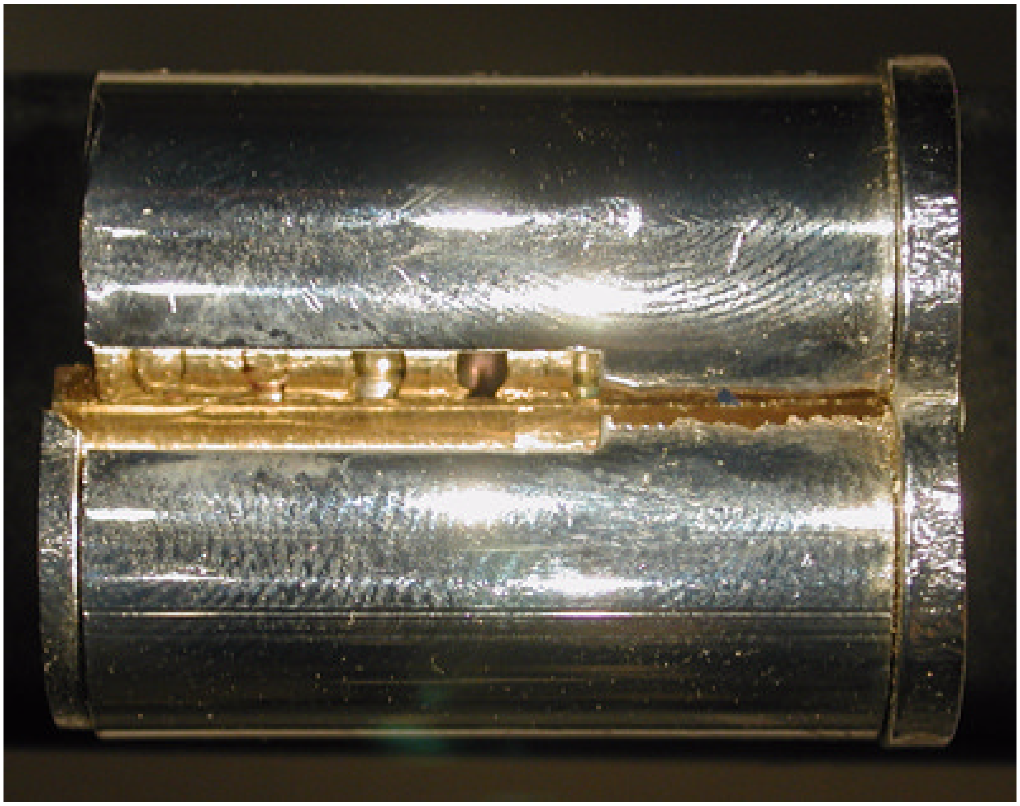
The **HPC CDJ-1** is a tool to drill pin tumbler cylinders. The bit is maintained perpendicular to the face of the lock while drilling. As much of the broken pins and springs are removed as possible, then a screwdriver is utilized to rotate the cam. Other drills have been designed for opening axial pin tumbler locks, although they should not be used if the mechanism contains hardened pins or ball bearings in the keyway.

A patent was granted to Watts in 1999 for a technique involving raising all lower pins within a lock, then drilling of the plug (**5987946(355)**). A similar patent was issued to Randall in 2000 for a technique to open padlocks through the use of a drill (**6151936(356)**). A similar patent was granted to Smith in 1998 (**5713225(357)**).

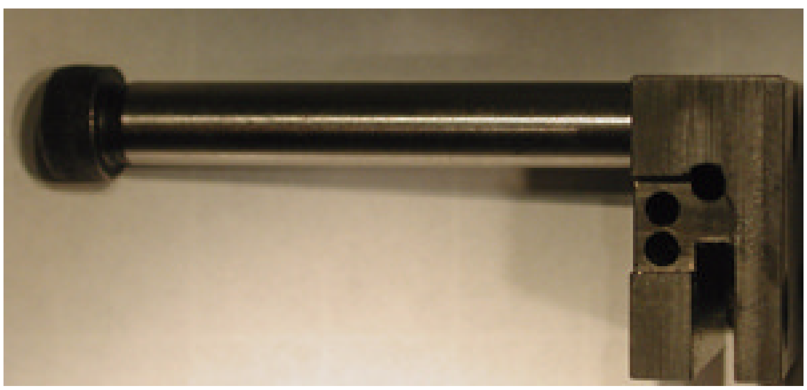


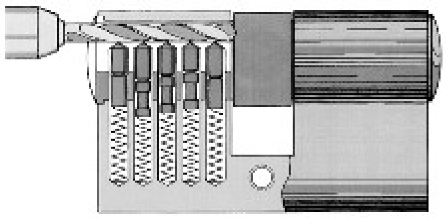
European profile locks are drilled at the bottom of the cylinder in order to destroy the pins at the shear line. Many of these locks incorporate hard pins and bearings to protect from this form of attack.

32_3.1.1.1.3.1 Removable Core Locks: Drilling the Control Lug

Peterson Manufacturing(358) produces a unique drill jig (IC-DJ) for removing the control lug from interchangeabe core locks. This procedure allows removal of the core without any damage to the shell. As shown in the photographs, the jig is utilized with a

key that acts as a guide for the drill points. All small format cores can be drilled.





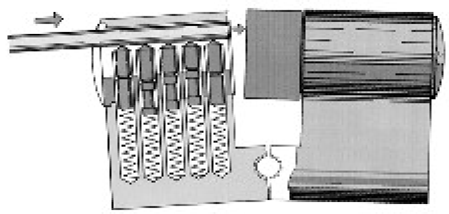


Figure LSS+3247 Peterson Manufacturing IC removal tool

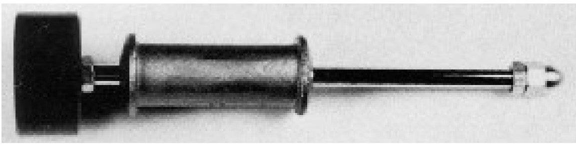
32_3.1.1.1.4 Drilling to Break Apart the Lock

Profile cylinders can be drilled above the pins in order that a piercer or rod can be inserted. Their purpose is to exert force sufficient to shear the thin metal that connects the inner and outer cylinders. It is then a simple matter to move the inside lock out of the way. A two-piece breaker kit is available for removing plugs. The kit consists of a drill guide and hardened



bit, together with a special handle. The plug is first drilled, then the cylinder is twisted and removed.

32_3.1.1.1.5 Dent-Puller or Slam Hammer

Cylinders are often drilled in order to insert a metal screw into the keyway. A slam-hammer, dent-puller, or other device is then utilized to violently withdraw the plug.

32_3.1.1.1.6 Hinge Screws and Pins

Hinge screws are often drilled as a common practice for entry to safe-deposit boxes.

32_3.1.1.1.7 Viewing Lever and Wheel Pack

Templates are available for many lever and combination locks to show precisely where to drill. This will provide a view of levers or tumblers, the location of relockers, and bolt works.

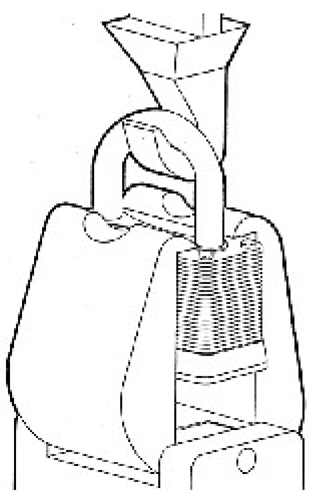
32_3.1.2 Cutting, Sawing, and Grinding

The operations of cutting and sawing utilize the same implements. A wide array of tools are available, both commercially and for the consumer. In addition, torches may be successfully employed as cutting devices.

32_3.1.2.1 Disc Cutter

The **disc cutter** is an extremely simple yet effective hand-carried device for penetrating almost any material. Abrasive grinding disks up to a foot or more in diameter are rotated at high speed

and engaged against the barrier material with pressure.

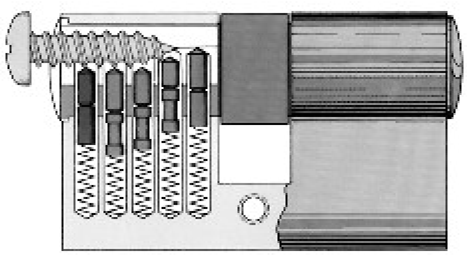


32_3.1.2.2 Laser and Water Cutters

Laser and water cutting tools are available that can sever many different materials. Lasers utilize focused coherent light beams to create extremely high temperatures in a very small area. Power consumption requirements limit the ability to produce a portable laser cutter. However, many manufacturers utilize industrial lasers to obtain .005" or better tolerance between doors and bodies of safes and vaults.

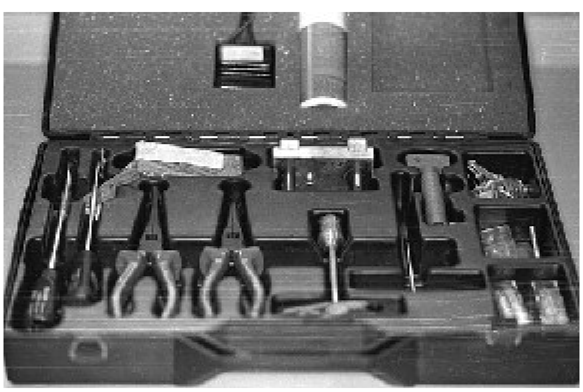
Water jets can also be successfully utilized to cut and penetrate metals. Essentially an abrasive process, a finely focused stream of water is directed in a cutting path.

32_3.2 Tension, Stretching, or Pulling

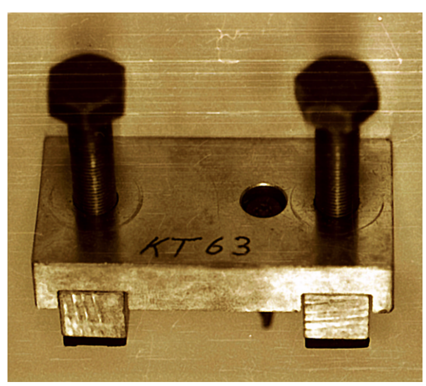


There are many techniques to pull cylinders and plugs from their housing. All rely upon the application of force that will overcome the tensile strength of the core materials. In the case of a pin tumbler cylinder, the pins must be sheared or the surrounding material must fail under stress in order for a plug to be released.

Extreme pulling force applied to a mortise cylinder may result in the shearing of retaining screws or stripping of threading on the lock body. Profile cylinders can be forcibly removed by breaking loose the retaining screw that holds the assembly within the security housing. The following tools and techniques are the most popular and direct methods for removing plugs and cylinders.



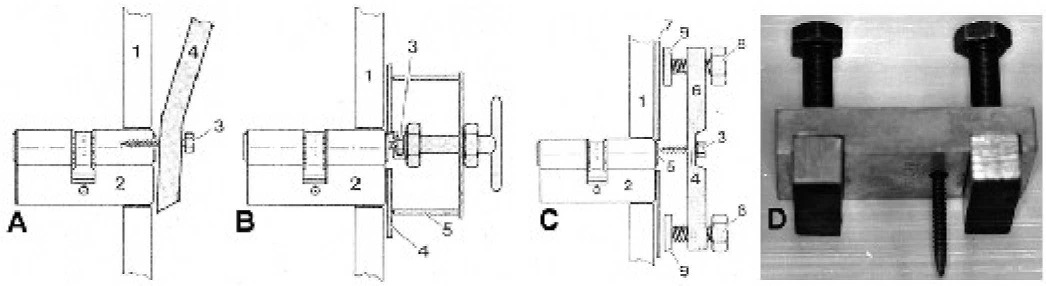
32_3.2.1 Nail-Puller

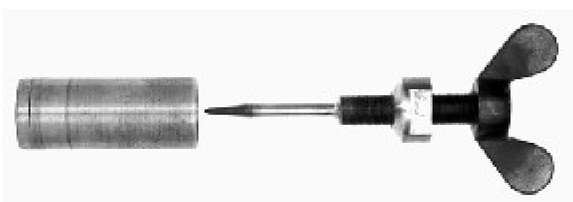


A plug within a cylinder or a profile lock can be torn loose without difficulty, if a metal screw is seated into the keyway and then withdrawn with sufficient force. A **nail puller** will provide sufficient leverage to remove the entire cylinder. In practice, a metal screw is first tapped into the keyway. A nail puller is then locked into place with the head of the screw, and located against the door frame. A block of wood may be utilized for additional leverage. Counterforce is then applied to rip the lock from its housing.

32_3.2.2 Dent-Puller

A dent-puller or nose-puller relies upon a similar operating principle to the slam-hammer, but accomplishes its task in a very different fashion. These devices, available from HPC, MBA, Lockmasters, and other vendors, provide a means to remove plugs, cylinders, and safe-deposit doors.

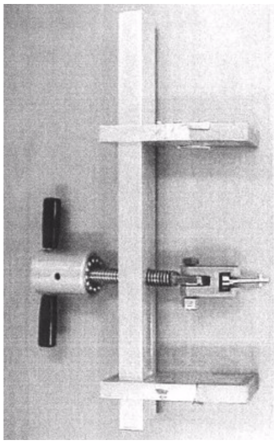




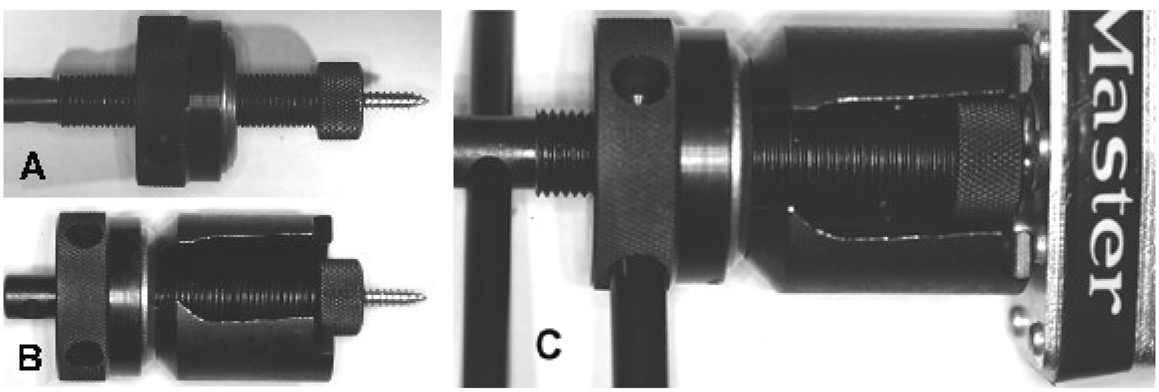
Exploded view 1, 2 3.

The underlying theory of operation relies upon the exertion of a pulling force that will exceed the tensile strength of the material to which it is attached. Like the slam hammer, the dent

puller requires that a metal screw be tapped into the target device. However, unlike the slam- hammer, slow and steady force is applied to accomplish removal, rather than a violent shock



All of the dent and nose-pullers utilize a long threaded shaft that is isolated from the target with a block spacer. The active end of the device is attached to the target and a counterforce is applied by advancing a collar on the threaded shaft. As the collar is moved forward, the screw will be withdrawn an equal distance.



32_3.2.2.1 Safe-Deposit Nose and Door Removal

One of the primary uses of the nose-puller is to open safe-deposit boxes. Thus, a more thorough discussion of the practice is presented here. In the above photographs, over one hundred safe deposit boxes were opened in a successful burglary at the diamond exchange in Antwerp, Belgium. A tool was designed to be inserted into the lever lock portion of the door. The jig was then tightened against the supporting frame, causing the bolt to be warped to allow the box to open. The burglary, which occurred in February, 2003, netted seven thieves more than $100,000,000.

Nose pullers are typically used to open safe-deposit locks where the renter's key has been lost. Generally, a blank key is placed in the keyway to keep the nose from spinning, while a hole is made for a 10-32 machine screw, grade 5 or grade 8. If this is not possible, then a 1/8" hole is made to accept a #8 stainless steel sheet metal screw.

Once the screw is anchored firmly, the spacer block is attached, and the entire assembly tightened. The shaft is then slowly

retracted to extract the nose. Once access to the levers is obtained, they can be manipulated into alignment in order to withdraw the bolt. In certain cases, the door must also be pulled. Depending upon the design of the tool, one or more contact points will present pressure against the inside of the door, where the nose was originally positioned.

The use of the nose puller, courtesy of Harry Sher.

32_3.3 Pounding, Driving, Prying, Fracturing

Poorly designed hardware is subject to a variety of attacks from pounding, driving, prying, and fracturing components through the application of force. The photographs below demonstrate a number of weaknesses of much of the locking hardware in use today.

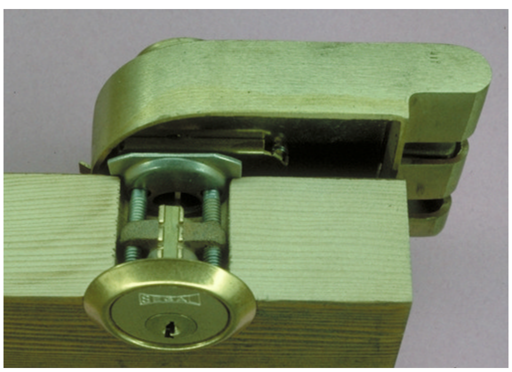


Figure LSS+3234 (ISP 14-3529 left, 15 right) The mounting for the cylinder is cast and

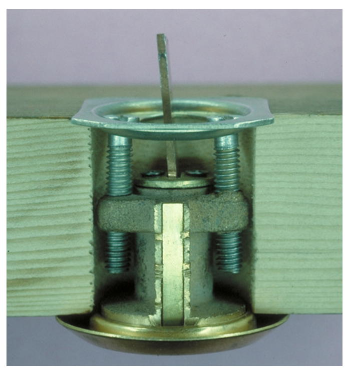

can be fractured, allowing removal of the lock.

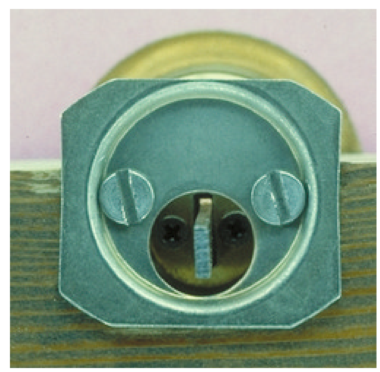

Figure LSS+3235 (ISP 16-3529 left, 17 right) Knob locks should not be used as the sole protection on exterior doors.

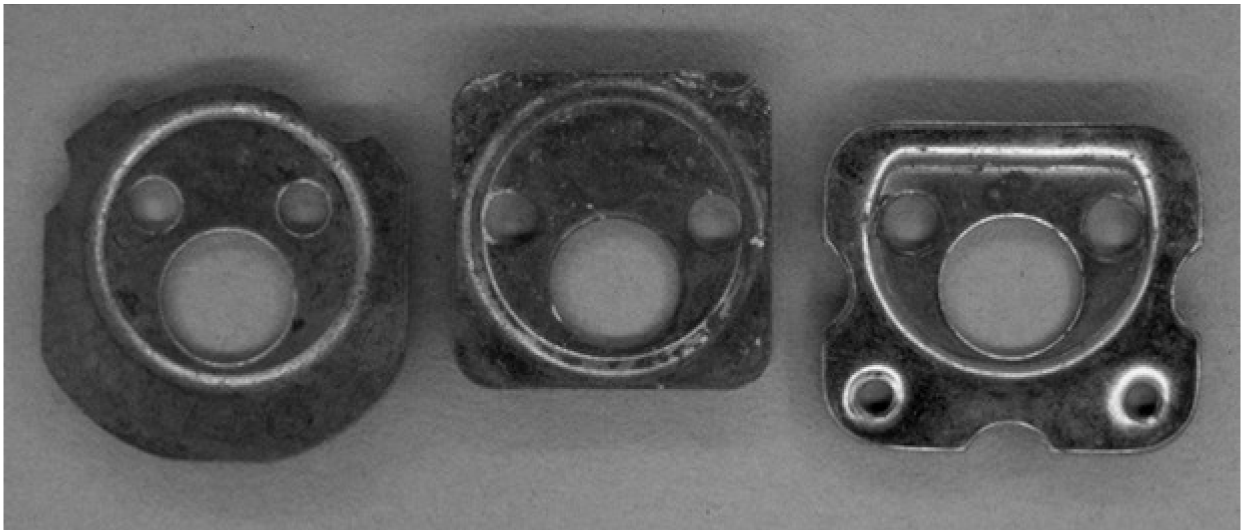

Figure LSS+3236 (ISP 22-3529 top left, 23 center, 24 right, 25 bottom). Rim locks must be mounted properly to increase their resistance to attack.

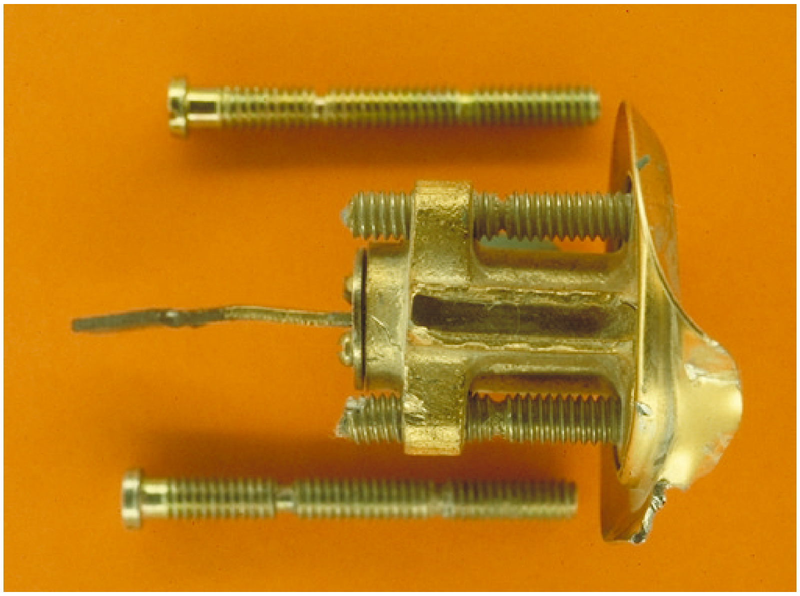

Figure LSS+3237 (ISP 26-3529 left, 27 right). Cylinders can be pried loose if not mounted properly.

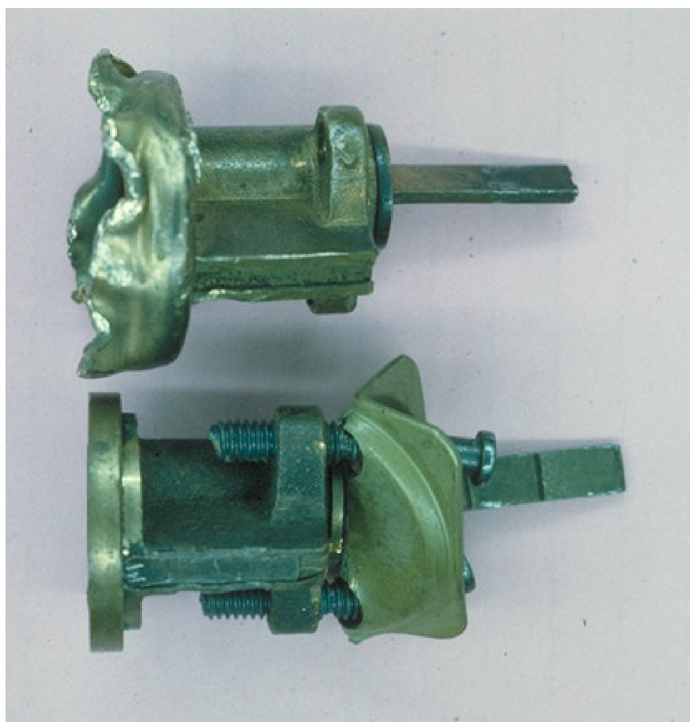

Figure LSS+3238 (ISP 28-3529 left, 29 right). In 28, the cylinder was

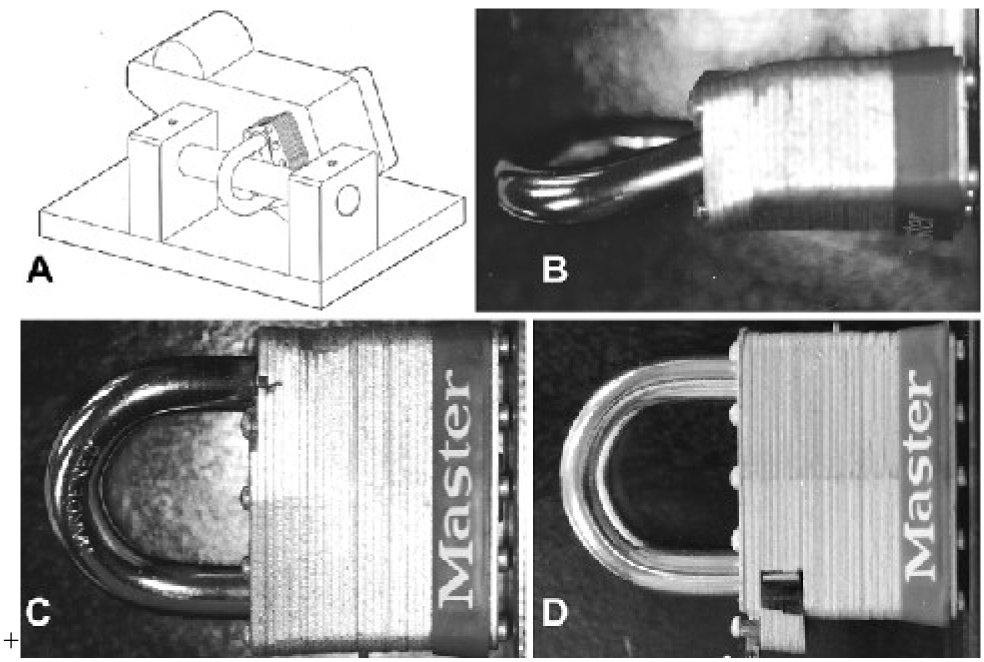

pounded through the mounting. In 29, another example of driving the cylinder through the door.

32_3.4 Bending

If a material can be repeatedly bent, it can be fatigued and fractured. Depending upon the design of the security device, it may be possible to bend or distort a locking component to allow bypass. Metal door frames are a classic example of bending to allow the bolt to pass. The design of most frames will cause the material to return to its original condition after the pressure is released.

32_3.5 Torsion or Twisting

Depending upon the physical design of a lock, locking mechanism, or housing, torsion or twisting force can be applied to break it.

32_3.5.1 Chain Wrench

A plumbers tool is quite effective in removing locks and doorknobs. Leverage is provided by a chain, linked to a mechanism that holds a pipe. In operation, it is placed around the lock and torque is applied. The chains will self-tighten and will shear the lock from its housing or anchor.

Another form of this tool can be made to remove guard rings from cylinder locks. A piece of pipe having a diameter just large enough to fit over the guard ring and cylinder is tightened with a bolt through its center. A rod is utilized to twist the end, thereby providing sufficient leverage to release the lock.

32_3.5.2 Wrench

Figure LSS+3239 (ISP 18-3529 left, 20 center, 21 right). A pipe wrench can be utilized to twist loose a key-in-knob or cylinder lock.

Flush-mounted guard rings are utilized to protect cylinders from being grabbed. Without them, a channel lock pliers, cylinder wrench, or a pipe wrench may be used to free a cylinder from its housing, once a foothold can be gained. These tools will generally adjust themselves to the lock; the cylinder is then twisted and turned. The result: setscrews will be sheared or broken, or the cylinder is ripped out of the jamb.

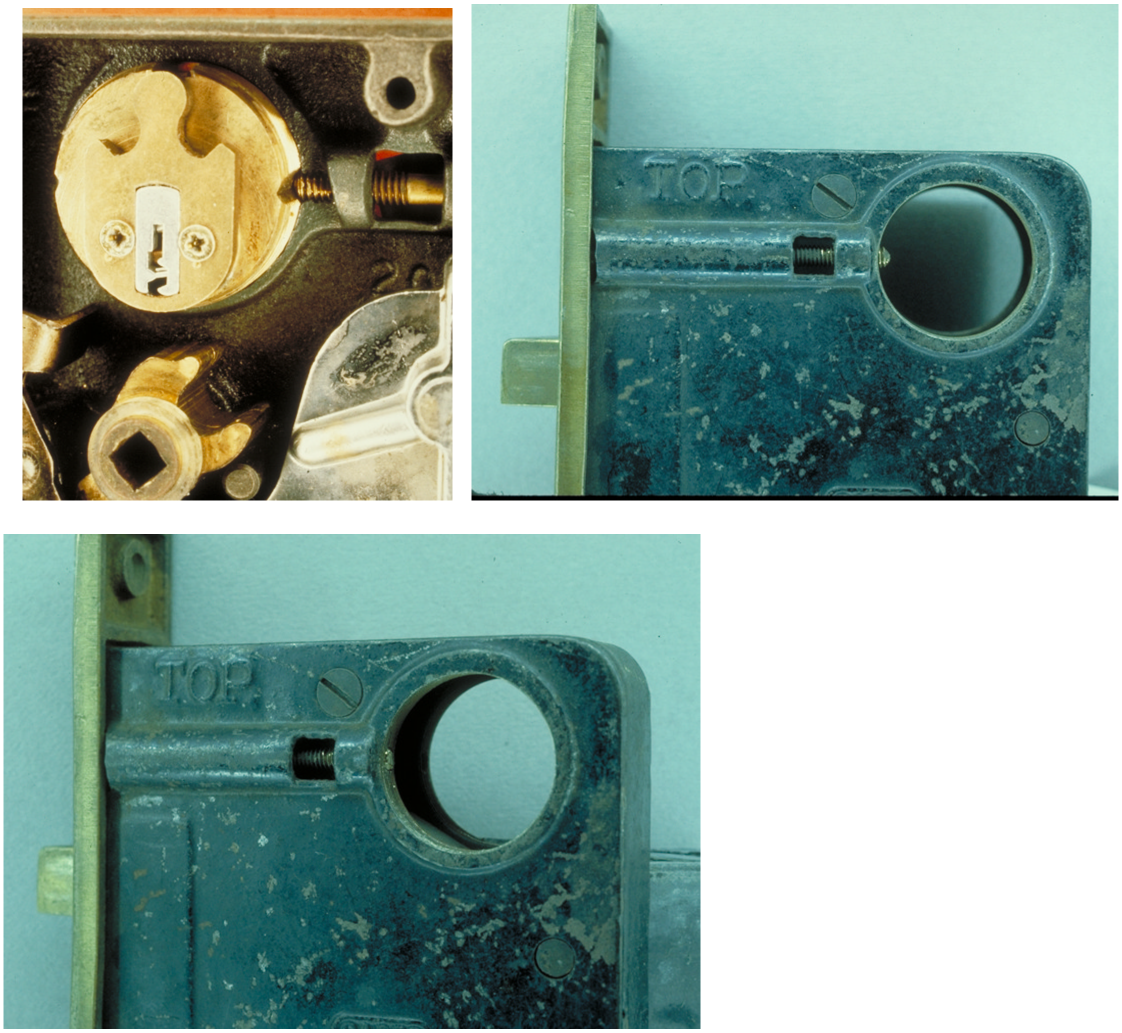

Figure LSS+3240 (ISP 11-3529 left, 12-3529 center, 13-3529 right). These series of photographs show the ease by which a cylinder can be removed by shearing the setscrew. There is little security in this arrangement. Courtesy of Illinois State Police, Bill Sherlock.

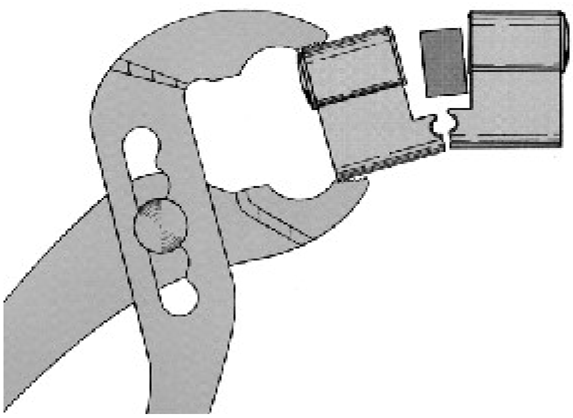
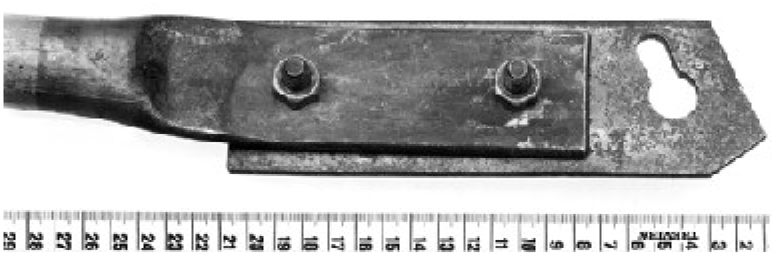
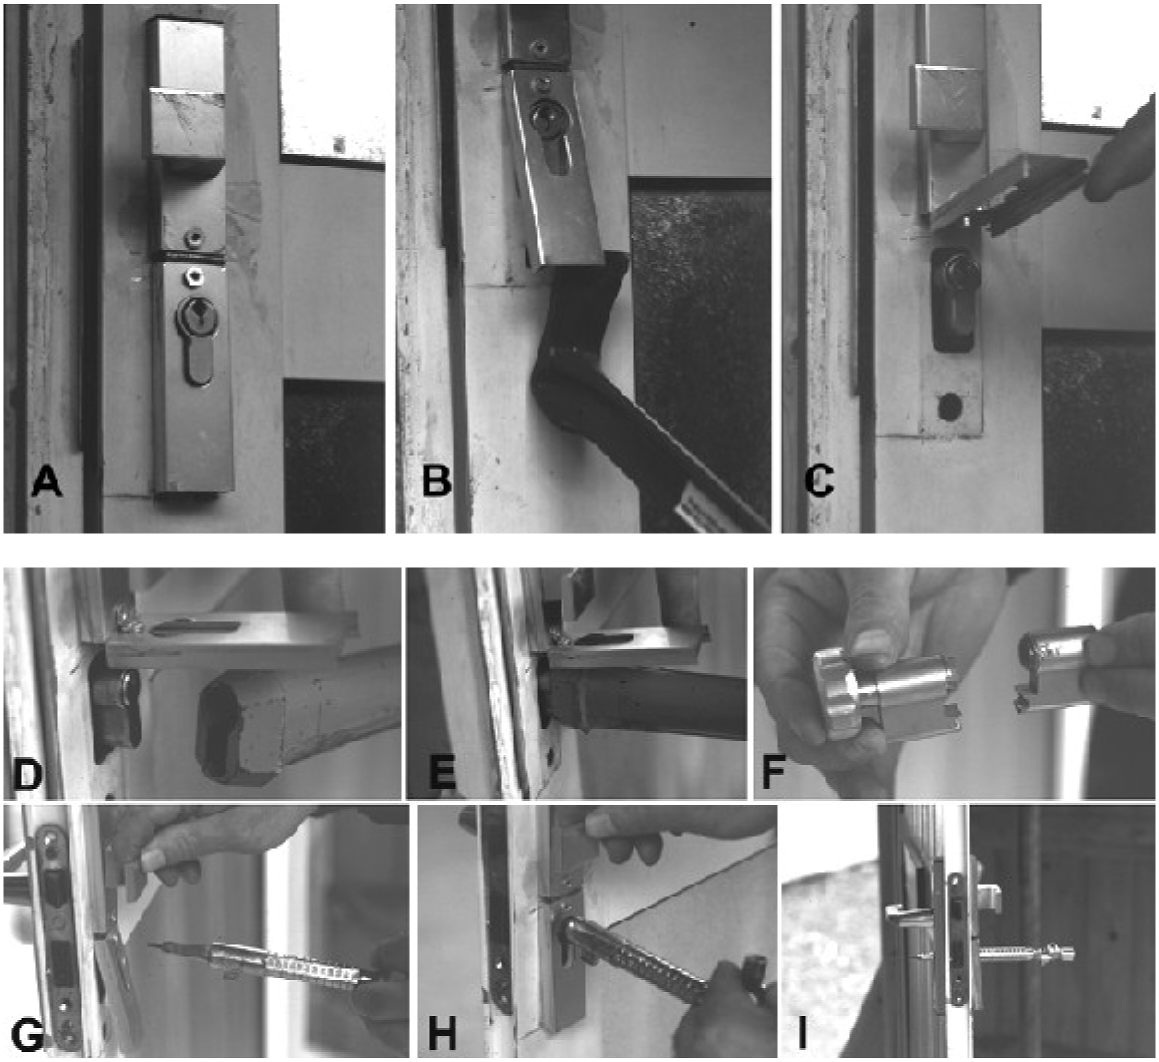
Cylinders can be forcibly removed by applying torque and destroying internal setscrews. The setscrews can also be removed during business hours to allow the cylinder to be unscrewed at a later time. Courtesy of Don Shiles.



A wrench attack on cylinders can be very effective. Courtesy of Don Shiles.



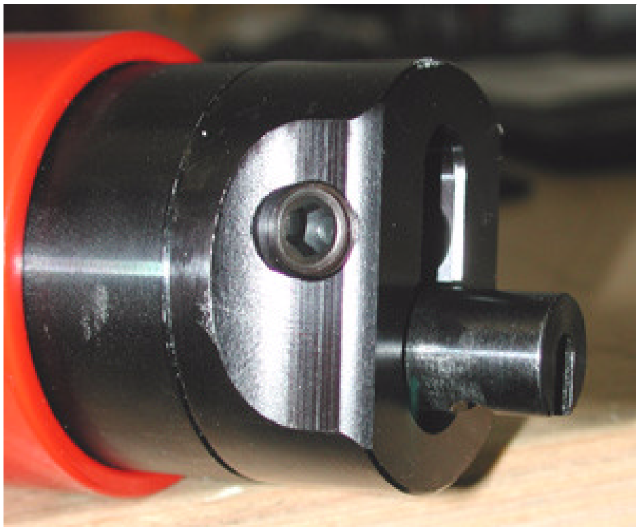
It is quite easy to wrench free a profile cylinder lock that protrudes from its housing. Once the outside half of the



assembly has been removed, the bolt can be withdrawn with a wire hook, screwdriver, or other tool.

32_3.5.3 Profile Cylinder Removal Tool

Unless properly protected, a profile cylinder can be easily dislodged using a tool designed to provide torque or twisting force. This form of attack may be prevented by first cutting a groove into the cylinder, then installing a 2 mm thick hardened metal plate. Several companies produce tools for removing profile cylinders. Tools produced by Sigma (UK) and MSC (Germany) are shown below, together with demonstrations of their effectiveness. The tool that is produced by MSC is a multipurpose device, and can be utilized on a variety of lock configurations. It also allows the forced removal of the core.



Exploded views 1, 2, 3.

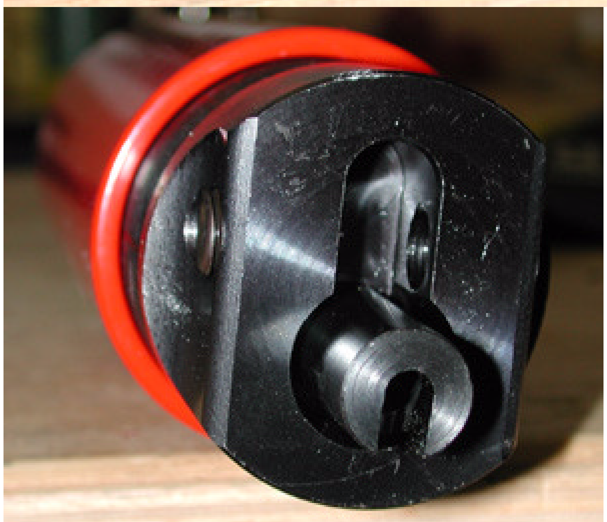


Figure LSS+3225 The MSC Lock Force tool can be used to remove profile cylinders from their housing.

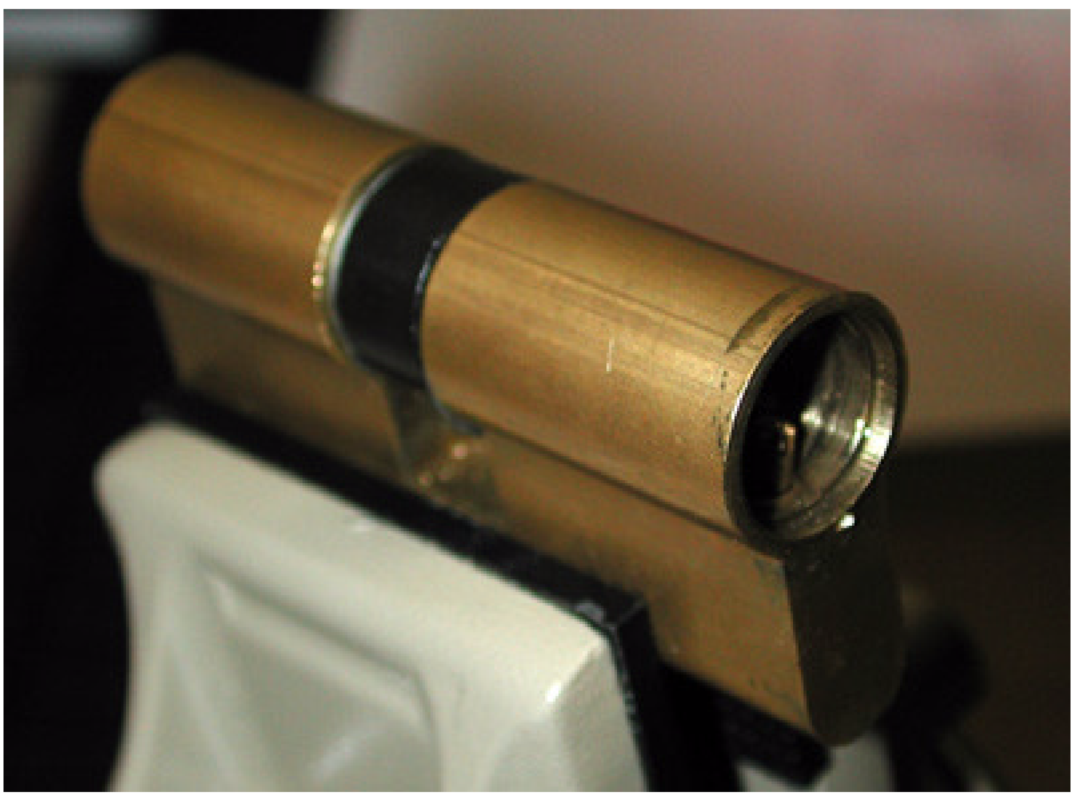
Figure LSS+3226 MSC provides different dies to allow the Lock Force tool to be applied to different cylinder designs.

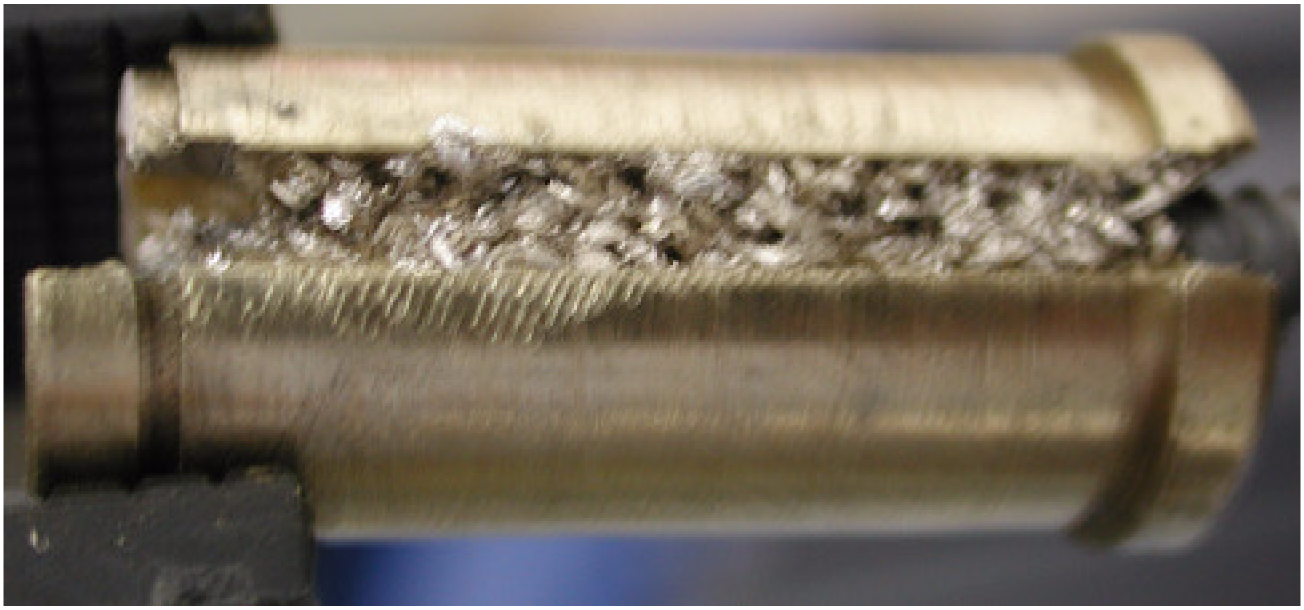
32_3.5.4 Core Removal Tool

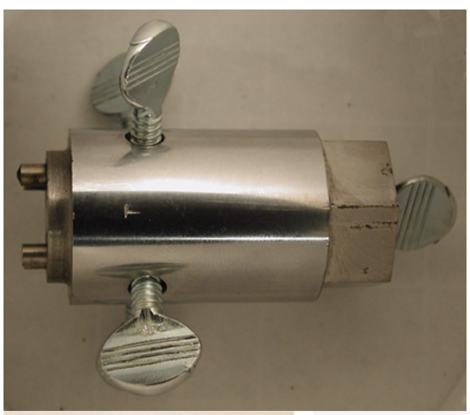
LSS201: MSC Lock Force tool, courtesy of MSC

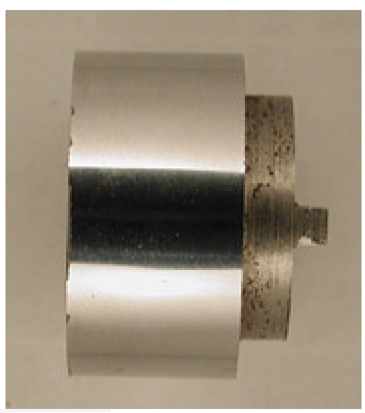


MSC in Hamburg, Germany produces a multifunction "Lock Force" tool for the removal of cylinders from their housing, and the extraction of cores through the application of reverse torque. The tool is actually a miniature dent puller, and is provided with attachments for several different profile designs.

The photographs show the extraction of a core from a profile cylinder. A special hardened screw is tapped into the keyway, then the tool is seated to the screw and reverse tension is applied. This causes shearing of the internal tumblers. A special collar is utilized to index the tool to the core. The tool can also be used as a slam hammer, as the sleeve is designed to move laterally along the internal shaft.







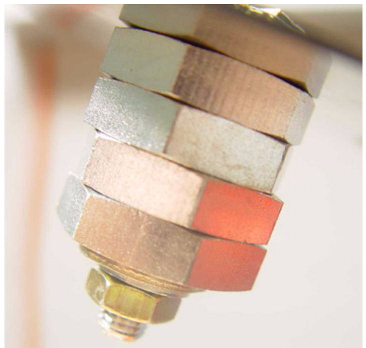


Figure LSS+3227 The MSC Lock Force tool is designed to remove a core from the shell.

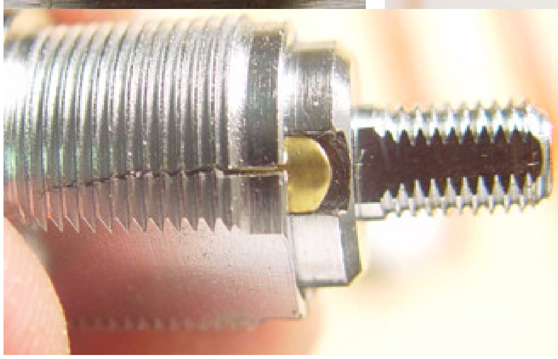
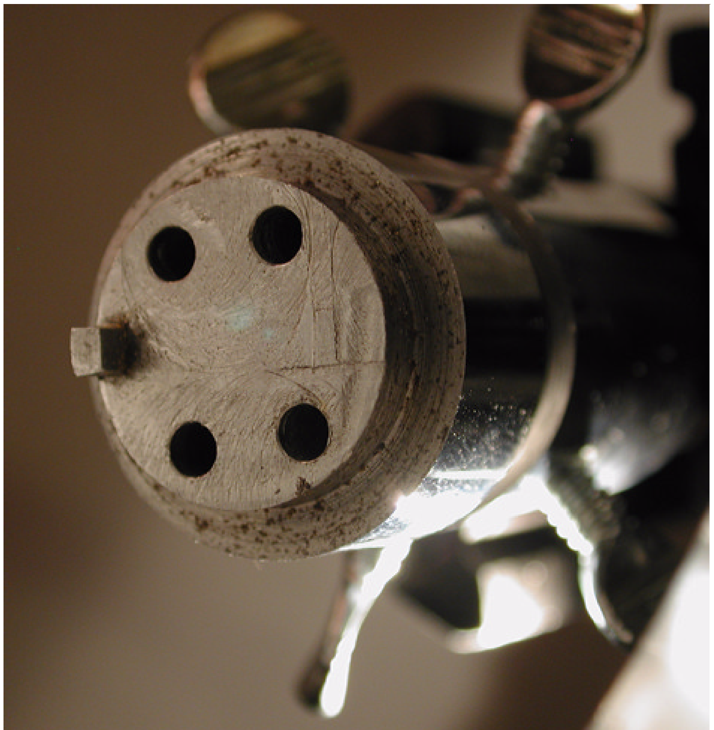
32_3.5.5 Application of Torque to the Plug: Opening the Medeco Cam Lock





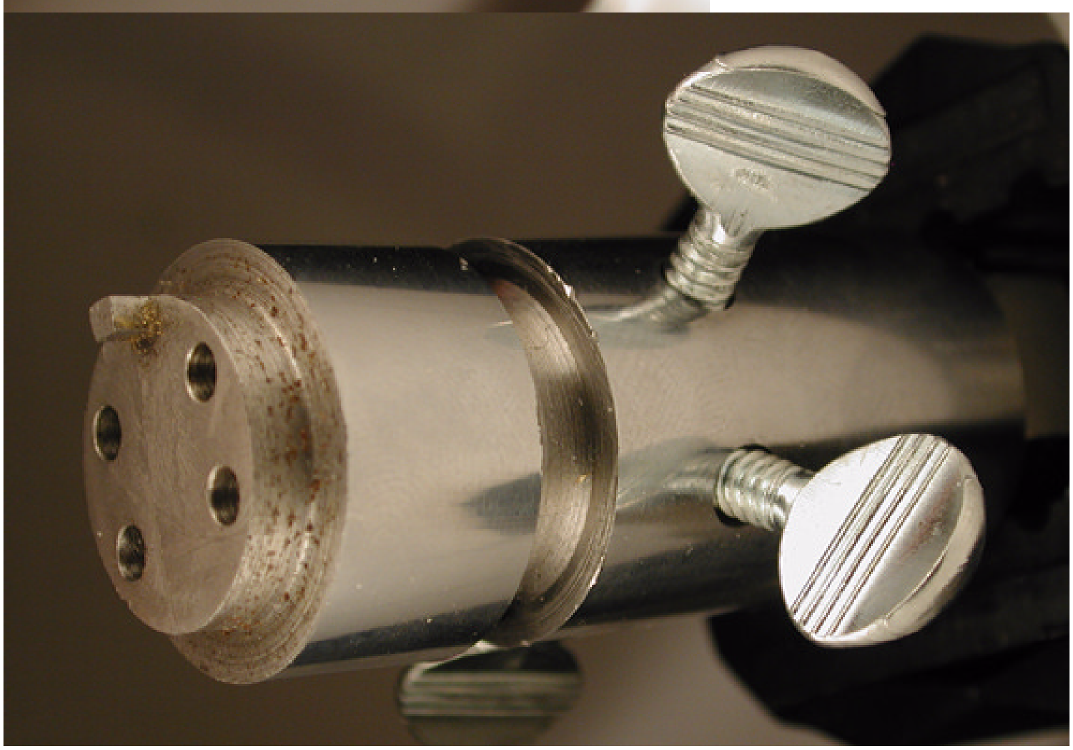


Figure LSS+3248 The Stealth Lock Systems bypass tool for Medeco cam locks is comprised of two pieces, as shown. The main body contains four hardened steel pins that link with the fact of the plug to allow the application of torque. The drill template (right) allows precise drill points to be marked on the lock. A dremel tool is utilized to create dimples that correspond to the holes in the steel template. The two pieces are linked together for ease in storage. The photographs (top right) show the back and front of the tool. The back view provides a drill template. The front shows the movable steel pins. The tool has a tendency to skip across the face of the cylinder. In the bottom row of photographs, torque was applied to a lock with nuts used for reinforcement. It can be seen that the tool allowed enough force to be linked to the shell that the housing was fractured.

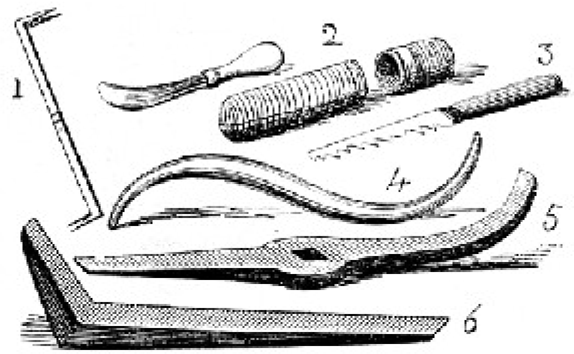
A tool to open the Medeco cam lock has been introduced by **Stealth Lock Systems.** This device is a two-piece design that is utilized to mark and drill the face of the cylinder in order for the protruding pins from the tool to mate and connect with the lock. The drill points allow for the application of torque to force the plug to an unlocked condition. Although the tool will allow the cam lock to be compromised, it does so in a manner that requires replacement and effectively destroys the mechanism. This device is described in this text because of the prevalence of the Medeco cam lock and the relative ease with which it can be destroyed.

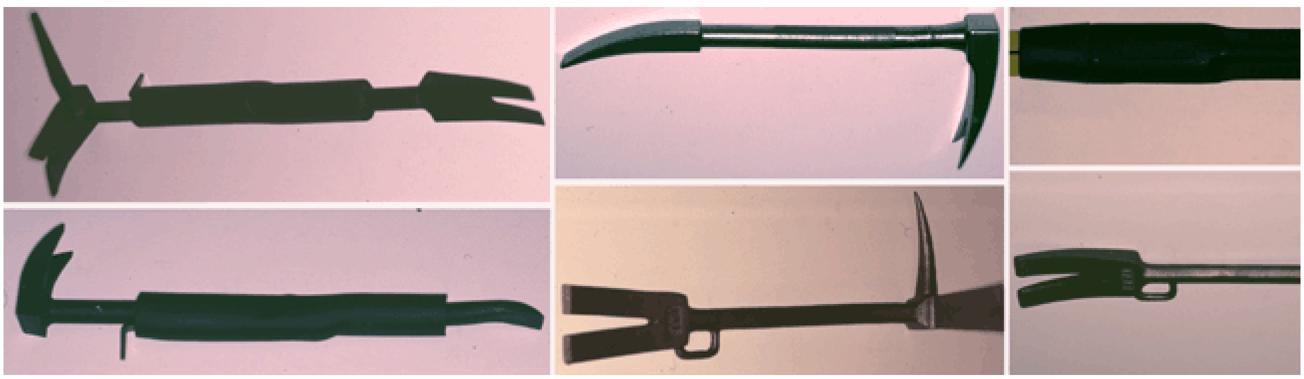
The device, which is really a sophisticated drill jig, is well made and relatively simple to use. It requires the use of the

following tools to effect an opening:

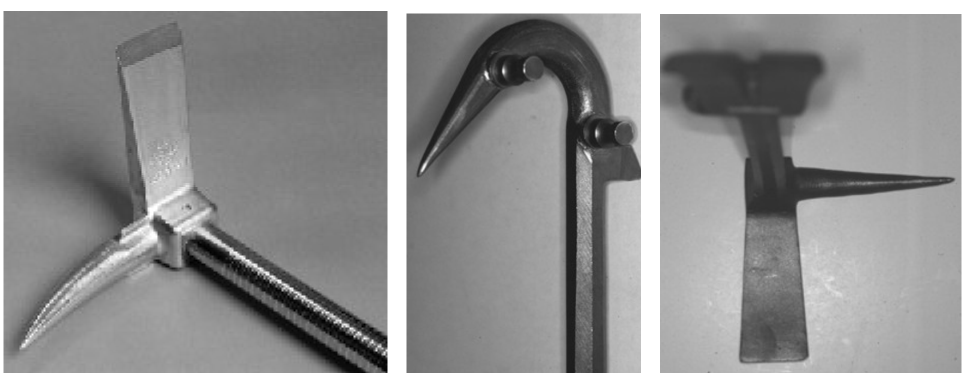
- **Dremel high speed rotary engine;**
- **1/8" shank diamond bit (small round head);**
- **1/8" drill bit;**
- **11/16" wrench.**



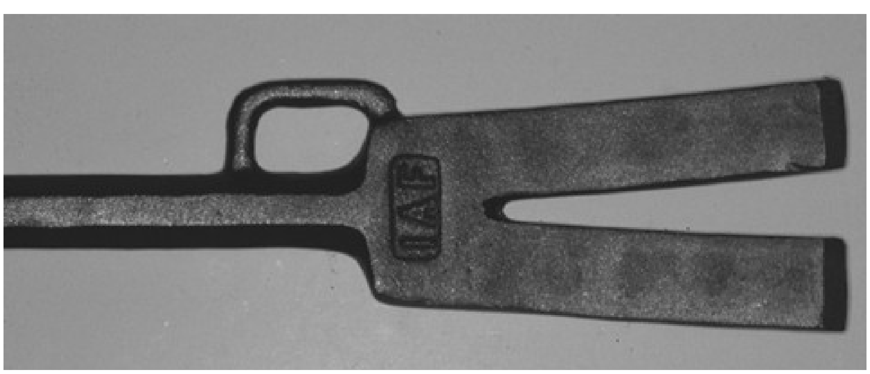
Opening a cylinder is a straightforward procedure:



- **Separate the main tool from the drill template;**
- **Locate and properly seat the template to align it with the keyway;**
- **Insert the Dremel drill through two of the four holes of the template and use the drill to create reference marks on the face of the cylinder;**
- **Use the diamond bit to create concave depressions for each of the marks, so that the link pins can properly seat to the face of the lock;**
- **Replace the drill with the 1/8" bit and make holes no greater than 3/16" depth in each impression;**
- **Place the hardened steel pins in each hole in the tool, and link to the face of the cylinder. The thumbscrews are utilized to adjust the length of each of the pins so they firmly seat. Then apply sharp turning motions with a 13/16" wrench. The lock can be opened with the application of repeated rotations.**

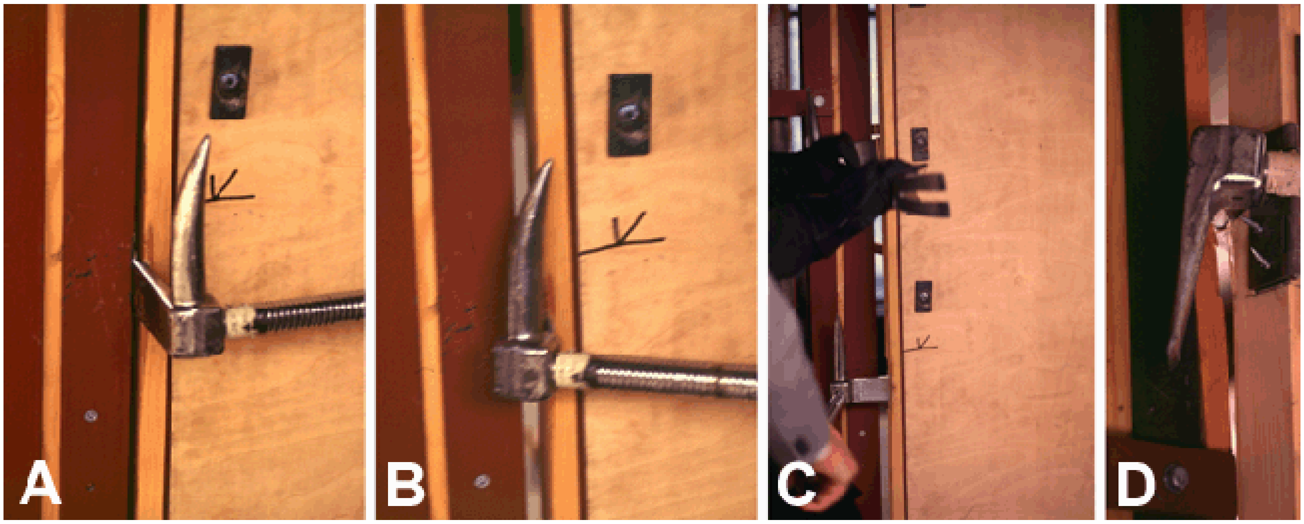


The manufacturer also produces tools to open the Tubar locks, and a line of picks for other mechanisms.



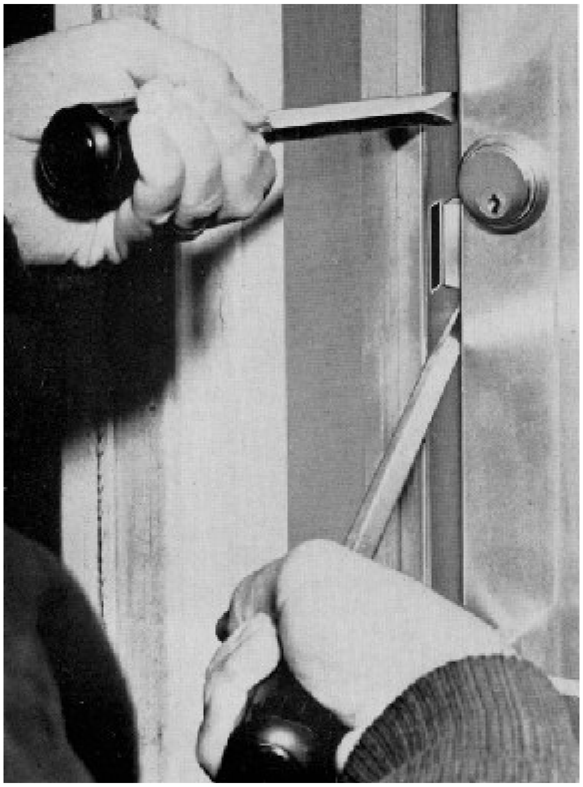
32_3.6 Opposing Forces Applied Simultaneously: Prying, Wedging, Peeling and Ripping

Many tools can be utilized to apply forces in opposing directions simultaneously in order to pry or wedge components from their normal position. Specific use is dictated by the design of the enclosure or security device.



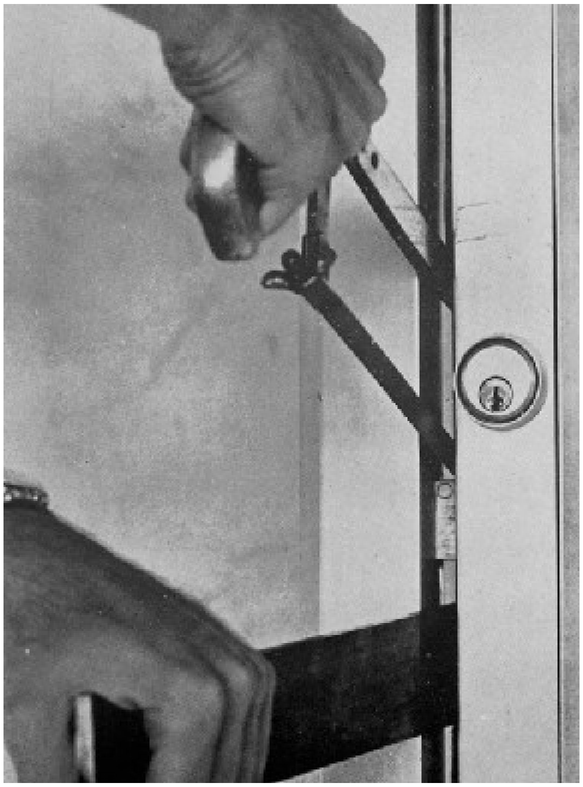
Exploded views 1, 2, 3, 4, 5, 6, 7, 8, 9.

Exploded view.



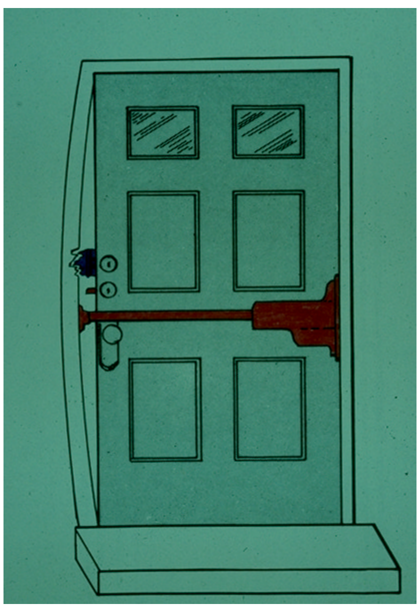
32_3.6.1 Peeling and Ripping

A technique known as **peeling** or **ripping** is popular for removing metal laminations that protect safes and vaults, generally fire safes with lightweight metal skins. The process is more thoroughly discussed in later chapters. It depends upon the use of a wedge or similar tool that will allow force to be exerted between layers of metal in order that they may be separated. The goal is to create or utilize a gap between active surfaces in order to exert force in two different directions. Length of the tool will directly affect leverage, which in turn controls the amount of force that can be presented to the metal surfaces.



32_3.6.2 Prying and Wedging

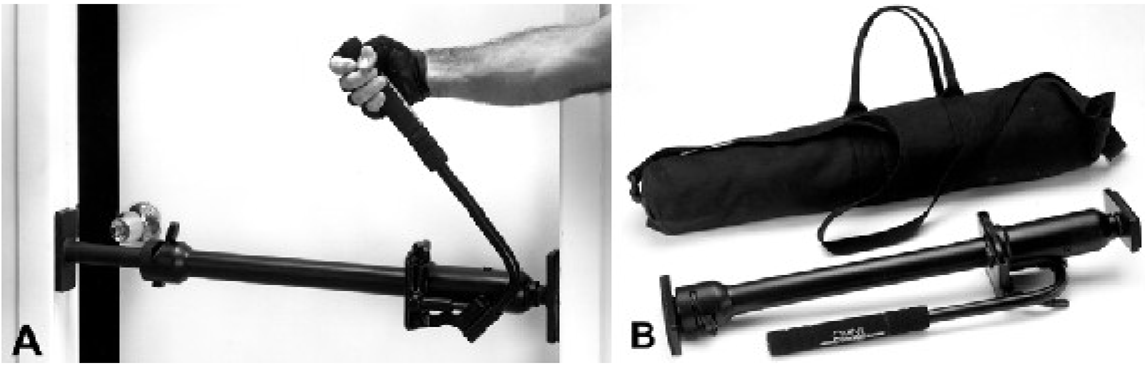
32_3.6.2.1 Jamb Spreading or Peeling

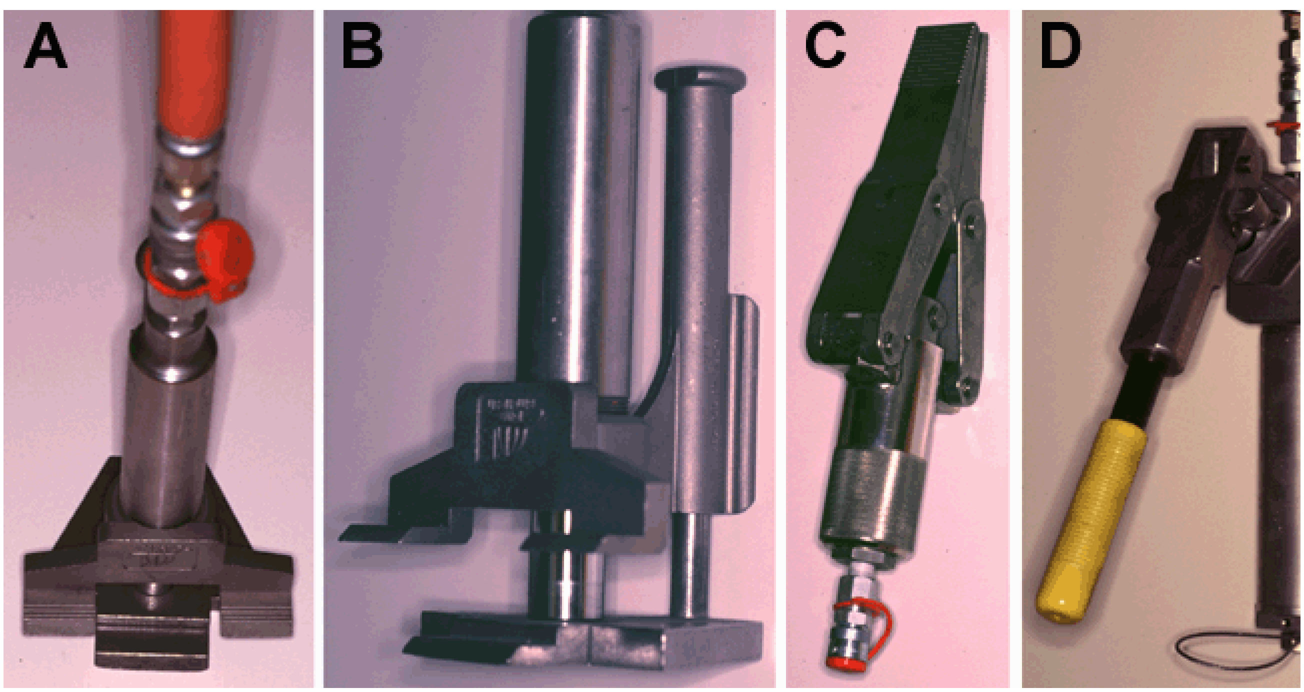


This is a technique to withdraw or displace the strike casing far enough to allow the bolt to clear the obstruction that block its movement.

Most bolt systems can be bypassed if enough of a gap is created between the lock and strike, thereby eliminating the obstruction to movement of the door. Although crowbars, pry bars and wedges may be utilized for the task, there are several hydraulic jamb spreaders available. They are capable of compromising almost any door frame with little effort.

The use of a hydraulic car jack with wood blocks is quite effective in spreading a jamb. One such device develops 4,000 pounds of pressure without any damage to the door frame. This type of spreader will not work on heavy metal frames, however.





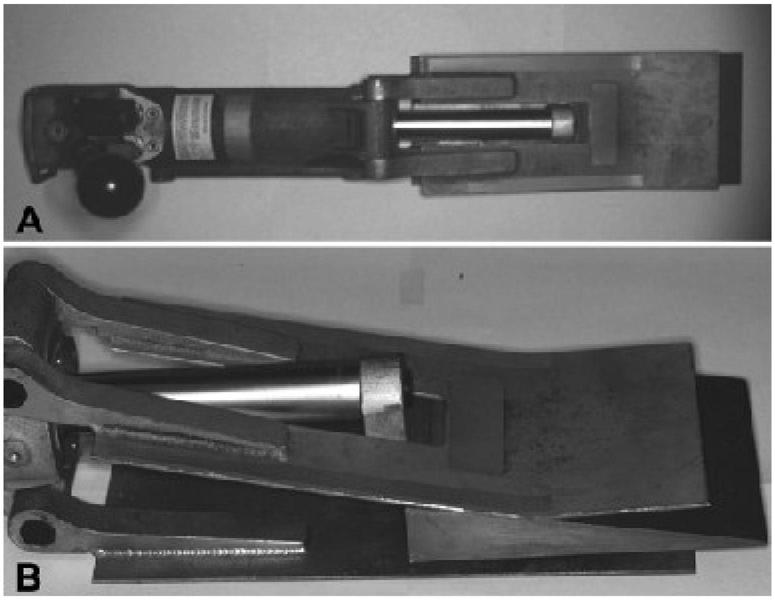


Figure LSS+3241 (ISP 39-3529) A diagram showing the principle of jamb spreading.

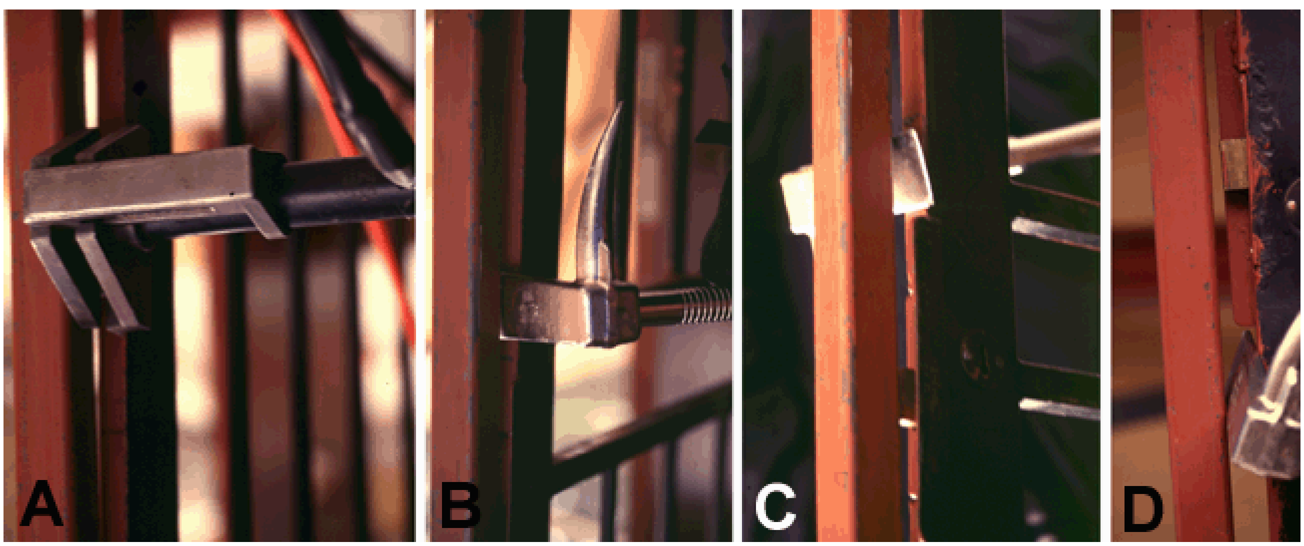
The **Hydra Force** and **Jaws of Life** are two other examples of jamb spreaders. Compressed hydraulic fluids or air pressure is developed by pumping and can be used to open a door within a few seconds. This type of spreader can develop 8,000-10,000 pounds of force.

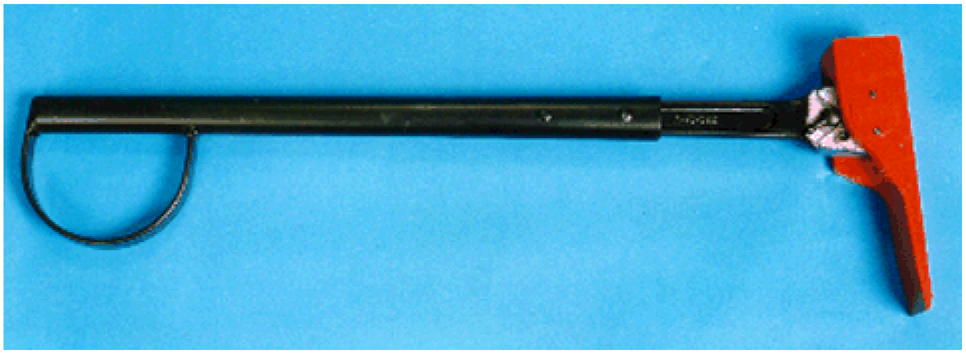


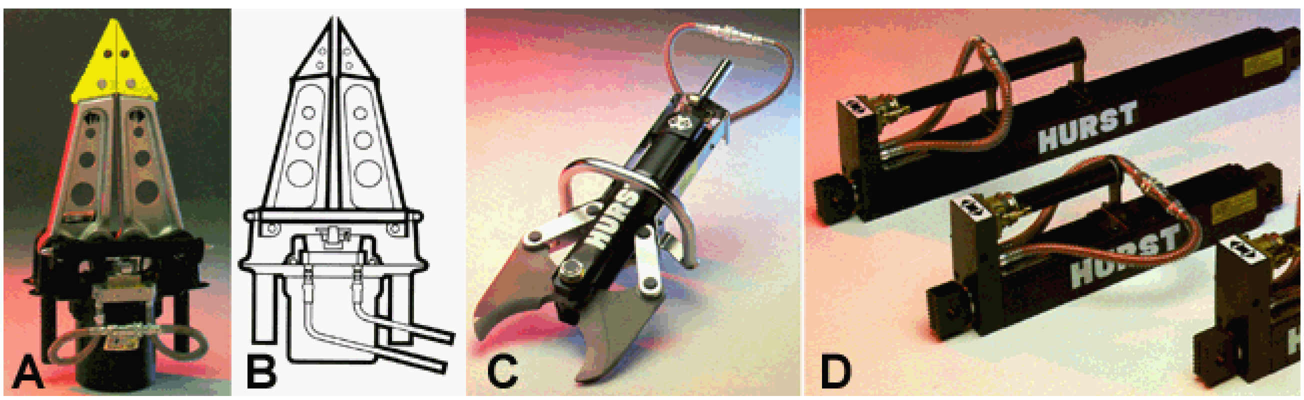
Exploded views 1, 2, 3, 4.

Exploded view 1, 2.

Sigma (UK) and Iowa American (U.S.) produce a series of hydraulic tools for rapid-entry teams, search and rescue, and paramilitary operations. Both of these companies are world leaders in the design of these tools. In the experience of the author, such devices can force open virtually any door within seconds.

Exploded views 1, 2, 3, 4, 5, 6.





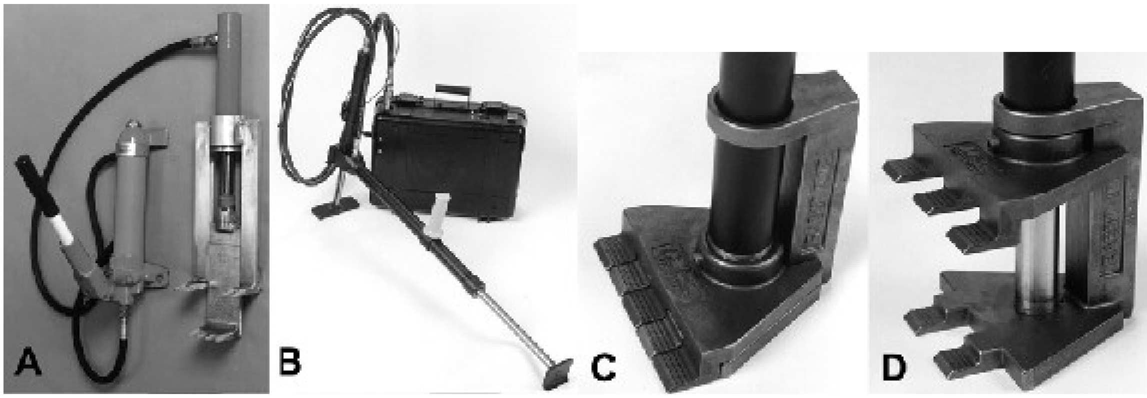


Figure LSS+3205 Sigma Ripper

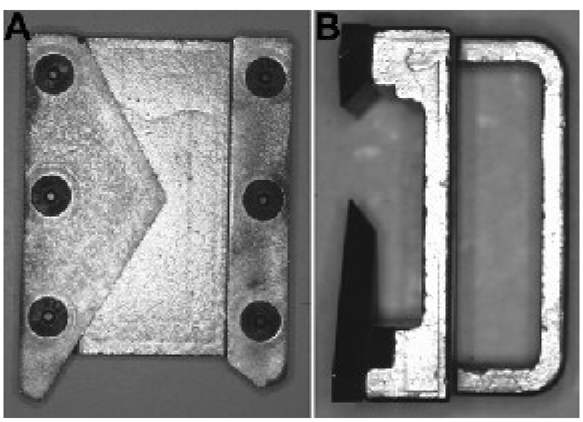
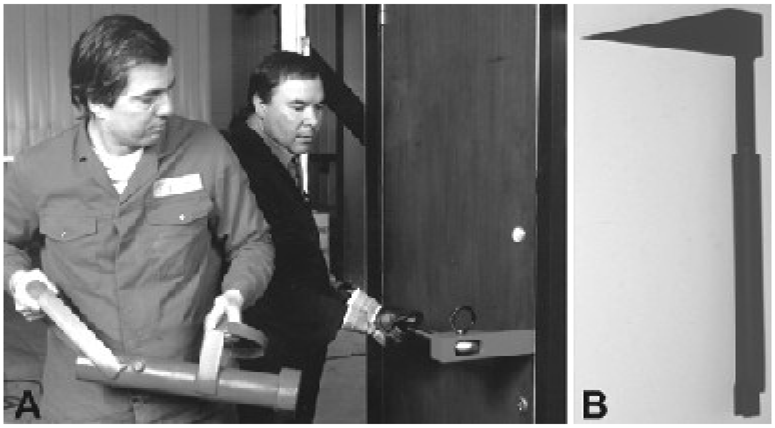
These tools are placed into the jamb between the sides of the door frame. Once seated, they will cause spreading. They will exert pressure against the frame, often at five or more different points. If the door is nailed shut, a sharp wedge can be initially driven into the frame with a hammer.



Safety precautions should be taken when using these devices because of the extreme hydraulic pressures that are generated and the potential for instant dislodging. Specifically, heavy gloves and goggles should always be utilized to protect against flying metal and fluids.

32_3.6.2.2 K-Tool

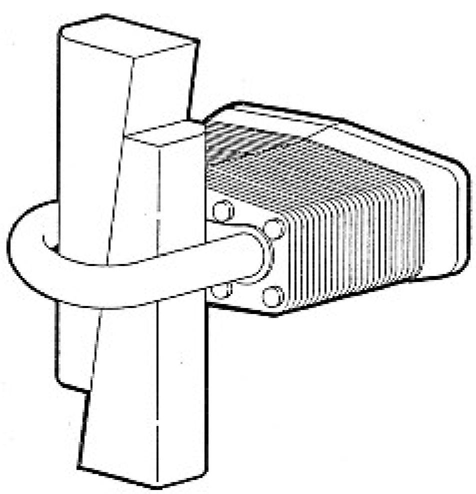


The **K-Tool** from Iowa American Company provides another means to remove a rim or mortise cylinder from its housing. This device, constructed in the form of a slotted box with an extremely sharp wedge, is initially forced around the lock to provide a firm grip. Its design will cause it to be locked onto the cylinder so that a pry bar or duckbill can be utilized to rip it loose from the door or frame.

Exploded view 1, 2.

32_3.6.2.3 Power Wedge (Duckbill)

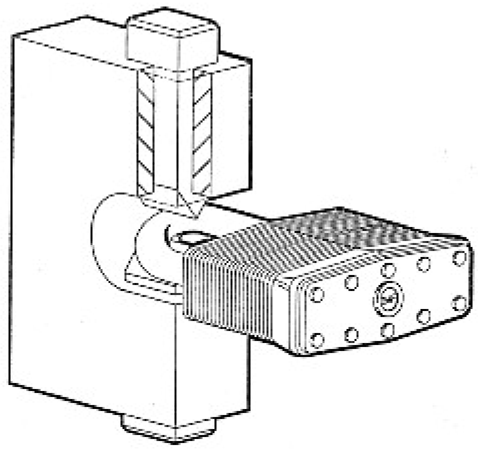
Another form of wedge that employs leverage will create energy from a graduated angle upon impact. The **duckbill tool** is primarily used to compromise padlocks and cylinders and is configured as an L-shaped crowbar.



Exploded views 1.

To open a padlock, it is placed into a shackle then struck with a sledgehammer. The force thus created will cause the shackle to be pulled from its anchor. When used with a K-Tool, almost any cylinder can be ripped from its housing within seconds.

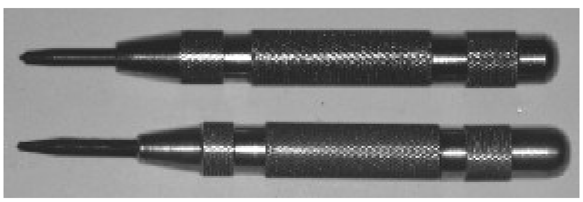
32_3.7 Breaking



Locking components may be physically broken, fractured, or ripped apart using a variety of techniques described in this chapter. If the material and its molecular structure can be altered or destroyed, the security of the device can be bypassed.

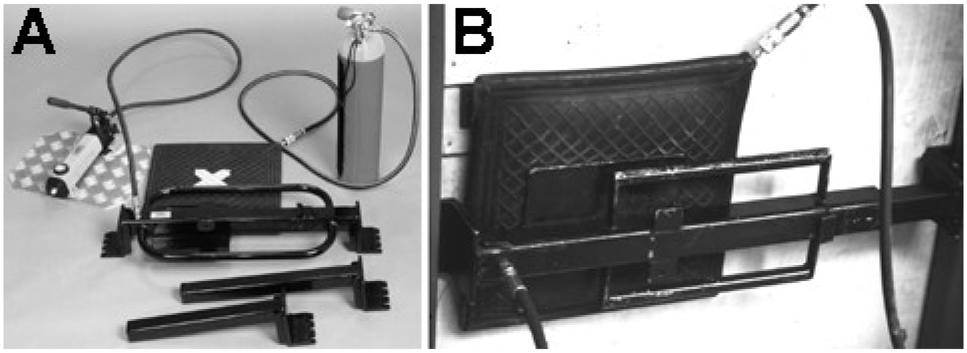
32_3.8 Compression

Some materials and components can be subjected to extreme compression in order to alter or destroy their structure. Wire

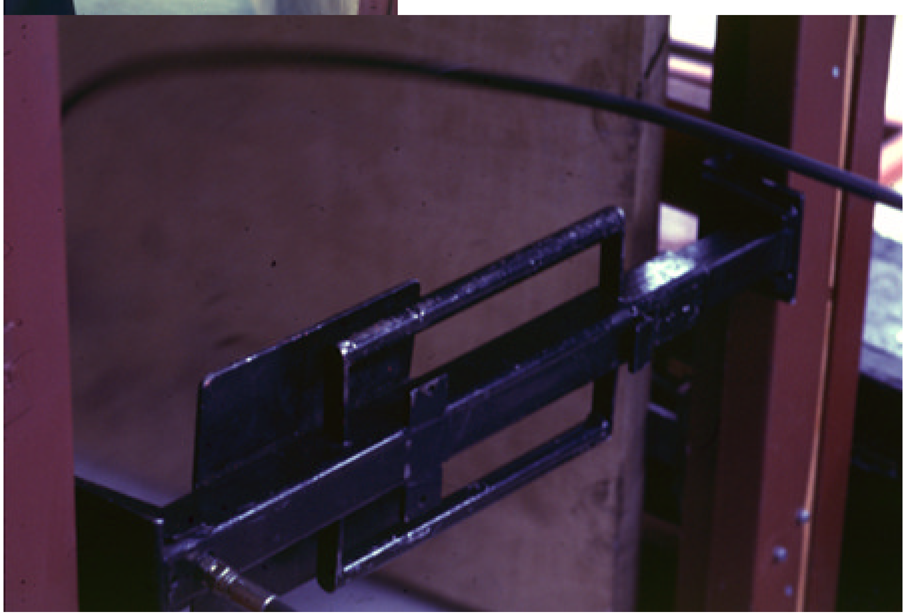


or bolt cutters, shears, and similar tools can be utilized to compress materials in order to reduce their strength.

32_3.9 Impact, Blows, and Shock

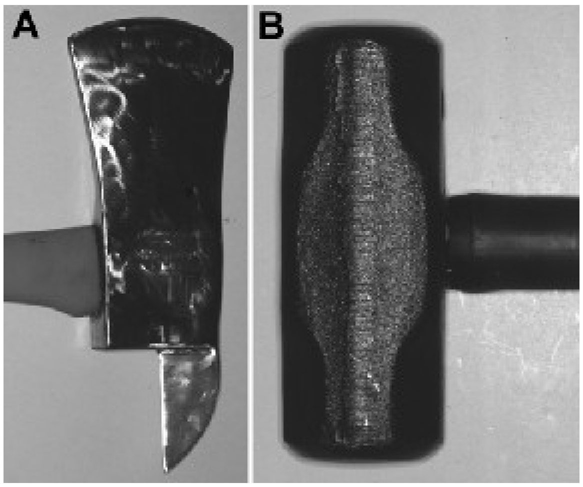


Safes, vaults, security devices, and barrier materials can be bypassed or destroyed when subjected to impact or blows caused by direct contact or concussion. Many tools and techniques are available for delivering and focusing such forces.



Exploded view.

In first-generation safes after the Industrial Revolution, it was a favorite practice to strike the metal sheets with a heavy hammer, causing deformation and the metal to pull away from the rivets. A lever or axe would be utilized to peel the face. Likewise, blows can be used to compromise a dead bolt locking arrangement. A well-known technique requires the placement of a bar at the top of a bolt, followed by the application of a downward force with a sledgehammer. This action will generally release the bolt from its housing.



A
B

Exploded view 1, 2.

Sigma produces a highly effective air bag system to compromise almost any door in seconds. It utilizes a heavy rubber pouch that is placed between a metal frame and the door. A hydraulic assembly is secured into the door frame to provide structural support to the air bag. Once inflated, the bag will force the door inward and shear any bolts that are holding it in place.

Exploded views 1, 2.

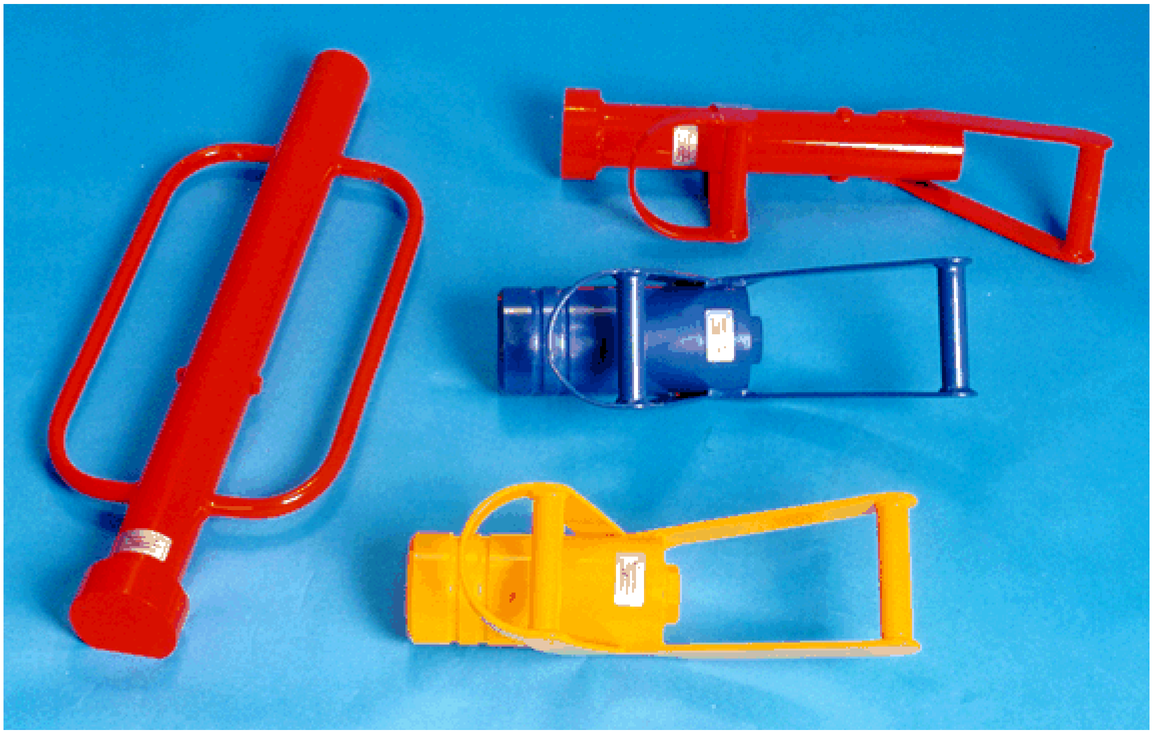
32_3.9.1 Bouncing Locking Components

Inferior-quality padlocks can often be compromised by applying shock to the shackle assembly, using a rubber or wooden mallet. This will cause the dog to retract, allowing release of the shackle. Likewise, impact pick guns are used to bypass pin tumbler locks.

Opening a padlock by bouncing the locking dog. Courtesy of Don Shiles.

Another common technique involves the application of shock to the walls of small safes used in hotels that employ spring-loaded bolts. Sufficient energy can cause the bolts to momentarily retract, allowing the door to be opened.

32_3.9.2 Battering Ram Door Hammer



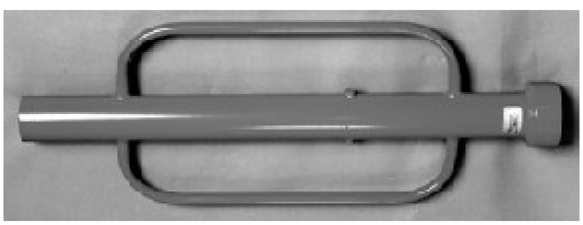


Figure LSS+3205 Sigma Ram Family

One and two-man battering ram door hammers have been developed for use by the military, security services, and rescue teams to effect rapid entry. These devices can generate a great deal of force through a combination of weight, physical design, and impact velocity. Interestingly, it appears that the first hydraulic ram was patented in the United States in 1851 (**7918(359)**).

Generally, these tools are made of steel and contain concrete. They can deliver up to 14,000 pounds of pressure. Once such device manufactured by Sigma (UK) offers eight times the force of a fourteen-pound sledgehammer. It can open almost any door in seconds. Iowa American produces similar tools.

Figure LSS+3201 Sigma Baby ram

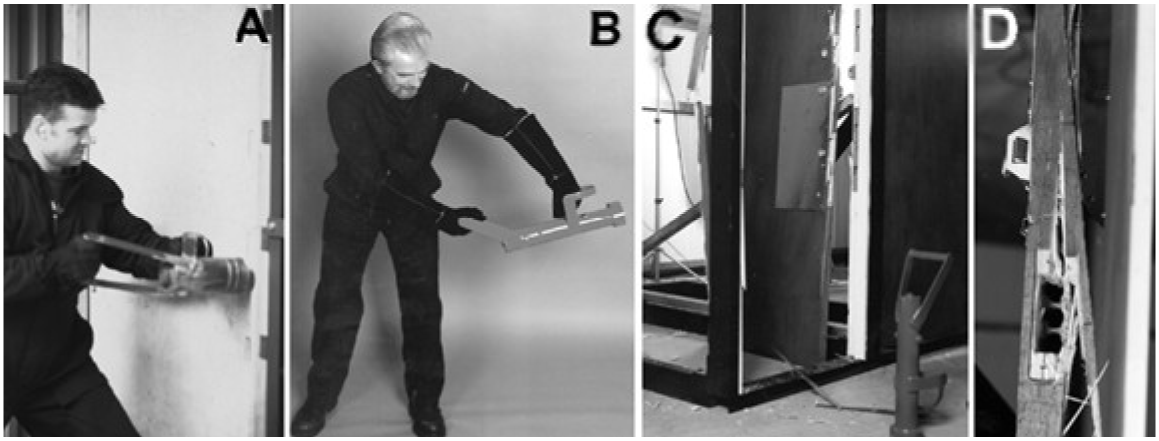

Figure LSS+3203 Sigma Firecracker ram

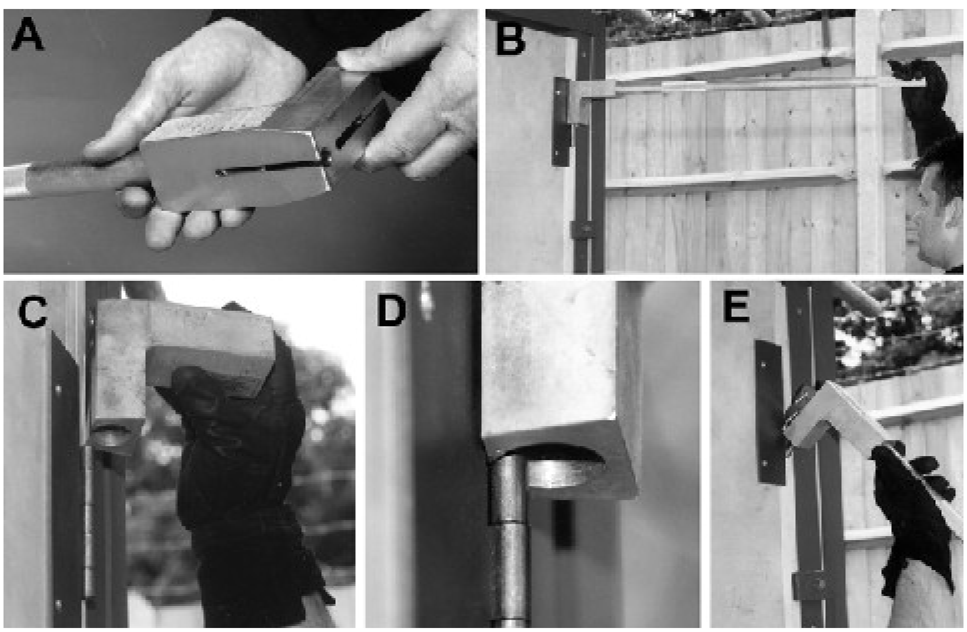
Figure LSS+3204 Sigma Mitts

In use, the ram is placed to hit a door on either the hinged or the locked side. Because of the tremendous capability to deliver focused energy, they are extremely destructive. Impact directed to the hinged side of the door may be preferable in order to insure officer safety.

Exploded view.

32_3.9.3 Slam-Hammer

The slam-hammer resembles a dent-puller and provides a means to exert a magnified pulling force to remove plugs, locks, safe dials, and other fixed components. The tool is quite simple in design and relies upon the multiplication of force by creating a momentum with a heavy sliding mass. The energy created by sliding the mass away from the target object will be transferred to that target object.



The tool is comprised of a long pipe that has a collar that is free to move over its entire length. The tip of the tool is designed to retain a metal screw that is tapped into the component to be removed. The round collar is quite heavy and is just slightly larger in diameter than the guide pipe. The weight of the collar, the length of the guide, and the speed at which the collar is withdrawn determines the amount of force that is applied to the lock. In operation, the front end of the slam-hammer is attached to the component to be removed through a self-tapping metal screw. The collar is moved to the tip of the device, then violently slid backwards. The counterforce or momentum that is generated when the collar **stops** at the end of the guide is transmitted to the lock or component.

32_3.9.4 Punching

Force may be delivered through punching, using a sharp-pointed rod, punch, spike, piercer, awl, or other cylindrical object. This is a popular technique to bypass bolt mechanisms and locks within safes. Access is first gained to the lock casing or bolt works by drilling a hole or knocking off the dial. The punch is then placed in a position to dislodge the lock by forcing the spindle forward. Shock, created by repeated blows with a hammer, will generally remove the lock case or bolt.

32_3.9.5 Chisel

A chisel with a sharp point is a favorite tool for bypassing hinges. In practice, the tool is used to spread the leaves and break a piece of the hinge. The sharp wedge is inserted and the hinge is pried loose from the door. Sigma produces a special tool to remove hinges. It is slid over the hinge assembly, then pried loose at an angle. **Hinge pins** can also be removed with a sharp chisel.

32_3.9.6 Shotgun Shells

Special shotgun shells have been developed to produce the equivalent of a shaped charge. These low-order explosives contain powdered metal or ceramics and will not ricochet.

32_3.9.7 Explosives

Explosives are chemicals that produce a large volume of gas almost instantly. The force that is created is measured in terms of violence rather than power. Explosives are rated in terms of **high** and **low order**; the classification denotes speed of reaction. The higher-order materials will produce gas more quickly. Explosives have been utilized for more than six centuries to open safes and vaults. Although today few safe penetrations are accomplished in this way, burglars sometimes turn to the techniques that were popular with older safes. In addition, SWAT teams can effectively employ plastic strips and placed charges to effect rapid entry.

The earliest use of explosives is claimed by the Chinese in the thirteenth century. A mixture of charcoal, saltpeter, and sulfur created gunpowder. This remained the principal propellant until just a few years ago. It is believed that explosives were not effectively applied to the task of opening locks and safes until the seventeenth century. See **Chapter 35** for methods of safe and vault penetration.

The early use of gunpowder in attacking safes was crude. As manufacturers refined their designs, so the safecracker became more sophisticated in his use of explosives. First, guncotton, then glycerol trinitrate was employed to open safes, beginning about the middle of the nineteenth century. In 1846, Sobrero was the first to produce a high-explosive liquid that caused a shock wave when ignited. **Nitro** would give safecrackers a new and powerful tool.

Until the middle of this century, dynamite has been the favorite explosive. In 1867, Nobel invented a stable form of the material, called Guhr dynamite, which was safe to handle. Gelignite, which is a combination of guncotton and nitro, was also developed by Nobel to compete with dynamite. Appearing as a dessert jelly, it was a favorite of safecrackers until about 1920.

32_3.9.7.1 Modern Explosives

Today, explosives can be safe to store, carry, and handle. Materials are available in many configurations and are offered in plastic, special shotgun slugs, compressed powder metal, or ceramics. An expert can place a shaped extruded charge to precisely f/ocus both force and damage. Explosives can be used

to blow apart hinges and locks and to make holes in doors or other barrier material.

Figure LSS+3202 Explosive Wall Breaching System

When hinges and locks are to be destroyed, the explosive is generally formed as a cord in the shape of a ring and wrapped around the obstruction to be removed. In the alternative, **thunder strips** may be placed over a door. These consist of soft, flexible foam containing 300 - 500 grains per foot of explosive. A slow blast applies pressure to the target material. Generally, an instant detonation firing system is employed.

See **Section 35_4.2.7** for an examination of the use of explosives in the penetration of safes and vaults. A comprehensive set of definitions of conventional explosives is provided at **Section 35_4.2.7.7.**

32_3.10 Application of Temperature Extremes

The application of temperature to surface material can be an extremely effective method of compromise. The object of such treatment is to alter the molecular structure of the target. This can cause a change in density, loss of temper, weakening, or distortion of the surface. It can also result in softening, brittleness, and shattering, or simply melt or vaporize barrier material.

32_3.10.1 High Temperature

High temperatures may be applied with a torch, thermic lance, or similar device. Chemicals may also be employed to induce an exothermic reaction. Thermite, for example, can develop high temperatures to melt barrier materials. Depending upon the technology and technique, heat may be directed to a very limited area as in the case of a thermic lance, or to a more general area with a torch.

To combat the effects of heat, most safe manufacturers place heat-sink material between layers of steel. Chubb, for example, utilizes a sandwich of copper and beryllium to draw heat away from the contact point of a torch. This technique is not particularly effective when a thermic lance is utilized.

32_3.10.1.1 Thermic Lance

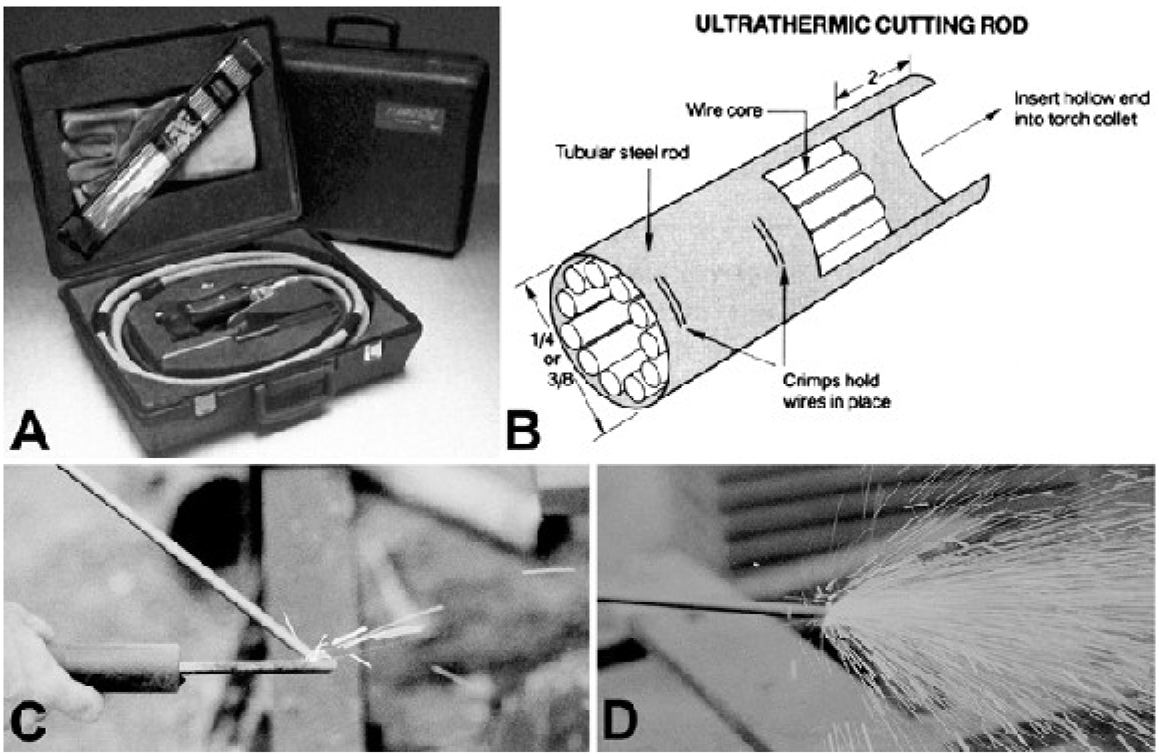
The lance has a long and distinguished history, dating more than a century. Initially used in England, it has had limited acceptance in Europe and the United States as a tool for forcible entry although many daring safe burglaries have been accomplished with the lance. Today, the exothermic torch is used in the repair of heavy equipment, plant maintenance, construction, dredging and marine emergency services, and safe penetration. SWAT teams utilize the technology for rapid entry, damage control, and rescue operations. It is particularly well suited for deployment in prison riots, where bar stock and heavy steel doors must be rapidly penetrated.

The modern lance is small, portable, and safe. With training, it can provide a means to penetrate any material. The lance is more fully discussed in **Chapters 5** and **35**.

32_3.10.1.1.1 Broco Exothermic Lance

LSS202: Broco Thermic lance description and use, by Tom Joos.

Broco(360) is the leading manufacturer of the exothermic torch. Their primary market is mainly for underwater repairs and construction. They have received two patents (**4069407(361)** and **4182947(362)**) for a binary metallic system used in conjunction with an ionized gaseous core. This provides a continuous cutting action of high temperature, extreme power, and great intensity.



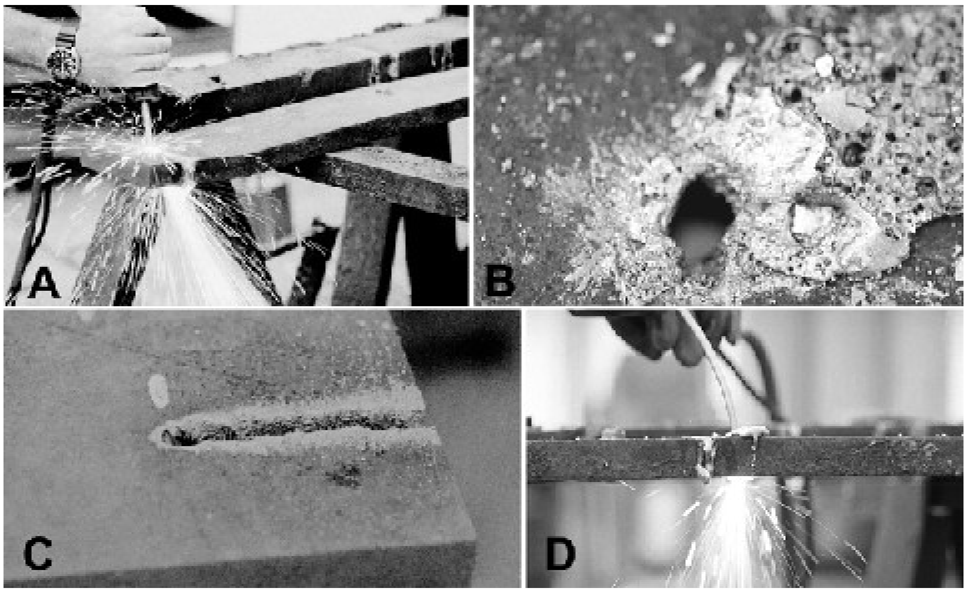


Figure LSS+3228 A smaller and newer version of the Broco thermic lance. This system utilizes a special oxygen bottle the newly designed trigger valve. The control valve can be utilized as shown, or connected via an extension hose to a separate oxygen source.

Figure LSS+3229 A close-up of the control valve with a rod inserted. The rod is inserted into a self-contained ignition system which requires no battery. It is pushed into the special capsule and will ignite.

The unique burning action of the Broco proprietary Ultra-thermic rods liquefies anything in its path, using the material itself as fuel. They will quickly cut or melt through almost any known material, including cast iron, steel, stainless steel, concrete, granite, nickel, titanium, and aluminum. The lance will even penetrate a spacecraft's heat-shield tiles and exotic metals. The Broco lance is completely self-contained and is ideal for

applications involving specialty gouging, piercing, or cutting. The Ultra-thermic rods burn in damp atmospheres, even when submerged in mud or water.

Prime Cut systems are safe and easy to operate because they do not require high amperage or potentially dangerous acetylene (or any other secondary fuel). The system produces little noise, smoke, or noxious gasses. Because the system cuts so quickly, there is minimal heat build-up. This enables the temper of the material to remain virtually unchanged. For detailed operating instructions and safety information, see the ***PRIME CUT Tactical Cutting Torch Kit PC/TAC and PC/MINI-TAC*** **OPERATING INSTRUCTION MANUAL.**

The lance is designed for simplicity of operation. It requires 12 volts DC for ignition and a single oxygen source with one regulator. The equipment is self-contained and portable and can be operated effectively by first-time users.

32_3.10.1.1.1.1 Lance and related components

The torch is straightforward in design and is fabricated from impact-resistant materials. It is engineered to be ergonomically efficient and to relieve operator fatigue. The system is provided with a flash arrester to eliminate flashbacks, and two collets to accommodate both ¼" and 3/8"diameter burning rods. All components are easy to remove and clean. The oxygen control lever is simple to work with in a gloved hand, allowing the

operator to "feather" the flow of oxygen during rod ignition and use.

32_3.10.1.1.1.2 Ultra-Thermic Rods

Broco's patented Ultra-thermic rods burn in excess of 10,000F at the tip and will cut, melt or liquefy virtually any known substance. The design of the rod incorporates a series of circular crimps to allow bending without restricting oxygen flow. This feature enables the operator to reach difficult or otherwise inaccessible places and ensures an even burn.

32_3.10.1.2 Oxyacetylene Torch

The Oxyacetylene torch has been utilized for cutting of metals and penetrating safes and vaults for over one hundred years. It relies upon the proper mixture of oxygen and acetylene to produce a flame of several thousand degrees.

32_3.10.2 Low Temperatures

Extremely low temperatures may also be utilized to alter the molecular structure of materials. Freon and liquid nitrogen have been successfully employed to make barrier materials brittle and subject to fracture upon impact. Supercooling of materials can be especially effective in the bypass of padlock shackles. Although some manufacturers add chrome and nickel or other materials as hardening agents, the less expensive locks are subject to the practice.

32_3.11 Other Forms of Attack

Acids and corrosive chemicals have been utilized to destroy barrier materials. Although difficult to work with, the application of acids can be quite effective in neutralizing security devices. Many solutions can be used to eat through metals, plastics, ceramics, and glass.

32_4.0 Evidence of Forced-Entry

This section provides information about tool mark evidence and the importance of proper procedures in collection, documentation, and analysis of materials (see **Chapters 24-27)**.

Forensic evidence of forced entry. Courtesy of Hans Mejlshede.

32_4.1 Tool Mark Evidence

Tools that have been used to commit a crime, found at the scene, or possessed by a suspect can often yield tool mark, trace, and many other forms of evidence in a criminal investigation. Tool marks can associate a suspect with a crime scene. This type of evidence can also provide an indication as to the type of tool that was used and the expertise of the perpetrator. It appears that the first substantive case involving the admissibility of tool mark evidence was decided by the Washington Supreme Court in 1930. That court held "the edge of one blade differs as greatly as the lines of one human hand differs from the lines of another." This landmark decision established the credibility and acceptability of tool mark evidence.

The surface and edges of any tool will always contain innumerable ridges and irregularities. These identifiable traits are unique to each tool and its surface material and are created both during the manufacturing process and because of wear. When the active portion of a wedge, crowbar, screwdriver, or similar surface forcibly encounters other materials, these traits may be transferred from one surface to another. Such tool marks can identify a particular tool just as reliably as the ridges and grooves of a spent bullet or fingerprint. When a tool contacts another surface and displaces material and creates any kind of mark, that impression can often be identified as having come from a particular instrument.

A tool mark can be described as an identifiable trait in the form of an imprint or impression that is created by an instrument, tool, or object upon a softer surface. Such traits are used to identify a suspect tool with a surface upon which contact has been made. Jimmy marks on a door frame, tool impressions on a cylinder, and drill tip marks on a safe all may provide information regarding the perpetrator.

Tool marks are generally associated with offenses related to burglary. It is not uncommon to develop such evidence in other criminal investigations, including possession of burglary tools, arson, rape, homicide, and espionage. It is critical that investigators focus on the **modus operandi** in order to determine possible tool mark indicia.

A tool can both transfer other evidence to the scene and carry away traces from anything to which it came in contact during the commission of the crime. Wood fragments, sawdust, safe insulation, metal filings or dust, explosive residue, splinters, paint flakes, oil, blood, or other contaminants or chemicals may be left behind, or be present on the tool or its surroundings (see **Chapter 25)**.

During a search, there is always an urge for investigators to attempt to match a tool with an obvious corresponding mark that is found at the scene. Valuable evidence can be lost by doing so. Foreign substances may adhere to cutting edges that may be contaminated and destroyed. Even more importantly, a mark and its characteristics may be altered, making a positive match difficult or impossible. Rigorous cross-examination can expose such mishandling and result in the suppression of vital evidence.

The examination of tool marks can yield the following conclusions:

- **The tool produced the mark;**
- **The tool did not produce the tool mark;**
- **There is not sufficient individual characteristics within the tool mark to conclusively determine whether the tool did or did not produce the mark.**

32_4.2 Burglar Tools

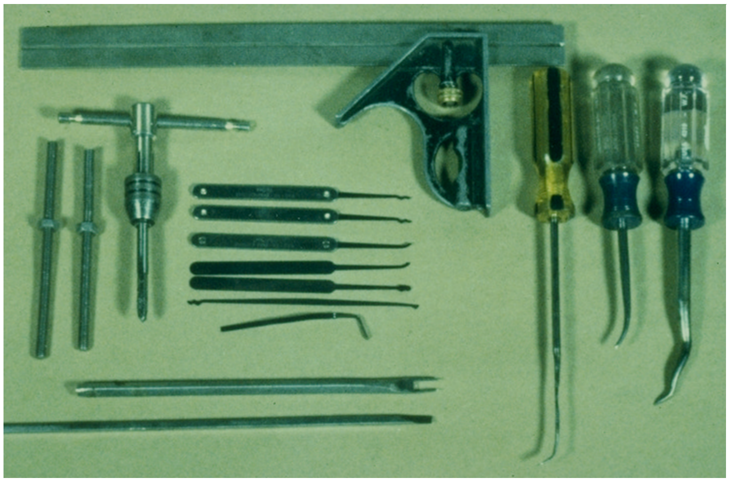

Figure LSS+3242, examples of burglary tools found at the scene of a safe job. (Photo ID ISP 100-3563, left, and 101-3563, right).

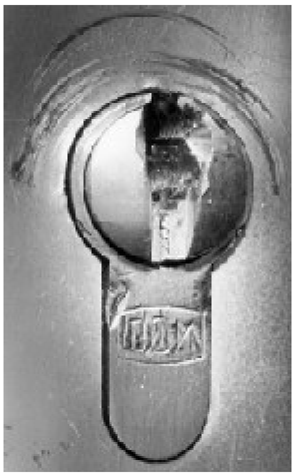
Tools found at a crime or in the possession of a suspect may provide physical evidence to link the perpetrator to the scene. These implements may also constitute an offense in their mere possession. The possession of burglar tools is a crime in most jurisdictions. The definition is illusive and depends upon many factors. Generally, implements, instruments, devices, or explosives that meet the following criteria can be described as burglary tools:

- **Suitable, or adaptable, or peculiarly adapted for use in breaking and entering;**
- **Possessed with intent to commit a felony or theft;**
- **Possessed with the knowledge of its character.**



The government must prove the elements in such cases, based upon the use of the tools and circumstances of its seizure. In certain instances, the identification of a burglary tool is prima facie. Such would be the case involving a cutting torch, thermic lance, or sledgehammer. Intent becomes the critical factor; it is often inferred from all of the facts and circumstances.

32_4.3 Types of Marks

Imprints are generally divided into two primary groups: **impressions** and **striations**. In some circumstances, a tool may leave both types of marks.

Impressions are indentations created upon a softer material by a harder one. The marks resemble a mold that duplicates the identifying characteristics of an object. Impressions can be created by a sudden impact, such as a hammer striking a safe or wooden door. In this example, we would expect a circular imprint of the hammer face on the surface. In some cases, irregularities upon such a surface could also be transferred back to the hammer.

Compression marks are another form of impression and can be made by the application of pressure between two surfaces. A screw driver, pry bar, or jimmy that is wedged between a door and frame will leave such marks.

32_4.4 Classifying the Mark

The admissibility of tool mark evidence is based upon uniqueness of signature; each tool will create a distinctive mark, like a fingerprint. When examined microscopically, minute differences will appear in cutting, striking, and the contact edge of similar tools. Tool marks are identified according to their **class** and **individual characteristics**. **Class** indicates the particular kind of mark normally associated with a specific type of tool. For example, marks can be differentiated between jimmies (crowbars and wedges), cutting tools (such as bolt and wire cutters), and wrenches (channel-lock pliers and vice grips).

Individual characteristics are a reverse, or negative image of imperfections impressed upon or transferred to a surface by the positive imperfections on the tool. Microscopic striations (lines and scratches) are formed on the tool by these imperfections.

Identifiable tool marks are actually complimentary to the imperfections on the tool's surface. It is the same as when the lands in a gun barrel become grooves of a fired bullet and the grooves of the gun barrel become the lands of the bullet. The technician compares the striation marks on the tool with known standards.

A study of class characteristics may suggest the type of tool that was utilized in a particular crime. In contrast, identification by individual characteristics can be extremely difficult. Impressions left on certain materials may be distorted or disappear with time. Wood fibers, for example, will bend, expand, and contract. Thus, there may be few if any microscopic marks for striae comparison in such cases.

There are two basic kinds of marks: **impact or impression** (one object striking another), and **striations** or **scratch** marks (an object moving against another surface).

Marks are further influenced by the **angle of progression** or **attack**. This angle is formed between the edge of the tool, key, or object, and the direction of travel of the intersection point. Significant criteria will result from a change or alteration in the angle of progression. Tools can produce a variety of marks based upon the combination of attack angles that result from movement of the contacting surface. The critical issue becomes the ability to identify a tool, and to ascertain what the significance changes in attack angles will have upon marks. That is, at what point will marks change, based upon a change in attack angle?

Most tools have non-sharp edges, and can be seen to have many rows of fine and coarse ridges. Factors that can influence the resulting mark, when considering attack angle include: **thickness of the edge of the tool; general shape in cross section**; and the **relative height and spacing of the irregularities** on its surface. In simple terms, this translates to changes in markings caused by insertion angles of a key within a lock, the rate of insertion, and the force applied)slow or fast). In addition, issues relating to the shape of each cut on the surface of the key must be taken into account, because, as has been noted elsewhere, marks may be caused by such irregularities in the bitting of keys.

32_4.4.1 Striations

A typical striated tool mark consists of parallel scratch marks that are cut into the softer material by a harder surface through sliding or lateral movement. Striae are reproductions of the cutting, prying or striking edge. These are also called shearing, abrasions, friction, or scratch marks. These marks are comprised of minute parallel ridges and valleys that are imprinted upon a surface by corresponding irregularities along the edge or surface, of the acting tool. From an evidentiary standpoint, the marks generally carry a greater significance than impressions, although they will not always provide clues as to the specific type of tool that created them. It can be extremely difficult, for example, to ascertain whether a particular striation mark was produced by a screwdriver, pry bar, cold chisel or wood chisel.

The real value of these marks lies in the investigator's ability to locate a tool whose edges have the same imperfections or traits as found on the imprints at the scene of the crime. Marks containing indentations or similar irregularities resulting from wear or damage to the tool provide the best identification. Striations are created when the edge of a tool has slipped, scraped, or been forced over a softer material. Generally made by a lever (pry bar or crowbar) or a tool with a sharp edge (screwdriver or chisel), the marks can match a suspect tool to the point of entry. Bolt cutters, pliers, snips, wire cutters, and shavings from a drill bit may all contain striation marks unique to the entry tool.

32_4.4.2 Striae and Impressions

Impressions can be most often located on windows, doors, safes, and other barriers. **Striations** are generally found on cash boxes, registers, door locks, safe dials, vending machines, and similar implements. Good impressions are rarely left on wood surfaces, although they should never be overlooked. Marks on painted surfaces are often clear and distinct.

The best striations will be produced on soft metal surfaces, such as brass or bronze door lock assemblies and hinges. Galvanized iron and painted sheet metals also are excellent materials to reproduce marks. Cutting marks that are a form of striation can be reproduced on wood with excellent definition. Photographs of tool markings showing their class characteristics are usually admissible in evidence to show the location of breaking and entering. It is extremely difficult to identify **individual** characteristics through photography because of the inability of the photograph to reveal the height and depth of the striation

marks.

32_4.4.3 Basic Tool Mark Examinations

Tool mark examinations may be conducted with or without the suspect tool. If the tool that is suspected of having made the mark can be used for testing, then the following comparisons can often be made:

- **Examination of the tool for foreign material deposits, such as metal, paint, oils or other debris;**
- **Establishment of the presence or non-presence of consistent class characteristics;**
- **Microscopic comparison of a marked object with several test marks or cuts that have been produced with the tool.**

Analysis **without the tool** can also yield valuable results:

- **Type of tool that was used, by class characteristics;**
- **The size of the tool, by class characteristics;**
- **Unusual features of the tool, determined by class or individual characteristics;**
- **Actions employed by the tool in normal operation, and in the present condition;**
- **Value of the tool mark for identification.**

Other related examinations can be conducted involving marks and similar indicia of contact. These include fracture matches, marks in wood and other soft materials, and pressure contact marks.

Fracture matches

These examinations are conducted to determine if a piece of material left at the crime scene was connected with or formed a part of a suspect item. Fragments from the following items provide examples:

metal bolt
plastic automobile rim
knife
screwdriver
wood gunstock
rubber hose
keys

screwdriver or other prying tool

Marks in wood

Can the marks that remain in a wood specimen, such as a door or window frame, be associated with a specific item or tool, such as drill bits, pruning shears, knife blades, pry bars or other implements.

Pressure contact

These examinations are conducted to determine whether two objects came into contact with each other.

32_4.5 Making an Identification from a Tool Mark

Tool mark identification involves both an analysis of the impressions, as well as other materials which may have come into contact with the tool or affected surface. The forensic analysis of tool marks occurs in several stages. First, the suspect tool and its markings are examined to determine the presence of trace evidence such as paint, putty or other foreign matter. If any material is found, an attempt is made to chemically and spectrographically identify it and link it to evidence from the crime scene.

From tests conducted in the laboratory, four primary factors must be considered in the analysis of a tool in comparison to an impression taken at the crime scene:

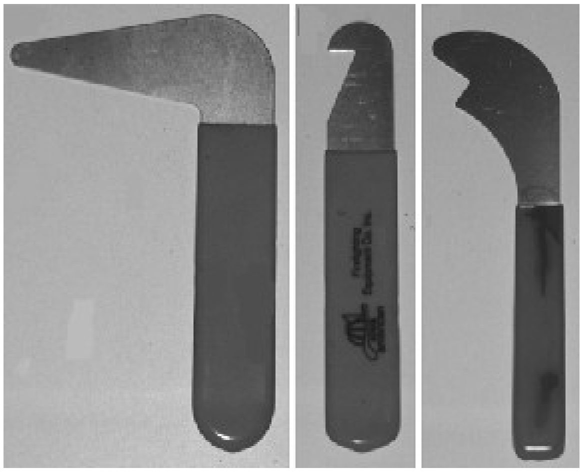
- **Direction of tool movement which creates the mark;**
- **Pressure;**
- **Angle of contact or Angle of Progression;**
- **Method of contact by different movements.**

Sample marks must be created by a suspect tool and compared against those taken from the crime scene. Test plates made of similar material to those upon which the impression was initially made are prepared. The edge, blade, or surface that created the mark is used to make a sample impression by pushing and then pulling the one side of the blade over the surface.

The test scratches are repeated with the other side of the blade. The push-and-pull action will help determine the direction of the blade movement when it made the original impression. Pressure and

angle must also be considered in analyzing marks. It is not unusual to produce a number of standards using various movements, angles, and pressure. Using a comparison microscope, the prepared plates are examined against the suspect tool for similarities in striations.

The quality and value of identification information provided by a mark is a function of and directly related to the tool and surface to which contact is made. Depending upon the materials and applied forces, marks may be transient or permanent. Thus, wood fibers in a window frame are generally compressed by the pressure of a jimmy. They will return to their original shape upon removal of the tool. Splinters may also become dislodged, thereby reducing the definition of the mark.



Tool marks found at a crime scene are typically a combination of impressions and striations. A mark, for example, may display both the impressed outline of the end of a pry bar or screwdriver and striations extending from the sides or ends of the impression. These will further identify the tool that produced the marks. Two common occurrences illustrate the point. A hammer blow on the surface of a safe may leave an impression mark. The head may glance upon impact and leave a sliding mark (striation). Likewise, a crowbar that was used to force a door will often leave a perfect impression. Striation marks are created as the bar is forced into position.

An impression can often duplicate the characteristics of a tool quite precisely and may provide information about its general character. The size or shape of the cutting edge, as well as the shape and the color of the tool, may be discoverable. The usefulness of a tool mark, even when it is an exact reproduction of the original, is of significance only if the tool that made it has irregular and individual characteristics. Thus, a jimmy that has never been used would have far less relevance than one whose surface has been pitted or damaged through previous contact with other materials. An impression will have little evidentiary value if it does not show distinct characteristics.

Impression marks may be found anywhere and are dependent upon the method of attack and the tools utilized. Generally, marks are found at the point of entry. A search should be made for tool marks based upon the design of the security device or mechanism and how it was compromised. Door frames, cylinders, sills, safe doors, glass, and any other place where it is likely that entry may have been effected can yield evidence.

32_4.6 Tool Marks at Crime Scenes

Most forcible entries produce some form of tool mark, both on large and small surfaces. Whether they are identifiable or not depends upon many factors. Investigators should expect to find such evidence in all residential and commercial burglaries, as well as other crimes.

Exploded views 1, 2, 3.

Tool marks may appear anywhere and on any surface that may have been exposed to a tool used for forcible entry. Never overlook the possibility that a small piece of a tool may have been broken or shattered. Tool marks are often found in the following areas:

- **Padlocks;**
- **Doors and door frames;**
- **Severed telephone lines;**
- **Safe doors and bodies, dials, dial covers;**
- **Hinge pins;**
- **Nail heads;**
- **Cylinders, both front and sides, when a drill jig is utilized to remove setscrews;**
- **Cylinder guard rings and lips of cylinders, when a plumbers tool (chain wrench) or K-Tool is used to rip the cylinder from its mounting;**
- **Doorknobs;**
- **Cylinder plugs, when a dent-puller is utilized;**
- **Cylinder setscrews, when heads of screws are**

drilled;

- **Internal areas of plugs, when picks are utilized;**
- **Surface of cam at the rear of the plug, when the bypass technique involves the use of a spring steel sharpened wire. Generally, it is forced to the back of the cam lock, then the cam is rotated to open, bypassing the mechanism;**
- **Scratch marks or indents that indicate a knife, ice pick, awl, or loid was used to move the bolt. Generally, marks will appear on the bolt and between the strike plate and frame;**

LSS203: Demonstration of the use of a loid, by MSC

- **Scratch marks on bolt works;**
- **Wood separated from door frame, indicating use of jamb-spreader;**
- **Impressions at the top and bottom of the lock, indicating the use of two screwdrivers to wedge the cylinder loose. This is especially common with Kwikset and other similar locking arrangements;**
- **Jimmy marks that were caused prior to the use of a pry bar;**
- **Use of hacksaw to cut through dead bolt;**
- **Marks from drills used to remove mounting screws from front of cylinder on Schlage locks;**
- **Magnetized areas of safe door, indicating the use of a magnetic drill press. The footprint of the press can often be determined by the use of magnetic spray or powder placed on the surface. The type of press can often be identified;**
- **Fine metal dust particles at the crime scene and on the clothing or in the hair of suspects;**
- **Broken tips of setscrew in door frame indicating shearing and that extreme torque was applied to the cylinder;**
- **Drill marks on the face of a cylinder, internal components, or on the door frame;**
- **Compression marks on door frames, indicating the use of a jamb-spreader. The size and depth of the impressions should be documented, as well as any striae. Tests may be conducted to determine the**

amount of pressure required to spread the jamb. This may provide a clue as to the manufacturer;

- **Marks on the door and frame, indicating the use of a jimmy, crow bar, and pry bar;**
- **Marks on bolt control mechanism in a mortise cylinder assembly, indicating how the cylinder was removed from the door;**
- **Dents, scratches, and metal chips missing from hinges;**
- **Wedge marks within the doorjamb, indicating the use of a wedge that has been forced into the jamb to effect spreading.**

32_4.6.1 Collecting Evidence

Investigators should gather any evidence that contains striae and anything directly associated with it. For example, in a burglary case, a striker plate and the screws holding it in place may be submitted to the laboratory. Although not readily apparent at the scene, there may be a minimal amount of striae on any component that may be sufficient for identification. The investigator must always be vigilant for indicia, including chips or larger pieces of broken metal that separated from a tool during the exertion of pressure.

32_4.6.2 Documenting and Preserving Tool Marks

Tool mark and related evidence should first be photographed, identified on the crime scene sketch, and, if relevant, a cast or mold should be taken. These procedures are required in order to record the extent, location and pattern of each mark. Macro-photographs and casts may be used for comparison purposes in the event the suspected tool is located. Special oblique lighting may be required to illuminate tool marks in order to produce images from which a comparison can be made. The author utilizes a 100 mm macro lens, ring strobe, and a fiber optic light source that produces an extremely narrow beam width which can be easily adjusted for maximum contrast. Photographs must document the location of the tool imprints in relation to the entire object. In a burglary, for example, the entire window, showing the placement of the jimmy marks as well as a macro of the marks, must be photographed.

Materials containing tool marks should be preserved whenever possible to maintain their original state. Moveable objects such

as safes, cash boxes, drawers, and cabinets should be retained. Unfortunately, this is often not possible or feasible due to difficulty and expense. For example, marks found on iron grillwork, a window frame, and sill or doorways present a problem. If it becomes necessary to collect these marks, consideration of several issues are required:

- **Whether the marks represent relevant details of a tool;**
- **Seriousness of the crime;**
- **Value of the object to be removed;**
- **Whether a suspect tool is available for a match;**
- **Likelihood that a tool will ever be found.**

If the object containing a mark cannot reasonably be removed, then the mark may be protected at the scene if it can be shielded from contamination or obliteration. The mark may be covered with a thin film of oil to prevent oxidation if necessary.

32_4.6.3 Modus Operandi

Tool marks can indirectly identify a perpetrator by establishing a **modus operandi.** They can also lead investigators to other more serious crimes. Information regarding the individual who used a tool may also be left at the scene of a crime. Thus, the skill level of the perpetrator may be reflected by the manner in which a tool is utilized. The method of attack may indicate the knowledge and expertise of the criminal about the security device or container and methods of compromise. Depending upon the sophistication of the tool or technique and the **modus operandi (MO)**, an accurate assessment can often be made as to who may have committed the crime.

Investigators should always be alert to markings and any inconsistencies in their creation. The fact that tool markings exist on a door or window does not always provide evidence that a burglary or other crime has occurred. The number, position, and character of the marks must be examined closely for consistency. It is a common ploy of criminals to simulate a burglary or arson, for example, to cover homicide, embezzlement, fraud, espionage, or other offenses.

Those intent upon establishing false leads will often overlook the fact that second marks should be present, or other unique indicia associated with the use of a tool or method of entry.

Consider whether the tool marks are placed in such a position that it would be highly unlikely that they actually contributed to the crime under investigation. The following information can often be derived from the crime scene with regard to MO:

- **Tools;**
- **Techniques;**
- **Sophistication of the method of attack;**
- **Skill level of the perpetrator;**
- **Knowledge and expertise with regard to a particular target;**
- **Position of the perpetrator during the attack with regard to placement and support;**
- **How the tool was held;**
- **Possibility that the forced-entry is a mask for another crime.**

32_5.0 Forced Entry Tools for Motor Vehicles

Although not within the scope of this text, there have been many devices and techniques developed for opening motor vehicles. Many vendors including HPC, MBA, and Tech-Train have a full range of tools for bypassing locks and locking systems in cars and trucks. Some of the more relevant patents have been included here for review. These include Jacobs (**6044672(363)**) for a steering wheel lock removing method in 2000, Markisello (**5701773(364)**) for a dual function apparatus for opening and removing automotive sidebar ignition locks in 1997, and (**5402661(365)**) in 1995 to the same inventor for a tool and method for turning on Ford sidebar lock cylinders, and in 1986 (**4586233(366)**) for a method of disabling various types of lock cylinders in General Motors vehicles, and in 1987 (**4682398(367)**) for a method for removing Ford ignition pin type cylinders.

32_6.0 Hybrid Entry Tools for Locks and Doors

There exists a classification of tools that can be defined for use in both covert and forced entry. These tools typically are utilized to manipulate, bypass, or destroy mechanical locking

mechanisms, such as locks, bolts, catches, and door handles.

32_6.1 Door Opening and Manipulation Tools

Many door opening tools have been invented and marketed during the past two hundred years. Typically, these can be slid under a door or through a mail slot and allow manipulation of locking components. Such a device was patented in 1996 by Helmers (**5540121(368)**).

32_6.2 Powder Technology Forced Entry Tools

Law enforcement, fire, rescue, and SWAT teams frequently must force open locked doors in order to gain access to a premises. Powder actuated tools are well known in the construction field for driving fasteners such as nails, studs, or anchors. This same technology has been applied by Berry in 1993 to a method of neutralizing a lock (**5237613(369)**). The system will disable or destroy a lock at which it is fired.

32_7.0 Specific Entry Problems for Doors, Gates, and Windows

Sigma has done an extensive analysis of the different types of barriers, doors, and locking systems with the view of expediting forced entry. The company has developed the appropriate tools to meet the demands of such entries. The following examples detail the most common types of hardware that will be encountered by entry teams. Ian Bauchop (Sigma) provided the narration, and was employed for almost fourteen years by the Metropolitan Police Force in London. His responsibilities included directing forced entries for that department. He is director of training for Sigma.

The KIBB Lock Company, Ltd. in Willenhall, England has developed a unique system for interlocking strike plates that can make forced entry significantly more difficult. Sigma has conducted tests with this system to determine specific techniques to bypass the mechanism, detailed in the video. The company also produces a variety of locks for different security applications. Note the demonstration of different forced entry techniques with traditional and interlocking strike plate designs.

BOOK THREE: PROTECTED AREAS

Locks, Safes, Vaults, and Secure Areas

Book III provides detailed information about safes and vaults: their history, construction, individual components, and penetration. The information in the next four chapters is not intended as a comprehensive treatise. It offers a detailed working knowledge of the subject to allow investigators and craftsman to understand the fundamentals of construction and bypass. Methods of penetration, both destructive and covert, are also examined. See **LSS+/^{x} CD/ROM** for a more detailed description of bypass techniques.

CHAPTER THIRTY-THREE: SAFES AND VAULTS

The Origins, Development, and Design of Safes, Vaults, and Strong rooms

LSS101: Discussion of safe design by Bill Sherlock.

33_1.1 Introduction

Not until the late eighteenth century did the safe maker begin to incorporate significant technology to frustrate attacks of the safecracker. In **Chapter 5**, detailed information was presented regarding metallurgy and its vital role in the production of secure safes and vaults. This chapter will briefly trace the history of the modern burglary and fire safe, the origins of the safe depository, and will analyze the construction of safes, vaults, and secure areas.

A burglary-rated safe or vault, in its simplest form, is a secure enclosure that offers resistance to penetration by various forcible methods. Once containers for valuables were classified as “safes,” their craftsmen sought to create increasing resistance and obstructions to forced-entry. Manufacturers and burglars have always been at war with each other; often the safecracker having developed more sophisticated technology than the safe maker. The "modern" safe began upon its tortuous road of development about two hundred years ago, probably near Wolverhampton, England. A great deal of the credit for the modern safe technology belongs to Chubb, and thus many of their accomplishments are chronicled here.

The origins of the modern safe and vault can be traced to wooden chests created in medieval times. These enclosures were originally reinforced and secured with hammered iron bands. The

primary concerns, at least initially, were artistic rather than security. Until the introduction of cast iron chests in the seventeenth century, these containers were often covered with very fine ornamental carving.

Commercial production of safes began in Britain towards the end of the eighteenth century. Their frames were covered with sheet iron, strengthened with hoop iron, and crossed at right angles on the outside and riveted through. Safes that were produced in Europe were often made to a very high standard of craftsmanship and ornament. Often, these containers were secured with a great number of bolts: as many as twenty-four in some instances. Unfortunately, once the lock had been picked, all the bolts turned together with great ease. Until the nineteenth century, no attempt was made to make burglary resistant chests fireproof.

The reader will find interesting the description of the security requirements of an **iron safe** by George Price in his book that was published more than one hundred fifty years ago. These same criteria apply today.

33_2.1 Construction of Safes and Vaults

33_2.1.1 Introduction

Safes and vaults are containers or enclosures that have been specially manufactured and engineered to provide certain standardized measures of protection against fire and forced attack. Design is dependent upon their classification and rating. Key and combination locking mechanisms will carry their own ratings independent from the enclosure. The older safes were constructed of heavy cast iron that was riveted to steel plates. Until the beginning of this century, quantity of metal rather than quality of construction was thought to provide the best security against attack.

As our technology and knowledge of metals increased, great strides were made. Today, safes are manufactured of pressed steel or other metal alloy. Unlike their forerunners, all metal pieces are now welded rather than riveted, using tongue-and-groove construction. The metals are also able to conduct heat more efficiently. Fire resistance ratings have been refined to the point where some safes are capable of withstanding atomic blasts.

Safes are rated as to the construction of doors and walls: laminated or solid steel is most generally employed. Laminated

steel is defined as two or more sheets of steel bonded together with no other material between them. The thickness of the doors is usually considered exclusive of the bolt works and locking device. Each door of the safe is usually equipped with at least one combination or approved key lock. Steel, brick, reinforced concrete, and manganese are used in the construction of vaults to surround doors and frames.

This chapter examines the components of safes, vaults, and strong rooms, concentrating on materials, placement, and construction techniques. Ratings and classifications will also be explained. The construction and mechanical operation of combination and key locks is discussed in **Chapter 34**.

33_2.1.2 The First Safes and Vaults

Records indicate that the first significant attempts at constructing treasuries and vaults occurred well over three thousand years ago within many different cultures. For example, Ramses III of Egypt first commissioned a treasure temple to be built. The Greeks stored their State valuables in a vault protected by great bronze doors. The Chinese kept their precious items in ancient chests. The Romans initially produced chests of wood and cast iron to secure cash and smaller valuables belonging to powerful government merchants. Over time, the "technology" of building these containers became more elaborate and complicated. Eventually, the weight of the lid, with its intricate bolt works and lockworks, required a great deal of strength to lift. The early construction practices made them difficult to close.

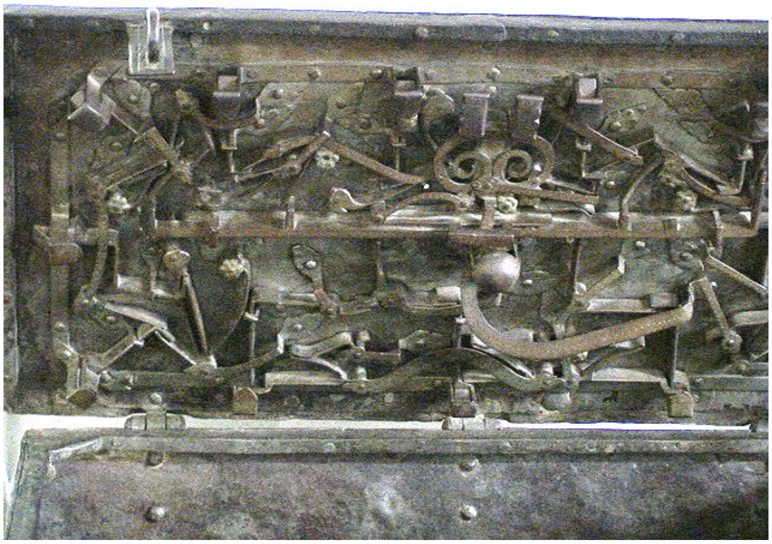

**Figure LSS+3301 A seventeenth century German strongbox, referred to as the Armada
or Nuremberg. See the link for an enhanced view of the detailed mechanism.**

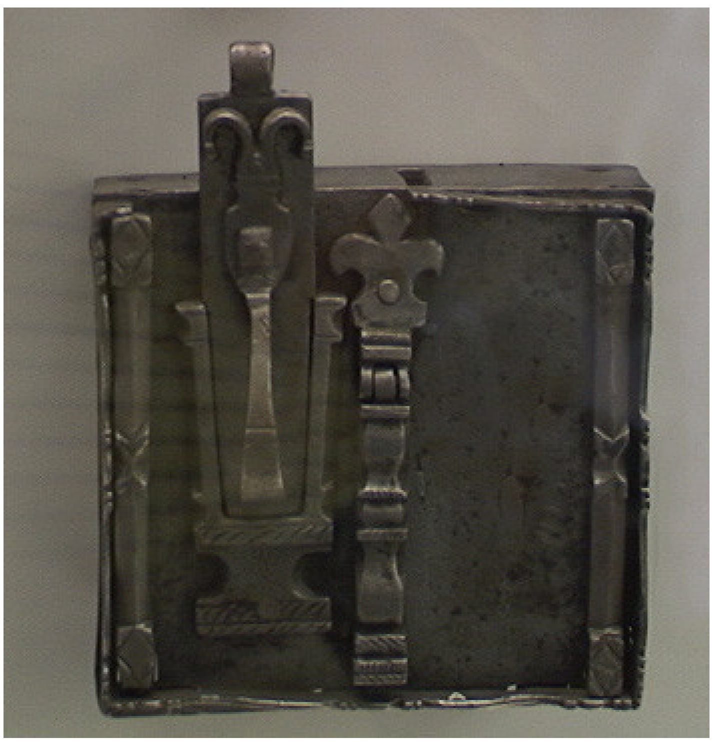

Figure LSS+3302 German chest lock, seventeenth century (left) and a French chest, sixteenth century (right).

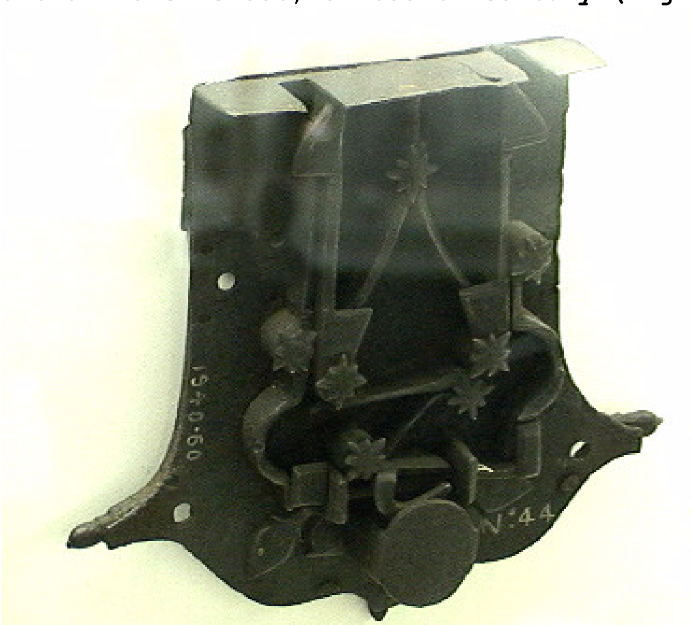

Figure LSS+3303 German chest locks, (left) seventeenth century, and (right) fifteenth century.

Necessity finally dictated that these chests were turned on their side and the lids made into hinged, swinging doors, thus creating

the first safes. These constituted an upright form of the strongbox or chest made of wood. They were lined both inside and out with iron plates held by rivets or screws. Shielded bolt works were the norm, although external hasps could also be found. These “safes” or strongboxes were first produced as a manufactured item at the end of the eighteenth century in London by blacksmiths. They were made on an individual basis using traditional metal-working techniques with quite simple specifications. Beginning in the nineteenth century, the public came to demand added security in their safes and vaults. Consequently, several companies began production of more secure safes to meet the needs of the community.

33_2.1.3 Metallurgy, Materials, and Construction Techniques

Once metals replaced wood in the construction of safes, blacksmiths and manufacturers concentrated on how to make the materials suitable for secure enclosures. As the craft of safe making advanced, metallurgy took on increasing importance and became a vital science to safe makers such as Chubb. The critical difficulty for the metallurgist has always been to produce a material which is hard enough to resist drilling and cutting, yet tough enough to withstand fracture under pressure or percussion. See **Chapter 5** for a detailed discussion.

Initially, iron was the predominant metal used in the production of safes and vaults. Then, carbon and iron were combined to produce steel. As the industry became more sophisticated, steel was mixed with metals that are more exotic, such as manganese. These would add special characteristics of strength, heat transfer, and drill resistance. When first introduced, iron ore was heated with charcoal to produce a spongy material that could be hammered into shape. Next, blast furnaces were developed that were equipped with bellows. These were utilized to blow air across the metal, allowing iron to be poured as a liquid called pig or cast iron. The problem with the new material was that it could not be hammered because it would shatter. It had to be poured or molded.

The availability of charcoal was responsible for Abraham Darby developing a smelting procedure with iron and coke at the beginning of the eighteenth century. A cheaper process, it made mass production possible. Puddling was the next advance. It was the outgrowth of smelting and produced wrought iron using a more sophisticated system and higher temperatures. Wrought iron was a

tougher material, would withstand stresses, and could be forged or hot- rolled into plates and strips. The technique was utilized by safe makers until the middle of the nineteenth century.

In 1856, Henry Bessemer developed a method to produce steel for a small fraction of the prior cost by blowing air through molten pig iron. In 1860, Chatwood the English safe maker took two sheets of iron and sandwiched molten metal between them. The effect of this innovation was that the center was extremely hard and would shatter or flatten drill bits. This was a much better solution than simply multiplying the number of iron sheets, as had been the practice until that time. The technique resulted in rolling high carbon steel to mild steel. This sandwich approach resisted cutting and torching.

Copper plates were located between the steel plates as a conductor of heat. This effectively prevented the steel barrier behind the layer from reaching melting point. Layers of metal were added for security and to perform secondary functions. Many grades of steel have been developed for use in safes. All are based upon the amount of carbon and temperature when added. If one percent carbon is present, the steel is three times stronger than iron. More carbon causes brittleness. The mixture can be finely honed for custom requirements. The addition of more than 2.5 percent carbon will produce cast iron.

As explained in **Chapter 5**, the relationship of temperature and carbon content is critical to the production of steel for use in safes. The needle demonstrates the salient characteristics. If a needle is heated to red-hot then cooled quickly in water, it will break easily but will be very hard. On the other hand, if it is heated then cooled slowly, it will bend like wire. This is known as tempering. It may occur many times by reheating to red-hot, cooling rapidly, reheating to a yellow color and then cooling slowly.

The surface of the material can be treated by a process known as **case-hardening** by increasing the carbon and nitrogen at and below the surface. This technique yields the strength of low carbon-steel with a very hard surface. Special alloy steels, such as stainless, can also be produced for hardness, strength, springiness, and resistance to wear and corrosion. In 1882, it was discovered that steel containing one percent carbon and thirteen percent manganese could be very tough if heated to 1,000C and quenched in water. It was only medium hard, but when

heated would become extremely hard at torch point. This combination prevents sawing, drilling, or filing, and is used today in prison bars and shells of safes.

Safe makers have utilized and developed many sophisticated combinations of metals to increase the security of their products. These materials are employed in the walls, doors, and internal areas of safes and vaults, depending upon burglary and fire resistance ratings. In one Chubb high-security safe door for example, there are ten layers of metal having the following configuration:

1. **Five-ply drill-resisting steel;**
2. **Two of these layers protected by three sandwiches of softer steel;**
3. **Anti-blowpipe material that is a form of concrete and hard mineral chips, with an embedded "I" section steel joist;**
4. **Layer of Siemens steel;**
5. **Layer of copper;**
6. **Five-ply layer of steel;**
7. **Proprietary alloy steel;**
8. **Two layers of Siemens steel;**
9. **Five-ply layer of steel sandwiched between the Siemens layers;**
10. **Anti-concussion spring diaphragm plate.**

Safe engineers must consider many design parameters when producing specialized materials for use in their products. However, their ultimate goal is always the same: prevent penetration, alteration, and compromise of the molecular structure of the materials. Three simple examples can illustrate design characteristics that can be accomplished through metallurgy:

- **Torch resistance must extinguish the flame or spits metal to make cutting very difficult;**
- **Metal in a crystalline form, called speigeleisen, has been used as a layer in a laminate to retain its hardness when heated. If an attempt is made to drill when this material is heated, the drill bit would immediately lose its temper, preventing further penetration;**
- **A drill is a cutting device that works through a process of detempering of the material it is acting**

upon, through reheating and slow cooling. A safe maker will add beryllium and copper layers as heat sinks so that the temperature required for softening cannot be achieved.

33_2.1.4 The Technology of Safes in the Eighteenth Century

From the archives at Chubb, the difficulties of making a secure safe are chronicled beginning in the late 1700s. The safe makers of Chubb and other companies experimented with many different metals, attempting to exploit their characteristics in an effort to stop the safecrackers from achieving their goals. By the middle to late 1800s, safecracking had reached what was considered to be state-of-the-art. Thieves had developed powerful tools, explosives, and various methods for forced-entry. For each advancement that was incorporated by a manufacturer, the safecrackers developed countermeasures.

The second half of the nineteenth century saw the introduction of many innovations by Chubb and other safe makers. They produced containers that afforded more protection from fire and burglars. During this time, the outer doors of fire safes were made of rolled iron or steel, while the inner portion of the door and frame were constructed of cast iron. Burglary safes contained steel plates with different hardness ratings, while joints were covered with forged bands. Drill-resistant metals were developed, such as cast metal and speigeleisen. These were capable of being chilled between outer and inner plates, forming walls. Solid blocks of chilled iron, no less than a foot thick, were grooved, keyed, or bolted together. Each manufacturer developed preferences in safe technology. Thus, Chubb chose to use layers of hard and soft plates, and high-carbon steel welded and rolled between layers of iron or mild steel. The high-carbon steel would provide resistance to cutting tools, while the softer metal would contribute to toughness.

33_2.1.5 Chubb: The First "Modern" Safes

In 1835, Charles Chubb patented his first safe. In that design, he improved upon both the fireproofing and burglarproofing of existing containers. The patent was for "Certain Improvements in the Means of Making Secure Receptacles for Property, such receptacles being either fixed or transported and being such as are usually called Strong Doors, Safes, Chests and Boxes." The early Chubb safe offered significant refinements for that era.

Case-hardened (carburized) or tempered steel plate was added to interior surfaces to increase protection from boring and drilling. In his specification, Charles Chubb used a strong box with side handles and a lid to illustrate his invention. He very quickly distinguished between fireproof wrought iron boxes and plain wrought iron safes in his sales literature. Soon, the safe changed in character from being an iron box mounted on its side, to being a receptacle in its own right.

In 1857, John Chubb received a patent for an improvement to prevent burglars from drilling a hole in the iron plate covering the safe lock. A steel plate was added to the lock cover that would damage the burglar's drill bit and prevent them from gaining access to the levers. Then, in 1865 and 1866, patents were granted to strengthen safe frames and bolt holdings. In addition, Chubb also introduced diagonal bolts that helped to prevent door frames from being bent outwards, which previously had allowed the door to be opened.

In 1874, Chubb's new 'Tee' iron safe was patented. This greatly increased the security of fireproof container construction by making it more difficult to remove the back of a safe and impossible (with the tools then at a burglar's disposal) to remove the inner lining and casing. Until the 1880s, safes were manufactured by constructing an angle iron frame to which metal sheets were riveted. Beginning in 1878, Chubb experimented with metal plate bending. At that time, a great deal of attention was directed to the fastening and securing of doors within the overall frame and housing. Cast iron doors and bodies appeared in the nineteenth century. Containers were later produced of rolled iron, then steel, as the science of metallurgy developed.

Many different boltwork schemes and designs were developed for security, including claws, clutches, hooks, screws, and interlace with the frame. The goal was to form a complete dovetail when door and frame would meet that would hold them together against any form of wedging. Chubb also provided extra security measures to further frustrate burglars. Options included electric burglar alarms, time locks, and keyless permutation combination locks that rendered gunpowder attack futile.

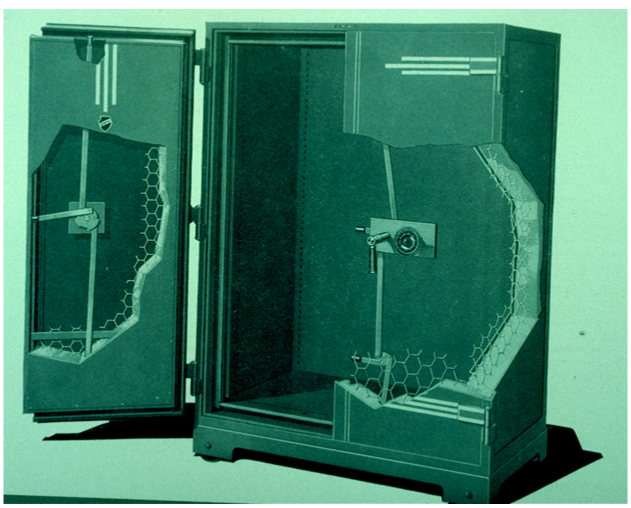
33_2.2 Development of Safes in the Twentieth Century

Directly because of the high number of safe burglaries in America, the U.S. Congress authorized the Secretary of the

Treasury to appoint a special commission to determine the best methods for safe and vault construction. This was the first effort to improve the security of safes used by the treasury, and occurred over a century ago. Experts hired by the Commission conducted exhaustive tests of all major safe brands. Their conclusion was less than assuring. The state of safe making in the United States was poor in terms of resistance to attack. In fact, it was determined that only the Corliss cannonball safe was secure because it was cast in the form of a sphere. One hundred years later, these safes are still found in courthouses throughout the United States.

The high incidence of attacks on safes and vaults both in the United States and in Europe provided the impetus for significant advances in the security of containers during the twentieth century. This need converged with improvements in metallurgy and manufacturing to foster the development of high-security containers. The efforts of safe makers for the past century to make a secure enclosure have primarily focused upon materials and techniques to prevent or delay physical access to locks and bolt works. They have concentrated on means of penetration using drilling, explosives, and the use of high temperatures or temperature differentials.

Early on, metallurgy became a vital science to safe makers. Advances in the science have produced sophisticated and complex barrier materials to meet the constant and difficult challenges presented by the safecracker. There is one essential theory of metallurgy that applies to safe construction: materials that are hard and strong are also brittle and will crack under repeated shock force. That principle has spawned two hundred years of research and innovation by the major safe manufacturers of the world.



Until late in the nineteenth century, limited materials and processes were available for producing and treating iron and steel; safe makers faced many difficulties in finding materials that would resist heat, concussion, and other forms of physical attack. In 1912, Chubb introduced anti-blowpipe metals into the body and doors of their safes, increasing resistance to attack by drill and oxyacetylene. Then in 1930, solid proofing material was first used in their containers.

It appears that Chubb and other companies introduced relockers during the 1930s. These devices would frustrate a safecracking technique using explosives or blowpipe to blow apart the lock. In

1959, Chubb introduced anti-arc alloy into safe doors as protection against oxy-arc cutting. This was followed in 1962 by the development and introduction of TDR (torch and drill-resisting) alloy. During the 1970s, new protective materials were introduced, based upon specially engineered concrete compounds that combined thermal strength and toughness with drill resistance. Advances in boltwork designs were also developed during this period.

Today, safes provide a high level of security based upon the design of their locks and advances in metallurgy. Although it is still possible to penetrate hard plate and outer barrier materials, the task has been made measurably more difficult through innovations in chemistry, physics and mechanical engineering. Locks can still be opened through manipulation, robot dialing, and drilling, but the requirements of commerce and security now offer a level of protection heretofore unmatched.

Within the category of burglary resistant safe, there are many different designs. These are shown below, and detailed in **Chapter 35**, with regard to their vulnerability and methods of attack.

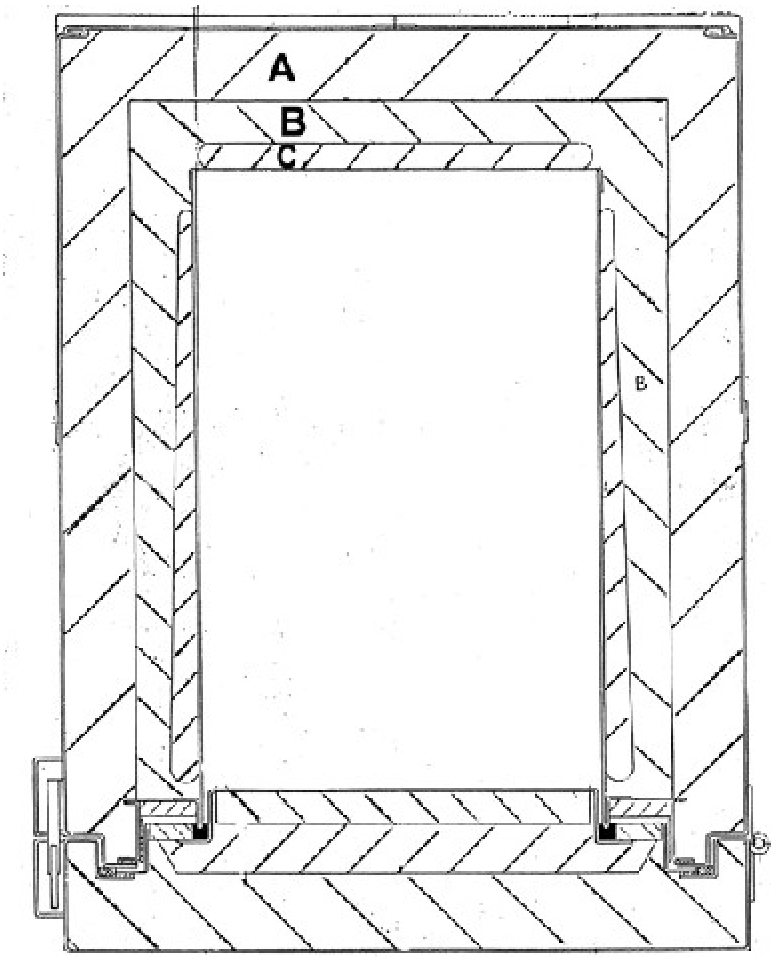
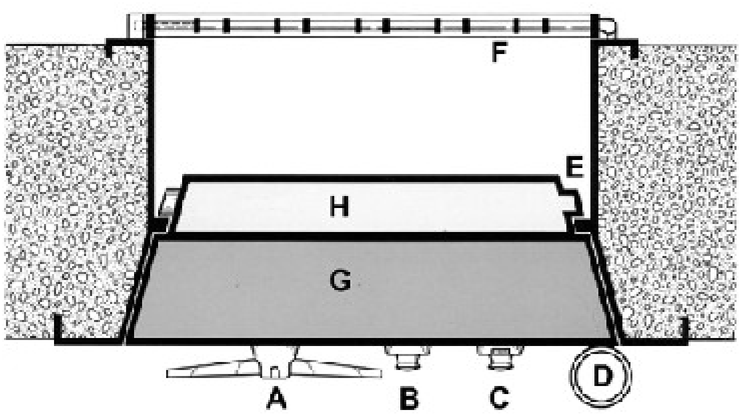
33_2.2.1 Vault Doors



Vault doors are but an outgrowth of a self-contained secure container; they provide the barrier for access into a larger

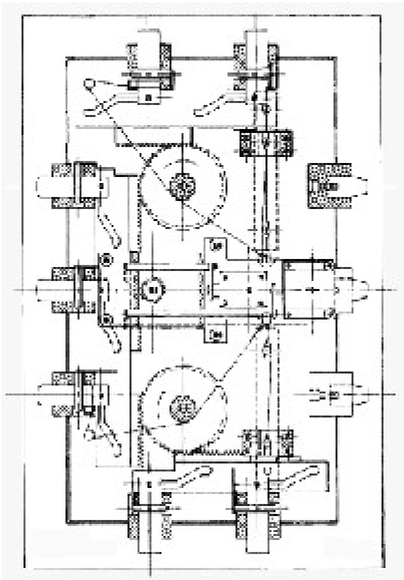
area. Found in office buildings, warehouses, and other secure areas, they are nothing more than a larger version of fire-resistive or free-standing plate door safes. Vault doors are classified for either fire or burglary. The fire ratings start at one hour and increase to a two- four- and six-hour protection. An additional distinction relates to how doors are set at the entrance to the strong room.



The doors that are set in the vault entrance are of the **grouted** or **non-grouted** type. Grouted door frames are set, then concrete is poured around the frames. Non-grouted doors are not permanent parts of the building and can be removed. If the building settles, the doors can be readjusted. Often, this is preferable because installation costs are reduced. The appearance of these doors can be misleading; bigger does not necessarily mean better or more secure. Penetration or bypass techniques are essentially

the same as with traditional safes because the construction methods are similar.

Generally receiving a “B” security rating, burglar-resistant plate doors will often have a maximum 1/2" thickness. Although "TL" rated doors do exist, they are quite rare. GSA rated doors in government facilities will often have added hard plate, relocking devices, or unusual lock positioning, making penetration extremely difficult for both the burglar and safe technician. Health and safety codes now require all vault doors to be equipped with an internal release to prevent users from being accidentally trapped within the vault. Releases can take many forms, depending upon manufacturer. They include push-in plunger, panic bar, and direct-drive handles. An internal release may also provide another method to open the door in the case of a lockout. For example, a stiff wire placed through a small hole can release the mechanism.



33_2.2.2 Bolt works

Safe and vault doors employ simple to extremely complex boltwork schemes in order to interlock moveable components to the body of the container. Multilevel and four-point systems will provide positive locking completely around the door. The bolts are usually interconnected to a series of deadlocking relockers.

33_2.3 Secondary Protection of Safes and Vaults

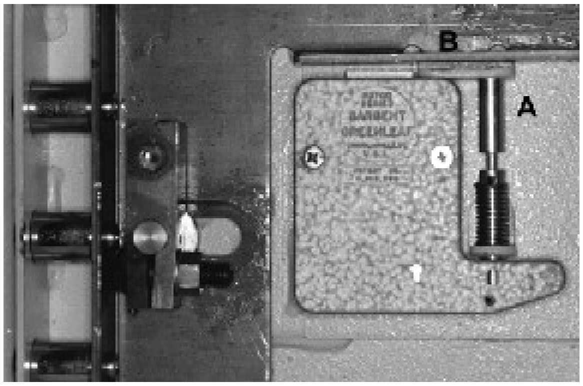
Secondary protection of safes and vaults can be incorporated through a variety of devices and techniques including tear gas and other noxious gasses, glass plate, thermal transfer materials, and relockers. Their use is often dictated by the security rating of the enclosure and price. Each technique is described in the following sections, with special emphasis on relockers.

33_2.3.1 Tear Gas, Noxious Fumes and Marker Gasses

Tear gas ejection devices are routinely incorporated in certain high-security safes. Generally placed behind the spindle, they will trigger upon impact. Materials may also be embedded within barrier layers to give off noxious gasses when heated by a torch or lance. Chubb and other companies also include materials that will generate markers in the form of dense colored smoke. This will make working on the safe almost impossible and will leave residue on anyone that comes into close proximity with the enclosure.

33_2.3.2 Glass Plates

Specially engineered glass panes made of Herculite or similar material, together with deflection, plates are placed in front of the combination or key lock to deter drilling attempts. In high-security safes, plates are located on all six sides to block penetration from any angle.



Glass is connected to tensioned **relockers**, discussed below. When shattered, the glass disintegrates, causing relockers to fire. This will make actuation of the bolt impossible without release of the relocking mechanism. Explosions, point-source concussion (such as from a drill point), and excessive vibration will break the glass and trigger the relocker.

33_2.3.3 Thermal Transfer Materials

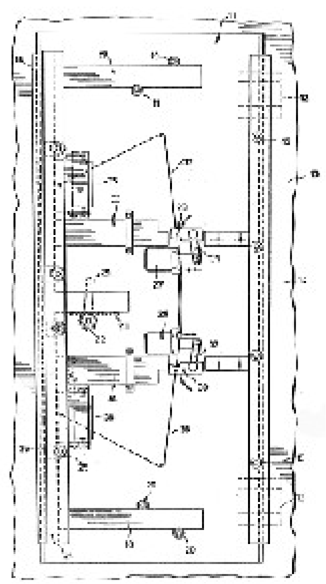
Sophisticated heat sinks are embedded in the barrier materials of the more secure safes. Layers of copper, beryllium, aluminum, and other metals are utilized to rapidly conduct heat away from a target area. Their function is to reduce the surface temperature below melting point to prevent cutting by a torch.

33_2.3.4 Relockers

When they are triggered, **active** and **passive** internal and external relocking devices are utilized to permanently lock the bolt-release mechanism. They are incorporated within combination and key locks and throughout the boltwork mechanism of all modern safes.

They are designed to protect against the following forms of attack:

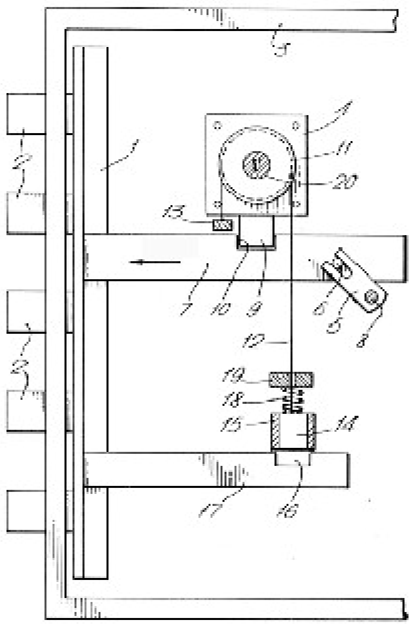
- **Punching the wheel pack;**
- **Drilling;**
- **Side-pressure of the bolt;**
- **Thermal attacks;**
- **Vibration and concussion.**



When "fired," a relocker will lock the bolts, throw extra bolts, drop deadlock pins into place, or disconnect the links to bolts from an actuator.

The design of a relock trigger requires that it be reliable for the lifetime of the safe. It must not be too sensitive or insensitive, and cannot be complex or delicate. It must be capable of surviving the normal vibration associated with door openings and closings and it must be rapid reacting. Complex

relockers are constructed with tensioned tourmaline line, connected to secondary bolts and some sort of sensor. As described above, sensors may consist of Herculite glass, weights, spring-loaded levers, pivots, or metal strips that are thermally activated.

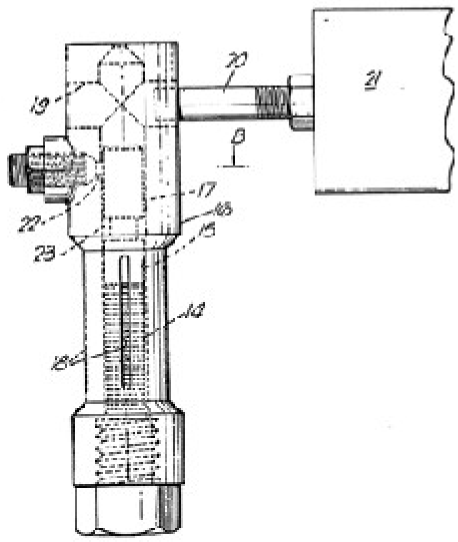


33_2.3.4.1 Relockers on Safe Locks

Internal relockers are mechanisms that deadlock the bolt, thereby isolating it from the wheel pack. The removal, distortion, or destruction of the lock cover or wheel pack usually activates them. Lock case relockers were developed in response to a common burglary technique in small safes that involved an attack upon the lock by punching. This method required that the dial be knocked loose and then the spindle to be driven into the safe and through the lock case. The wheel pack would be removed, thereby eliminating the fence-gate relationship. Using a wire tool, this technique allows the bolt to be retracted through the spindle.

Relockers may be rudimentary or complex in their design and function. Removal, damage, breaking of the lock case cover, or distortion of the wheel pack will prevent the bolt from being withdrawn. The action will cause the trigger to spring outwards, forcing the opposite end to enter a recess in the lock bolt thereby deadlocking it. This design is based upon a simple lever pivot retained by the position of the lock case cover. So long as the cover is loose, the relocker will be engaged. In the more sophisticated design, simply replacing the lock cover will not

reset the device because the relocking pin operates independently of the trigger. A lock within which the relock trigger has fired will allow the combination to be dialed, but will prevent the dial from retracting the bolt.



There are many designs for internal relockers within lock bodies. Depending upon the manufacturer and vintage of the mechanism, these can appear as a brass tab (Yale), a formed wire (LaGard), a pivoting lever (S&G), and a spring-loaded pin (Mosler). Whichever design is adopted, the primary function is to prevent the bolt from being retracted. Manufacturers will generally place **lock case** relockers in one of two positions:

- **Within the lock case. They are activated by the breaking or removal of the wheel pack, complete lock, or handle shear device;**
- **Within the door. They are triggered by breaking or removal of the lock case cover.**

If the lock cover becomes loose or detached from the case, a lockout problem will exist that can be extremely difficult to solve. This condition can occur from normal opening and closing of heavy vault doors. A more detailed discussion of combination

lock relockers is presented in **Chapter 34** and disclosed in several U.S. and British patents. See U.S. Patents (**4266488(370)**, **4470275(371)**) and British patents (**2172931A(372)**, 2179094A, **2241983A(373)**, **2119011A(374)**, **2069589A(375)**, 2114649A).

33_2.3.4.2 Thermal Relockers

Thermal relockers make inoperable the bolt-release mechanism upon the application of heat to the walls of a safe or its lock. Materials that are sensitive to rises in temperature are employed to release tensioned mechanisms, thereby triggering various relockers. The **thermal link** or **fusible link** is activated by a rise in the internal temperature of the enclosure or of the barrier material. A "fusible link" consists of two overlapping metal pieces that have been bonded with low-temperature solder. A ring is formed on each end of the link. One end is attached to the target area of the combination lock or barrier material; the other to a rod, wire or chain that is in turn connected to a remote relocker. The link will retain a spring-loaded bolt that, if activated, will block action of the primary boltwork. Heat above a predetermined threshold level (release temperature) at the target point will cause the solder to melt, firing the link. Fusible links can be installed anywhere within the door.

33_2.3.4.3 External Relockers

External relocking devices outside the lock case will deadlock the bolts or bolt- retracting assemblies, or directly act as secondary bolts to secure the door. Most relocking mechanisms,

by whatever name, are spring- or gravity-activated bolts or bolt blockers placed in critical locations within the container. They may be connected to the lock case, handle, walls, or glass panels.

The glass plate relocker is activated by shock, vibration, or point source pressure caused by drilling. The specially formulated glass in some ways resembles the type used in automobiles. Panes are placed in front of the lock case and are anchored in flexible rubber grommets. These are utilized to minimize the potential for fracture in normal use. Tensioned wire or string is attached to the glass plate. So long as these wires are spring-biased, the relockers will be held in position, thereby inhibiting their plungers from being released. If the glass is chipped, scratched, subject to excessive vibration or pressure, or is contacted by a moving drill point, it will shatter into minute fragments.

33_2.3.4.4 Handle Shear Pins

Handle shear pins are another form of protection used in conjunction with relockers. They are designed to break loose and disengage the linkage if excessive force is applied. The handle shaft is also purposefully weakened during manufacture, so that it will break if too much torque is applied.

33_2.3.4.5 Bypassing Fired Relockers

Relockers are designed to offer anyone attempting to penetrate barrier material a great deal of difficulty. They are intended to cause substantial delays to both the safe technician and burglar. In the higher quality safes, there may be several different types of relockers randomly placed. The author’s rule: if not sure of the type or location of a relocker, don’t drill or take any action that may trigger a device.

Relockers can be bypassed by drilling at a precise location that will allow their retraction. Generally, a template is required for accuracy in result. Based upon their design, the drill point locator for the trigger should allow for the disengagement of the mechanism by either pushing or pulling.

33_2.4 Safe Classifications and Ratings

Safes can be categorized as either fire or burglary resistant. Fire safes will protect the contents against destruction from

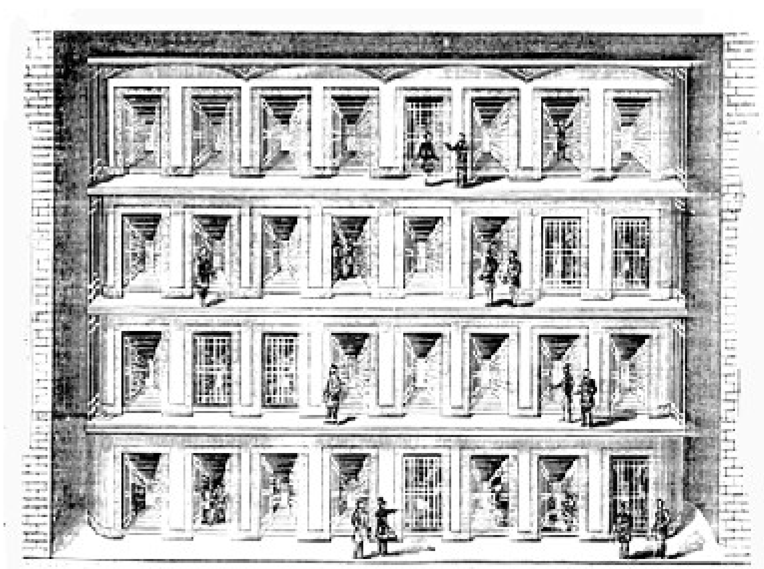
heat; burglary, against unauthorized access. Some safes also have both fire and burglary ratings, but generally there is a compromise in characteristics. A safe utilizing plastics has been developed by Chubb to provide both forms of protection. Although Chubb was awarded the first patent for such materials, there will doubtless be others in the future. See **Chapter 37** for a more detailed discussion of ratings and classifications.

33_2.4.1 Fire Ratings

Fire ratings are based upon temperature and time: the likely maximum temperature to be encountered and the time until the fire will be extinguished form the primary guidelines. The internal temperature of the safe, based upon these two parameters, will determine which materials can be stored within. Underwriters Laboratories provides ratings based upon three primary tests: **endurance**, **impact**, and **explosion hazard**.

33_2.4.2 Burglary Ratings

Underwriters Laboratories and other world testing organizations have developed comprehensive standards for testing locks and safes against both forced and surreptitious entry. Safes are rated for their resistance to torch, tool, and explosive attack in terms of time and sophistication of required equipment. Locks are classified as to their resistance to forced-entry, manipulation, and other forms of bypass.



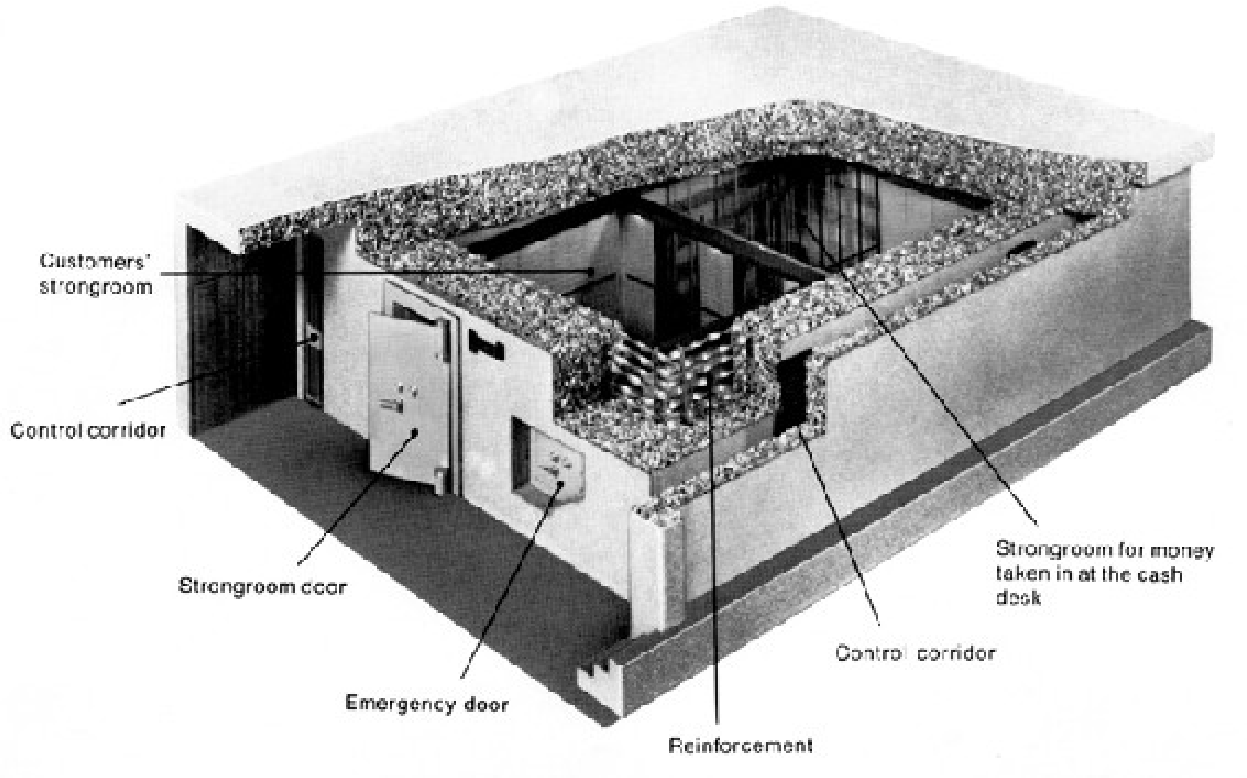
33_3.0 Safe Depositories, Strong rooms, and Vaults

33_3.1 Introduction

In the medieval period and the Middle Ages, owners of property would conceal their valuables behind thick stone walls made inaccessible with a wide and deep moat or in cellars protected by hardwood doors. In the United States, valuables were placed below ground. The development of safes and strong rooms is also traced by George Price in **Chapter 8**. The idea of the safe depository was conceived and first introduced by Francis Jenks in New York. By 1861, he obtained a charter for the "Safe-Deposit Company of New York" that was to eventually become the National Safe-Deposit Company of America.

The initial design for vaults required that they be placed underground and have thick brickwork and sheets of iron as a lining. The next progression involved the same methods of assembly but with improved components. The American Hough and Harper Vault, in the 1880s, for example, used chilled iron from blocks weighing 1,700-10,000 pounds each. These were dovetailed together on each edge and set in a granite base bound by steel rods. Within a quarter century, this construction technique was made obsolete by the advent of the oxyacetylene torch.

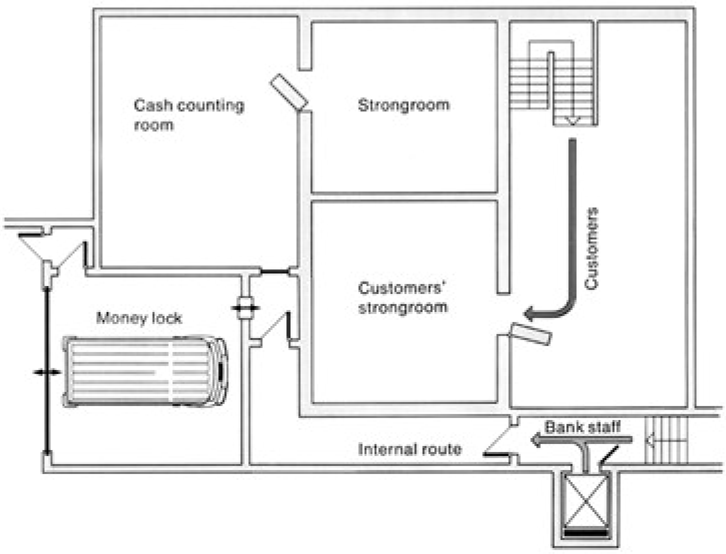
By 1870, the safe-deposit concept appeared in Britain; the first company was the National Safe-Deposit Company on Queen Victoria Street in London. Requiring seven months to construct, there were thirty-two separate vaults located on four floors. The bottom level was forty feet under the street and had thirteen feet thick outer walls and layers of sheet steel. The hydraulically-operated doors were a foot thick and weighed five tons.



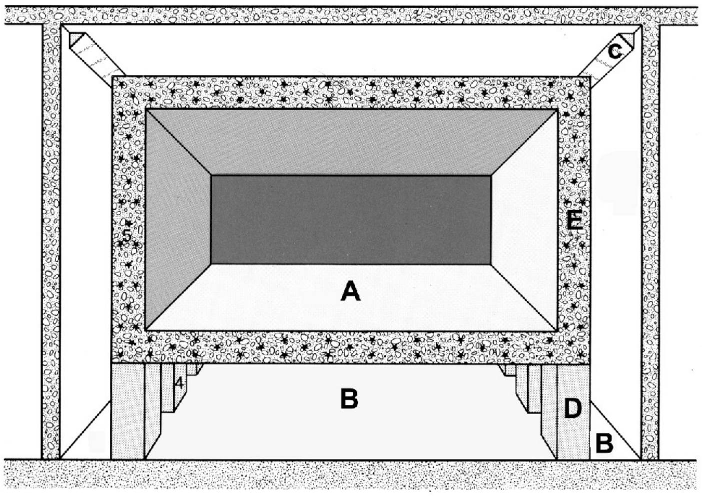
In the 1880s, safe depositories were quite popular. In Chancery Lane for example, there were 40,000 separate lockers. Generally, safe-deposit companies would associate themselves with safe makers. By the 1890s, Chubb was the major manufacturer in Britain of safe-deposit vaults and strong rooms. Today, the rental of safe-deposit boxes is one of the primary services offered by banks. The rise in popularity of safe-deposit vaults can be traced to the economic growth and changes in society that allowed the individual to accumulate wealth. It was not until the 1890s that banks actually got involved in providing this function to

their customers. Today, virtually every financial institution contains a safe-deposit vault.

33_3.2 The Modern Strong room

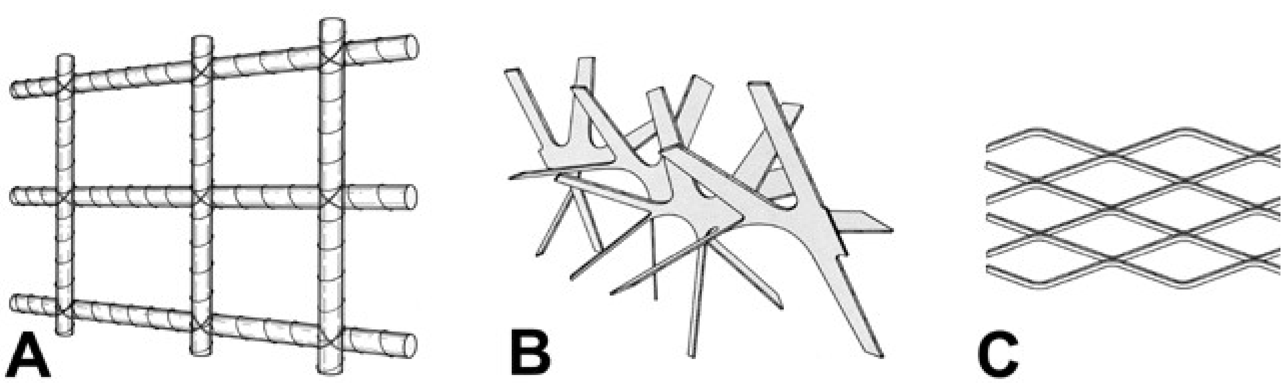


A strong room is nothing more than a large safe with every individual element magnified in its design. They are primarily required to protect high-value items such as gems, trade secret information, magnetic and optical media, precious metals, company data, and cash.



The walls, doors, locks, and defensive systems must be engineered to withstand a prolonged professional attack, as well as war or natural disaster. Interestingly, only one vault has been tested and survived against atomic blast. The strong room at the Teikoku Bank in Hiroshima was close to the center of the explosion and yet remained intact.

The level of security of a strong room is based upon the value of the contents. Even the most secure strong rooms can offer limited resistance against sophisticated burglary tools, such as diamond-bitted drills or oxygen lances. The entrance to a strong room must be massive, and have an extremely precise and tight mating between doors and frame. Doors may weigh up to thirty tons and are often two or more feet thick. Often circular in shape, their tolerance will allow zero gaps to achieve a tighter fit. They may also be rebated, having an interlocked tapered zigzag pattern. Most modern doors use the “plug” technique rather than stepped.



Generally, the newer vaults will utilize two locks and a time lock. Many will also have two doors. See **Chapter 34** for a detailed discussion of combination locks. Walls are designed and constructed based upon perceived risk: fire or burglary being the prime consideration. Construction techniques generally call for multi-ply walls consisting of brick or concrete, reinforced with steel bars. A second ply will generally consist of open-hearth steel, which is itself protected by yet more layers of chrome steel and flame-cutter resistant materials.

The specially formulated concrete used in vaults is usually a minimum of 18” thick and can take up to one year to cure. Simple concrete is not secure and can be penetrated by pickax or drill. Chips of hard stone or metal are often embedded in the mixture in order to deflect and break drill bits.

Concrete must be reinforced with steel for strength and rigidity. Regular steel rods are generally too thin and widely spaced to be effective barriers; their size makes them easy to cut. Initially, "I" beam girders such as railway steel from tracks was utilized in a close pattern, resembling a fence. Twisted bar with two kinds of metal were subsequently employed. This consisted of mild steel rapped around an anti-blowpipe metal core. The improved configuration offered more protection against penetration.

The concrete and reinforcing material must be intimately mixed to form a unified body. Ideally, the steel must present a number of surfaces that form a perpetual recurring obstruction to penetration. A basket weave pattern created between steel and concrete is usually the most effective.

Strong rooms will also contain an elaborate framework of steel

girders. These are often placed in H sections, interlocked, and embedded in concrete and are designed to provide the maximum barrier to penetration. Sophisticated alarm and constant monitoring capability is also required.

During construction, the vault is often finished first, then the protecting structure built around it. Vaults should be considered a separate entity, completely self-contained and independent. They should not be relied upon for structure or support.

33_3.2.1 Designing New Strong rooms

Critical considerations for the design of any strong room include:

- **Location of the building;**
- **Position of the strong room within the building;**
- **Size and type of the strong room;**
- **Supervision and security.**

33_3.2.2 Location of the Building

Proposed sites must be evaluated with respect to their proximity to underground galleries or shafts, because subways or sewage systems can provide a relatively safe access point for attack. Construction sites or businesses located near the vault where oxygen cylinders or heavy tools could be utilized for penetration may constitute extra risk. Particular attention to surroundings is required where vaults are to be built in remote areas. If an underground garage is located next to a strong room, care should be taken that no cars are parked there at night. If that is not possible, then parking should be forbidden in the area around the strong room. If it is impossible to avoid positioning a strong room beside, above, or below rooms that are used by other persons or entities, then access to these areas must be guaranteed by security staff, and electronic monitoring should be in place. No power or water supply should be available in the immediate vicinity of the strong room that would make it possible to use heavy penetration tools.

33_3.2.2.1 Placement of the Strong room within the Building

Generally, strong rooms are constructed on the lowest floors. The

precise location is based upon many factors including expediency, security, building material specifications, and cost.

33_3.2.2.2 Expediency and Convenience

The shortest transport routes for cash and other valuables will often dictate the position of the strong room. Movement of materials should never leave the protected area of the vault. Thus, access to counter areas and other internal cash transport routes, customer safe-deposit boxes, and other secure areas will determine where the strong room is to be located. Proper design requires that all areas wherein cash is transported, counted, accessed, dispensed, or stored should be next to the strong room.

33_3.2.3 Construction Requirements

The floors and walls in most facilities simply cannot meet the physical requirements of a strong room. In the properly engineered installation, strong rooms are usually placed on supporting columns to insure structural integrity. The alternative requires that they be sunk into the groundwater or built on solid rock. The security offered by ground water should not be overestimated, as the conditions can change based upon many man-made or natural causes. The outside walls of a building or of adjacent buildings should never be utilized as the primary barrier for the vault.

33_3.2.4 Security Considerations

All sides of a strong room should be capable of supervision and monitoring. Rooms adjacent to the strong room that are not permanently occupied pose a security risk, because they are good places for initiating break-in attempts. These include filing offices, closets, or maintenance rooms for air-conditioning and heating equipment.

One unique approach to this problem involved the placement of a strong room onto the facade of a high-rise building. The wall that formed the entrance to the strong room was part of the façade; the rest of the enclosure was constructed to hang in the air. Only one wall could be tackled from within the building; all other surfaces were situated in the air and could be seen from every side.

33_3.2.4.1 Security Analysis of Existing

Strong rooms

It may be prudent to analyze existing strong rooms to assess their security. This should only be attempted with a full set of blue- prints and building plans. Special attention must be paid to older buildings, because early construction techniques often called for the use of brick or quarry stone. These materials and the procedures for making joints are totally inadequate to protect against modern burglary tools.

Security may be enhanced by inserting new walls, floors, and ceilings of prefabricated concrete blocks that can be linked together to form secure barriers. Generally, an old strong room that has been upgraded will require a new door. Determine if there are other unsecured doors leading into the vault. Attention must also be paid to openings that have been covered with concrete or lined with building material.

Access routes must be carefully evaluated, especially those that are adjacent to strong rooms. Likewise, the storage of tools near vaults should be discouraged. Finally, alarm systems that were installed years ago should be analyzed in terms of modern bypass techniques.

33_3.2.5 Size and Design of the Strong room

The strong room should be designed of sufficient capacity when first constructed so that later expansion is not necessary.

33_3.2.5.1 Openings in Walls

The number of openings in the walls must be as few as possible. These generally include:

- **Doors (the number is dependent on the demands of organization);**
- **Emergency doors;**
- **Ventilation openings;**
- **Deposit tubes of night safes.**

33_3.2.5.2 Strong room Secure Areas

Several secure areas are usually incorporated within strong rooms:

- **Areas for money received at the cash counter; Secure areas for money taken in at cash counters usually only need one door. Where strong rooms are also used by customers, they should be separate from other areas, both physically and in terms of access routes. The use of alternative transfer methods such as money lifts is not recommended because they offer additional openings and the potential for compromise.**
- **Customer safe-deposit vault;**
- **Special rooms, such as a silver chamber;**
- **Receiving-safe of the night depository;**

Special precautions must be taken to ensure that the deposit shoot that is connected to the outside opening of a receiving safe or night depository cannot be attacked or bypassed.

- **The receiving safe should be located in the strong room to store money taken in at the cash desk. A safe with an adequate security rating should be utilized.**

33_3.2.5.3 Control Rooms and Corridors

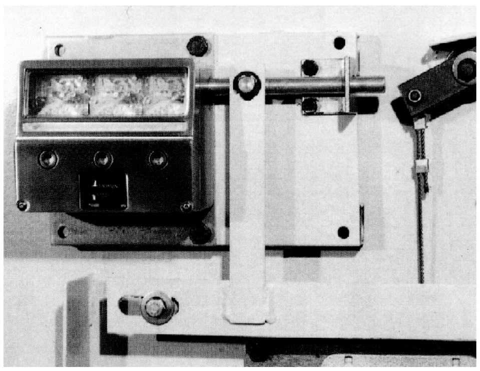
Constant monitoring of floors and ceilings and observation from all angles of all outside surfaces of the strong room must be possible at all times. If after an alarm has been activated there are no traces of a break-in within the interior of the strong room, control corridors make it possible to check the outside surfaces.

In order to expedite observation, the strong room is usually built on supports with floors forming the ceilings for the room below. Monitoring should also be possible in spaces between floor and ceiling, especially if the room above is not utilized by security cleared personnel. Control corridors are placed between strong room walls and outer barriers. In such cases, the outside walls should not have the strength of the interior, so that they will yield to hydraulic pressure in case of an attempted penetration. The width of control corridors should not exceed 600 mm; narrow spaces make the use of power tools difficult.

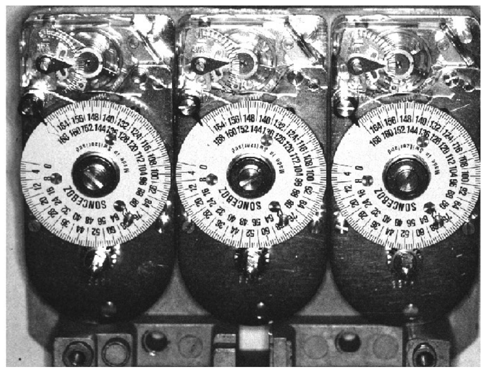
33_3.2.5.4 Walls, Floors, and Ceilings

Burglars will generally direct their efforts to walls, ceilings, and floors rather than vault doors due to their inherent strengths. Thus, each must be sufficiently secure in their individual design and construction. The thickness of strong room floors and ceilings must at least be equal to the walls. The doors should be at least fifty percent as thick as walls. Modern installations generally require concrete whose absolute minimum compression strength is at least 450 N/cm^2 after twenty-eight days. In some jurisdictions, government agencies recommend 600 N/cm^2.

Additives may increase the strength and physical resistance of concrete. Steel splinters, plastic threads, and other materials can provide greater flexibility. They will prevent the immediate destruction of the structure when explosives are employed. They can also protect the material from being destroyed by power tools such as hammers, chisels, hydraulic spreaders, and paving breakers. If properly engineered and implemented, such precautions can offer significant resistance to most cold tools with the possible exception of a diamond-bitted core drill. However, such measures will afford no protection against thermic lances and in fact can enhance their ability to vaporize the material. Reinforcement is frequently embedded in the innermost section of the strong room wall to minimize this threat.



33_3.2.5.5 Strong room Doors



Doors to vaults and strong rooms must have at least the same strength and penetration resistance as that of the outer walls. Doors are generally laminated with many layers of different materials, each to present a barrier against a specific form of attack. Cold tools, torches, lances, drills, and concussion are all considered as threats.

Doors should be equipped with at least two separate and independent acting locks and further protected by a time lock. This design will generally prevent a lockout. Time locks, as detailed in **Chapter 34**, will usually contain three separate movements. Any one of them will release the boltwork. Generally, if a lockout does occur, penetration is accomplished through a wall rather than the door, using core-drilling equipment. Once a breach is made, the door will be opened by a safe technician from the inside.

33_3.2.5.5.1 Time Locks

Time locks disable or block the boltwork within specific timing parameters. When activated, the locking mechanisms cannot be opened, even if the correct combination or key is utilized. There should be no bypass available within the time lock in order to prevent hostage-taking and other means to circumvent the safeguard. During normal business hours, day doors and day locking mechanisms are utilized to provide a lower level of security.

33_3.2.5.6 Ventilation

Secure ventilation shafts should be present in the walls, providing openings of no more than 50 mm diameter tubes. They are usually encased in concrete and separated. Within the strong room, vent access should be sealed with a flap or a bolt to prevent objects from entering. Externally, tubes should be connected with steel plate that is anchored rigidly to the concrete.

33_3.2.5.7 Supervision and Monitoring

To insure maximum security, electronic alarm systems must be capable of monitoring walls, adjacent rooms, and all interior areas. Typically, video surveillance, motion detection, and seismic sensors are utilized.

33_3.2.5.7.1 Motion Detection Systems

Motion sensors will generally incorporate long-range microwave and proximity detectors. Reliability will require that a coincidence of at least two individual sensors be present before an alarm signal is validated. Microwave and infrared are often utilized in one device. Capacity systems can also be employed to

monitor specific targets such as safe-deposit vaults and individual safes. These devices will alarm whenever anyone approaches the target. Surface trips on doors are also standard. See **Chapter 40** for a detailed description of alarm devices.

33_3.2.5.7.2 Alarm Circuits

Wiring between sensors and the central station monitoring facility must be supervised, preferably electronically and visually. Video surveillance may also be essential. Fiber optics, RF transmission, and use of dedicated data circuits or the Internet make real-time video observation both feasible and economical.

33_4.0 Fire Safes

33_4.1 The Early Development of Fire Safes: Enclosures and Materials

Fire safes are specifically designed to protect contents from the effects of high temperatures; burglary resistance is of secondary concern. Today, there are many configurations available for record, document, and data storage. Traditional enclosures, as well as record and data vaults will successfully maintain the integrity of paper, magnetic, and optical media, even in the most intense fires and explosions. Materials used in fire safes must have special properties in order to create a heat sink and buffer for high temperatures. Materials used for fireproofing must be incombustible and non-conductive of heat.

Generally, diatomaceous earth, Portland cement, vermiculite mica, gypsum, and wood chips may be used as insulators. Many proprietary compounds have been developed by fire safe manufacturers that are often but a unique mixture of these materials. Initially, wood satisfied the requirements for a fire-proof layer to absorb heat. The material, thickness, consistent and even distribution, and lack of any gaps through which heat could be transmitted allowed the material to perform satisfactorily.

It appears that the first patent for a fire-resistant chest was granted to Robert Scott in 1801 in England. Scott introduced the essential elements for the construction of such enclosures. See also the **Milner patent** for one of the first fire safes, and **Chapter 3** in Price for a detailed history of the development of

fire safes. His “fire-resisting safety chest” was produced of iron plates crudely welded at the corners. The significance of his patent was the utilization of an internal lining of metal that formed a cavity on all sides into which charcoal or wood, steeped in a salt solution, was packed. Chubb and others made improvements to the original Scott patent. Chubb was the leading manufacturer in the development of fire safes; they still maintain their superiority today and have perhaps the largest fire testing facility in Europe.

Successive linings of sheet metal enhanced protection from fire. A unique improvement, these metal sheets were fitted together to create interspaces. These were filled with air or slow heat-conducting materials such as burnt brick, pottery, wood ashes, charcoal, and coarse sand.

In order to ensure that the proofing material was packed tightly in the interspacing, Chubb introduced the use of flat cases or bags made of sheets of cartridge paper, folded in round forms. Hollow molds were filled with the proofing and inserted into the cavities. The proofing material in early Chubb safes consisted of sawdust packed in tins. Later, loose sawdust mixed with **alum(376)** (a double sulfate of aluminum and potassium) was utilized.

It appears that the first fire test of a Chubb safe occurred in 1836. Papers were enclosed in a fire-proof box and exposed to the furnace of a 22 hp steam engine. In the test, the box became red-hot in three minutes and remained in that state for a considerable time. Reportedly, the papers were “perfectly uninjured” when removed. These new iron chest safes gradually came into use as depositories for documents, bank notes, books of account and other valuable papers and property. Originally, they were either mounted cupboard-fashion on piers of brick or built into walls. They were also regarded as secure against burglars. Three years later, Chubb patented “Improvements in Apparatus and Machinery for Preserving Books and other papers, documents and articles from fire”. This apparatus was commonly known as “the well safe.” It was attached to machinery that lowered it into a chamber to increase its protection from fire.

A new and superior fireproofing material was introduced in 1873 that was designed to take the place of sawdust. It was called “**infusoria**,” and consisted of diatomaceous earth. In a much improved and purified state, it is used today for the same purpose. Infusoria is actually the residue of algae silicate

skeletons found in fossil deposits mined from land that was once below the sea. It was mixed with alum to create the most effective balance of properties. Initially, a 6:1 mixture of infusoria to alum was recommended. Later, that formula was modified (in 1876) to a 4:1 mixture. Originally, the alum was packed wet until 1879; then it was placed into containers in a dry state.

Today, fire record safes must protect floppy discs and other fragile magnetic and optical media. These special containers have required the development of new materials that will absorb heat during a fire as well as stabilizing the temperature rise below a critical point. One exception to the traditional design of containers for fire or burglary protection is the Chubb Planet. This safe carries both fire and burglary ratings and is one-third the weight of traditional enclosures. It is constructed of plastic that is rated to withstand 1,000C for one hour. The material is extremely hard and is unique to Chubb. It can be poured to form strong rooms, safes, hasps, and other special items.

33_4.2 Design Theory of Fire Safes: Heat-Absorbing Materials

The underlying theory for the design of virtually all fire safes is quite simple: keep the heat that is in the outer layers from reaching the internal components. Channels of air and specially developed materials will accomplish this result.

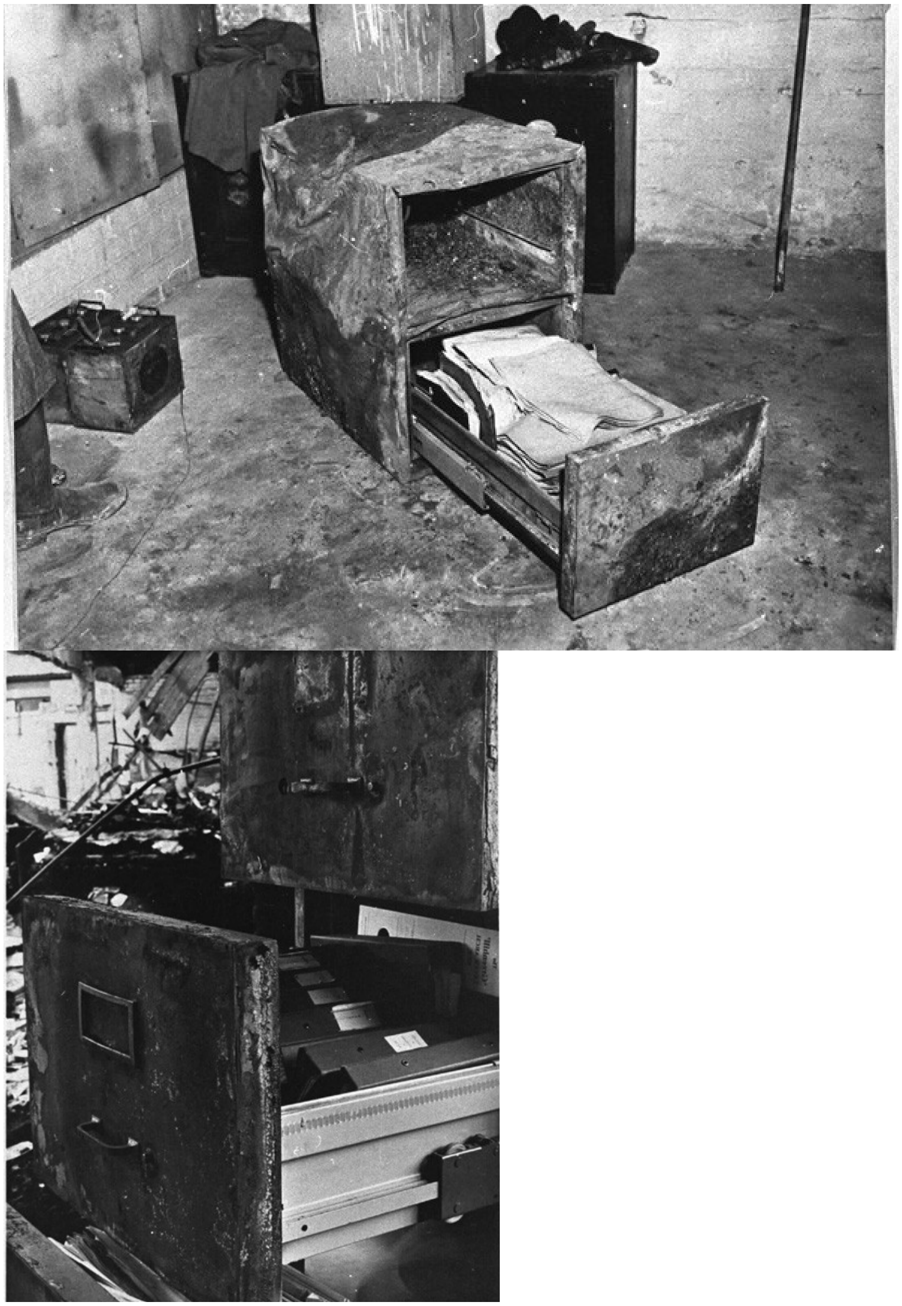


Figure LSS+3308 Examples of fire protected file cabinets.

Safes that are exposed to fire will cook inside; the materials within become quite brittle. If the safe is opened prior to cooling, then the contents will come to a flash-point and burst into flame. Air is a poor conductor of heat. Thus, much like a thermos, layers of contained air can retain high temperatures. If other materials are utilized, even a more efficient storage

medium could be provided. In initial safe designs, certain "poor" conductors would combust with the heat, minimizing their efficiency. This was true for example, when charcoal and sawdust were mixed. The answer was to compress the material, allowing no air gaps.

Later, chemical treatment was applied to fire-resistant materials. Usually salt, the crystals would contain water that would release at a high temperature. Asbestos, fire clay, slag wool, silicate cotton (resembles fiberglass), cement, plaster of Paris (dry or mixed with water), cinders, ashes, or slag have all been used as insulators. The result of pouring acid on marble chips would produce carbon dioxide and a fine white powder that also made a good inert insulator. Sheets of sawdust and alum bonded by Koalin or gum, as well as gypsum chips are quite popular. By the twentieth century, fire-resistant materials were inexpensive. Most manufacturers utilized sand, cedar wood sawdust, alum, and soda. These materials were compressed to eliminate as much air as possible.

33_4.2.1 Diatomaceous Earth

Quite popular for use in fire safes, this material is made from silicates composed of fossilized algae from land that had originally been under the sea. It retards the transmission of heat because each particle constitutes a minute air pocket. Diatomaceous earth would be dried and mixed with pure crushed alum, to form heat buffers in many fire safes.

Chubb and many other manufacturers utilize Portland cement diatomaceous earth (PCDE) sand and an aggregate with wire reinforcement. The mixture will retain up to seventy percent of its moisture and never actually dry. When heated, the material will absorb high temperatures and generate steam. Cement is always the outer barrier. Caution must be exercised that the concrete is not fractured during manufacture, transport, or placement, as any cracks will create a heat path.

33_4.2.2 Materials for Data Protection Cabinets

Enclosures designed for the storage of records must meet more stringent standards for temperature control. Data protection cabinets will often utilize phase-change materials that will modify their molecular structure between liquid, solid, and gaseous states at different temperatures. Typically, the materials will suspend states between liquid and solid at about

49 C. There are generally three protective layers in data cabinets: a phase-change layer, polyurethane foam, and a PCDE layer.

33_5.0 Terminology: Safes and Vaults

Many terms are used to describe the components or measurements of locks, safes, and vaults. The more common of these that specifically pertain to safe and vault construction are defined below. Terminology directly related to combination locks is presented in **Chapter 34**. A comprehensive list of terms may be found throughout this Infobase and in the **www.security.org** Infobase. They are utilized as the nomenclature to specifically define drill points in safe lock diagrams found in that Infobase.

Alloy Hard Plate: Hard plate is a combination of materials that create an extremely drill-resistant barrier (see **Chapter 5)**.

Arbor: Same as spindle.

Cam: The cam and drive wheels are the same component and control retraction of the bolt.

Cannonball Safe: The name that was used to describe a group of round door safes produced from the late 1800s until around 1920. They were so named because most were cast in the shape of a sphere and resembled a large cannonball sitting on a pedestal.

Carbide Chips: Carbide chips, an extremely hard material, are contained in alloy hard plate.

Carriage Bar: A flat bar that provides the linkage within the safe door to retract all of the locking bolts in unison.

Compression Bar: This consists of a metal bar mechanism that is mounted across a safe door to control its position with respect to the body. When the bar is rotated, it will force the door inward to a full locking position. The opposite action withdraws the door from its entrance.

Door Thickness to Bolt: This measurement will define the distance from the surface of the door to the center of the locking bolt.

Door Thickness to Lock: This will define how far to drill before entering the lock case. The measurement will include hard plate,

air gaps, and copper or other materials between the door and the lock.

Drill Point: This is the precise position, located through measurement and reference to the safe lock, where a hole is to be made for safe and vault penetration. A drill point locator overlay, or a direct measurement may be utilized. The standard convention utilized in the industry and in the drill point Infobase on **www.security.org** requires that measurement be made from the center of the dial through the indicated number on the dial ring. A line is extended outward at the angle created by drawing a straight line through those two points for the required distance. The coordinates are written as **D times L**, where **D** is the dial number through which a line should be drawn from the center and **L** is the length of the line. Thus, a drill point of **98 times 2** would require that a line be drawn through the dial number 98, extending two inches.

Drive Wheel: See cam.

Drop-in Point: This is the exact place where the fence enters the wheel gates.

Handle Rotation: This is the direction to turn the handle to lock or unlock.

Lock Bolt: The portion of the lock that blocks the main boltwork from retraction or opening. It is directly linked to the wheel pack and drive cam. The bolt may extend and retract, may roll back and forth, or may be absent altogether. In the latter case, the boltwork of the safe may be directly controlled by the final turn of the drive cam.

Lock Mounting Type: This will define the mounting position of the safe lock. There are four possible orientations: vertical down (**VD**), vertical up (**VU**), right hand (**RH**) and left hand (**LH**). This information is critical when penetration is by drilling.

Lug Door: A door style that requires rotation to lock or unlock.

Relockers: These devices, either internal or external, are utilized as secondary protection to prevent penetration of safes and vaults. **Internal Relockers** are located within a lock case to prevent the bolt from being retracted. An **External Relocker** will block the movement of a cam or bolt bar. They are separate bolts

that prevent the door from opening.

Relocker Drill Point: This location would indicate the precise position to drill in order to release a fired relocker.

Spindle: The long threaded rod that connects the combination dial to the drive cam and wheel pack.

Wheel Pack: The wheel pack consists of the three or four individual gated wheels within a combination lock and is connected to the spindle. Materials utilized for wheels are brass, steel, aluminum, plastic or nylon. Synthetic materials are used in high-security **1R** locks to protect against radiographic attack. Depending upon the manufacturer, these may be called delrin, acetal, celcon, or polymeric.

Zamak: A composite of aluminum and zinc having good qualities of casting and tensile strength. It is used for making lock cases and other components (see **Chapter 5)**.

33_6.0 Identification of Locks and Safes

A proper determination of the manufacturer of the safe and lock is critical for a successful penetration. When a safe has been repaired or upgraded with a newer lock, identification can be more complicated. There are many characteristics to identify a safe, safe door, or lock. Identification may be made by:

- **Recognition of the manufacturer by general appearance;**
- **Manufacturer logo or identification label;**
- **Artwork, designs, logos, or imprints;**
- **Dial and dial ring design;**
- **Does dial ring have a change index;**
- **Dial index design: line, star, arrow;**
- **Left-hand or right-hand door;**
- **Handle-center to dial-center measurement;**
- **Location of the dial;**
- **Numbering on dial;**
- **Markings on dial;**
- **Dial type and finish;**
- **Number, location, and type of locks;**

- **Logo on lock dial;**
- **Shape and design of keyways;**
- **Number of levers within a lock and bitting pattern;**
- **Door size, shape, design, and color;**
- **Body color (original);**
- **Corner shaping and design;**
- **Hinge style: vertical, horizontal, bolted, welded, specially shaped;**
- **Enclosure generic description;**
- **Container is on wheels;**
- **Distributor label;**
- **Overall enclosure size, shape, weight, and color;**
- **Mounting of enclosure;**
- **Opening handle design, shape, action, location, and position with reference to the dial;**
- **Distance between opening handle and dial;**
- **Location of contact points;**
- **Direction of bolt rotation;**
- **Hinge design;**
- **Wheel or caster design;**
- **Body construction: plate steel or composite;**
- **Handle style: "L", "T", round, plastic, brass, chrome, black, flat, round or tapered;**
- **Wheel count in wheel pack;**
- **Determine left and right contact points;**
- **Force handle toward opening: does it affect the dial.**

CHAPTER THIRTY-FOUR: PERMUTATION LOCKS

Combination Locks

Master Exhibit Summary

34_1.0 History and Development of Locks for Safes and Vaults

The modern combination lock is a refinement of letter or number padlocks that have appeared during various periods in history.

Originally known as permutation locks (262271), these devices were initially developed for convenience and not for security. In fact, until relatively recent times they were never taken seriously and primarily thought of as a novelty.

Figure LSS+3409 Examples of early combination padlocks. Shown is an Italian nineteenth century puzzle lock (left), another example of a permutation lock, origin unknown (middle), and an eighteenth century four wheel lock.

The original locks utilized numbers, letters, or symbols as an index to move critical locking components into alignment. Regardless of the design, they required that one or more discs or plates be rotated or otherwise moved so that some form of protrusion (fence) would retract into a recessed area (gate).

The design of the mechanical combination lock, as it is known today, began prior to the Civil War; it is an American invention. Although combination locks are utilized in other areas of the world, in most locations keys have been preferred over numbers. That is because physical keys have traditionally been more difficult to compromise. At least in Europe, it was the feeling that requiring that something "material" be utilized to open the lock would enhance security.

Figure LSS+3410 A copper tobacco box with lock, eighteenth century.

Commerce can be said to have created the demand for the lock. Although technology would progress at a rapid pace, the basic premise that relied upon the wheel did not. Today, as always, the combination lock is favored in the U.S., while key locks (lever) for safes and vaults are predominant in Europe. Some manufacturers utilize both for a higher level of security.

Mark Bates (MBA) and Lockmasters are the two leading companies in the United States that provide tools and training to the safe and vault industry worldwide. They also have the finest collections of antique safe locks, keys, and time locks. The following photographs and descriptions were provided courtesy of Mark Bates, and offer an insight into the designs that were prevalent for the past two hundred years, and which led to the state-of-the-art in modern safe and vault locking mechanisms.

Yale Quadruplex Safe Key

In the United States, there are four primary manufacturers of combination locks: Sargent & Greenleaf, LaGard, Federal (Lori Company), and Yale. S&G is the oldest and most well known company. S&G was founded in 1857 by James Sargent and Hobart Greenleaf. Sargent had a background in lock design; Greenleaf supplied capital for the growth of the company and was originally in the military. The company was originally located in Rochester, New York. In the 1950s, it was purchased by Harry Miller, one of the pioneers in the development of modern combination lock technology. The Miller family owned the company until about 1982. Harry Miller, who originally was employed by Diebold as an apprentice, worked for the government throughout the Depression and war years developing high-security locks. Miller was granted many patents for designs and modifications to combination locks. See for example (**2575674(377)**).

During World War II, his background became vital to the United States, because he was an expert in new lock design and manipulation. He would later conceive of the first electronic lock and would develop manipulation-proof devices. In 1949, the State Department summoned representatives of the industry in an attempt to gather information regarding the covert entry of safes and loss of valuable information. Harry Miller gathered a sample of every lock installed by the government in order to determine how they could be manipulated and compromised. Consequently, several patents were issued to S&G. In the process, the company acquired the most comprehensive collection of combination locks in the world.

34_1.1 Predominant Manufacturers

As noted, there have been four predominant safe lock manufacturers in the United States since the industry decided upon standardization. S&G is the favorite, providing its 6700 series lock to most safe makers. Except for the relock trigger, the R6730 has not changed in size and mechanical configuration since the 1920s.

LaGard is the second largest lock manufacturer in the United States. Their products can be found on many fire and burglar-rated safes, including GSA containers. This company and its founder, Nick Gartner, have been responsible for many significant innovations in mechanical design and electronic systems.

Many other companies outside the United States produce combination locks. Some of them adhere to the U.S standards. The locks produced by many other manufacturers cannot be interchanged with the accepted footprint.

Figure LSS+3411 Examples of early designs of modern Yale three-wheel combination locks. (left) is shown a three-wheel lock produced about 1920; (right) is an S&G manufactured about 1948.

34_1.1.1 Other Combination Locks

Information is presented here on locks that can be found on safes, chests, and other containers that are utilized throughout the Department of Defense. These include the Diebold 180, Yale)C5, and S&G 6600 series. All locks meet the criteria of AR 380-5, paragraph 5-102. Some of the following material has been excerpted from the **Intelligence Materiel Division Technical Data Handbook No. 2.**

Some background data may be helpful in tracing the history of these locks. About 1980, Sargent & Greenleaf manufactured a 6600 series key-change combination lock that was originally certified by Underwriter's Laboratories (UL) as Group 1. This 6600 series differed from the earlier 6600 hand-change series of the 1950's and 1960's, which were true Group 1 and 1R locks utilizing the classic S&G anti-manipulation feature. That consisted of a split drive cam controlled by the center arrow knob (butterfly), which allowed the nose of the drop lever to engage only when the arrow knob was actuated.

The 1980's version (using the 6600 series designation), is a key-change type utilizing a drop lever that has a roller bearing installed in the nose. This roller bearing was eccentric in shape to give erratic readings when manipulation was attempted. In April 1982, the S&G Model 6600 Series Combination Locks were tested against Military Specification (MILSPEC) MIL-L-1556E for manipulation resistance. Both the S&G Model 6600 Series Key Change Group 1 and Group lR failed the 20 man-hour resistance to manipulation.

The Defense Industrial Supply Center, Philadelphia, Pennsylvania, was notified and arrangements were made between S&G and the U.S. Government to replace those 6600 series combination locks that failed the MILSPEC with either the S&G 8400 or 8500 series combination locks.

Because of the various styles of dials and dial rings on S&G products, the only positive way of determining the S&G Model 6600 Series Combination Lock of the 1980's is to remove the back cover plate and inspect the drop lever. Changing combinations on the 6600 Series lock is the same as that of any other S&G key change lock.

Another combination lock manufactured by LaGard Corporation of Torrance, California, was introduced into the system. Model 1800 RL was originally certified by UL as Group 1R. In December 1982, this lock was also tested against the MILSPEC for manipulation resistance. This lock failed the required manipulation resistance of 20 man-hours.

Although both the S&G Model 6600 Series Combination Locks and the referenced LaGard Group 1R Combination Lock have been certified as either Group 1 or Group 1R by UL, these locks have proven susceptibility to manipulation. NEITHER THE S&G 6600 SERIES COMBINATION LOCKS OF THE 1980'S NOR THE LAGARD COMBINATION LOCKS

ARE TO BE USED AS REPLACEMENT LOCKS ON GSA APPROVED SECURITY CONTAINERS.

Diebold Model 180 Series

These key-change combination Locks may still be found on old containers and safes, but are no longer manufactured. They do not meet Group 1 or Group 1R requirements.

To Unlock:

(1) Rotate the dial a minimum of four times to the LEFT. Stop EXACTLY at the opening index mark the fourth time the first number of the combination has reached the opening index mark;

(2) Rotate the dial to the RIGHT. Stop EXACTLY at the index mark the third time the second number of the combination has reached the opening index mark;

(3) Rotate the dial to the LEFT. Stop EXACTLY at the opening index mark the second time the third number of the combination has reached the index mark;

(4) Rotate the dial to the RIGHT, pausing a moment at zero, and then continue turning to the RIGHT until the dial stops. The locking bolt is now retracted. This enables the handle of the drawer or door to be "thrown", allowing it to be opened.

NOTE: Always turn the dial slowly and evenly. Spinning the dial is unnecessary and may cause loosening of component parts that could cause a lockout.

Changing Instructions:

This lock is considered a "0" (zero) change lock; therefore, no changing index is provided.

(1) Operate the lock on the old combination, stopping when the last number comes to the opening index at the top of the dial ring;

(2) Insert the change key through the hole in the back of the lock case. The key must be inserted until the end comes to a stop on the bottom of the case. Turn key to LEFT (counterclockwise), as you face the inside of the door, through approximately half a

revolution to stop;

(3) Select three numbers on which to set the lock;

Figure LSS+3408 Diebold Model 180 Series

(a) Keep numbers above 10,

(b) Below 90, and,

(c) A minimum of 10 digits apart.

(d) Use high, low, high or low, high, low; i.e., 32-19-71 or 19-71-32.

(4) Rotate the dial LEFT (counterclockwise), stopping when the first number aligns with the opening index the fourth time around;

(5) Rotate the dial RIGHT (clockwise), stopping when the second number aligns with the opening index the third time around;

(6) Rotate the dial LEFT (counterclockwise), stopping when the

third number aligns with the opening index the second time around;

(7) Rotate the change key to the RIGHT (clockwise), as you face the inside of the door, approximately half a revolution to stop, and withdraw the change key;

IMPORTANT: The lock is now set on the new combination. Operate the new combination several times before you close the door to be sure that it works correctly and that you know the combination. If the lock fails to operate, a mistake has been made.

Procedures If Combination Fails:

(1) Remove the cover of the lock;

(2) Arrange the three combination wheels so the key hole in the wheels is in line with the keyhole in the cover. This is easily done by inserting the key through the wheels and into a hole in bottom of the case. Be sure not to turn the key while the cover is removed;

(3) Withdraw the key, and replace the cover;

(4) Insert the key and follow changing instructions from the beginning;

Yale Model OC5 Series

These hand-change combination locks may still be found on old cabinets, but are no longer manufactured. They do not meet Group 1 or 1R requirements.

To Unlock:

(1) Turn the dial a minimum of four times to the right stopping exactly at the opening index mark the fourth time the first number of the combination has reached the opening index mark;

(2) Turn the dial to the left, stop exactly at the opening index mark the third time the second number of the combination has reached the opening index mark;

(3) Turn the dial to the right, stop exactly at the opening index mark the second time the third number of the combination has

reached the opening index mark;

(4) Rotate the dial to the left, pausing a moment at zero, and then continue turning to the left until the dial stops. The locking bolt is now retracted. This enables the locking linkage to be retracted by the handle, thus allowing opening of the door or drawer.

NOTE: Always turn the dial slowly and evenly. Spinning the dial is unnecessary, and may cause loosening of component parts, which could cause a lockout.

To Change Combination:

(1) Open drawer or door and release bolts to locked position. This will prevent inadvertent lockouts due to drawer being closed without attached wheel pack and released relock. (If unit is equipped with a locking bolt interlock, it will be necessary to depress the interlock plunger before the bolts can be thrown.);

(2) Remove cover from lock by removing two screws attaching cover to case (on some safes, it may be necessary to remove a panel or small circular cover from the inside of the door or drawer to expose lock);

(3) Remove retaining clip from wheel post;

(4) Remove wheels and spacers and align in proper order for reinstallation. (These wheels are generally not numbered as to sequence.) The last wheel removed from the post is number-one wheel and the first number of the new combination, etc.;

(5) Hold number-one wheel assembly with numbers up and push the center disc upward until it is removed from the outer ring. Rotate the center disc until the setting mark is opposite the desired number on the ring. Carefully press the center disc back into position until it is flush with the outer ring. Change the combination number on the remaining wheels in the same manner.

NOTE: When selecting numbers for the new combination, use recommended methods as listed below:

(a) Keep numbers above 10;

(b) Below 90, and

(c) Ten digits apart;

(d) Use high-low-high or low-high-low;

(e) Whenever possible do not use numbers ending in 5 or 0.

(6) Replace parts on posts in proper sequence. Numbered side of wheels are to face up. When the retaining clip is replaced, make sure that it is properly seated in the groove on the post;

(7) Turn the dial off zero, and then replace the cover and screws. Tighten screws firmly to preclude vibration causing loosening and allowing the relock to trigger;

(8) Try the lock at least twice on new combination with door or drawer open to be sure the lock is set properly and operates smoothly;

Bode-Panzer Combination Dial Lock

The Bode-Panzer Combination Lock, which is manufactured in Hanover, West Germany, is also included in this text because of the quantities found in use throughout Europe.

To Unlock:

(1) Rotate the dial to the RIGHT, and stop when the first number of the combination reaches the opening index for the fourth time;

(2) Rotate the dial to the LEFT, and stop when the second number of the combination reaches the opening index for the third time;

(3) Rotate the dial to the RIGHT, and stop when the third number of the combination reaches the opening index for the second time;

(4) Rotate the dial slowly to the LEFT to stop;

NOTE: This is just the opposite of locks manufactured in the United States.

IMPORTANT: When dialing, you may stop and resume turning the dial as often as you like without changing the direction of the turn. If you overshoot your mark by rotating the dial beyond the number

required, the unlocking procedure must be started over again; otherwise the mechanism will not work. Such dialing mistakes do not affect the lock in any way.

Each lock delivered by the factory is set to a combination of three numbers which are divulged to the buyer in a special registered letter. The lock must be reset immediately after its receipt to a new three-number combination to preclude compromise. Before you start changing the combination, write down the three numbers which you intend to use for the new combination on your lock. In the interest of security, it is recommended that you select three numbers as far apart from one another as possible (with intervals of at least 10 digits), distributing them as evenly as possible over the dial. Do not use numbers ending with a 0 or a 5, exclusively.

To Lock:

Rotate the dial to the RIGHT at least five times;

Changing the Combination:

Change the combination as follows. The Bode-Panzer Combination Lock is considered a "0" (zero) change lock; therefore, a separate changing index is not provided. The single index mark suffices for both opening and combination changing procedures.

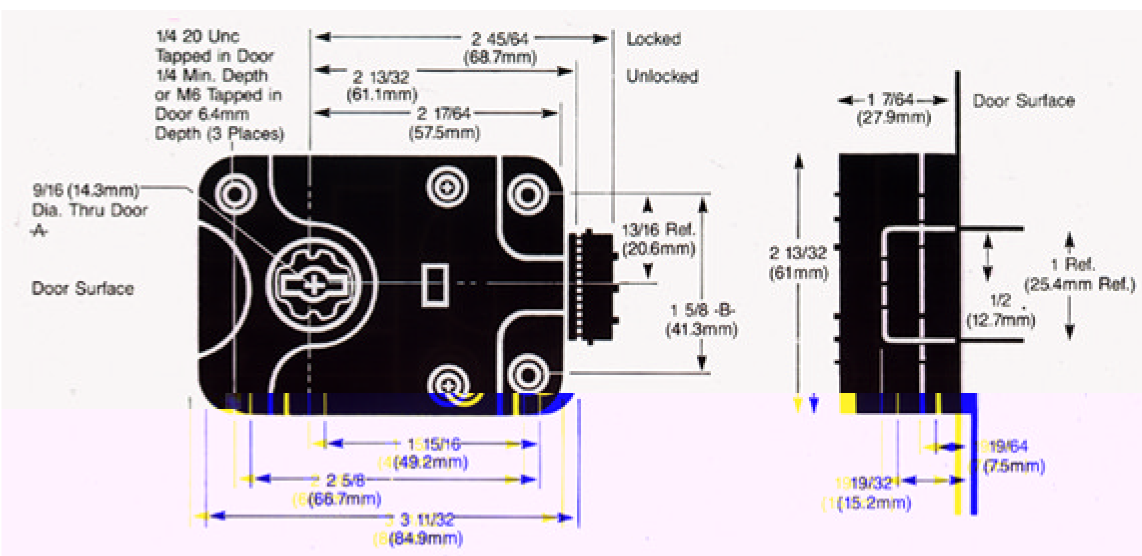
(1) Proceed exactly as described in the Unlocking instructions without making the last turn to the LEFT;

(2) Insert the combination change key as deeply as possible into the change key hole provided in the back of the lock;

(3) Turn the change key 90 degrees to the RIGHT, and leave it in that position;

(4) Rotate the dial at least five times to the RIGHT, and stop when the first number of the new combination reaches the index mark;

(5) Rotate the dial to the LEFT, until the first number has passed the index twice, and stop when the second number reaches the index;



(6) Rotate the dial to the RIGHT, until the second number has passed the index once, and stop when the third number reaches the index;

(7) Rotate the change key 90 degrees to the LEFT, until it can be extracted. Extract the change key;

(8) Rotate the dial to the LEFT, until it comes to a stop. The lock is again open.

34_1.2 Industry Standardization

Until the 1930s, there was no industry standardization of locks utilized in safes and vaults with respect to their size and the design of protective cases or enclosures. Prior to standardization, locks came in many different configurations and were custom mounted for a particular safe. Some locks did not even have cases to protect the wheel pack. Manufacturers began the process of adopting common footprints for lock cases to allow interchangeability for any container. The only company that did not follow suit was Mosler. Their lock case did not conform to the rest of the industry until the 1970s when they introduced the Model 302.

Today, only two safe manufacturers actually produce their own locks: Mosler and Diebold. Other than for GSA Class 6 security containers, these companies will always utilize their own locks on their enclosures. Until 1989, only the S&G 8400 and 8500

series were acceptable to the United States government on GSA security containers, and thus Mosler and Diebold were required to utilize them.

Individual locks may differ in the way they function, but the overall operating principle is the same. For example, it may be required to return a dial to zero and be depressed in order to engage the lever. Relock triggers may be slightly different in design and placement. Locks may have a zero change function and different dial and ring designs. Other than the Yale OC5, most locks are extremely close in their dimensions, and thus they may be easily interchanged. With few exceptions, the mechanical components are identical and thus:

- **The wheel diameters are essentially the same size;**
- **The wheels are equipped with moving flys;**
- **Each lock uses a pivoting lever with a fence;**
- **All locks utilize the same method of bolt retraction;**
- **All locks are equipped with a relock trigger;**
- **The physical drop of the fence is in the same location.**

There are some differences between S&G, Mosler, Federal, LaGard, and Yale. These include:

- **Yale retracts the bolt with the dial turned counterclockwise;**
- **Mosler, Federal, and Yale mount wheels on the lock case cover rather than a wheel post;**
- **The drill points will vary because the drop in points are different: Yale OC5 is 80, Mosler is 91, LaGard, Federal, Diebold, and S&G is at 97.**

34_2.0 Combination Locks: Operation and Theory

34_2.1 Introduction

As described elsewhere in this text, there are several primary means to provide security within any lock. In the key lock, single and double-acting detainers, keyways, guards, wards, and

other devices have been utilized to enhance resistance to bypass. The introduction of gated wheels in the combination lock provided yet another technique for making locking mechanisms more secure by eliminating any physical opening. As will be discussed subsequently, the mechanical combination lock suffers from certain fundamental limitations in its design. Electronic locks can overcome such problems and offer far superior reliability and security. Perhaps the most advanced of this new technology is the revolutionary Mas-Hamilton X-07. A detailed analysis of this lock is presented later in the chapter because of the impact that it has had on the entire security industry.

34_2.2 Combination Locks v. Key Locks

The modern combination lock offers significant advantages over any other type of mechanism:

- **The lock generally offers from one million to one trillion distinct permutations, making random openings and cross-keying impossible;**
- **No key can be lost, duplicated, or compromised;**
- **Greater resistance to bypass, including picking, manipulation, and radiographic attack;**
- **Mechanical reliability.**

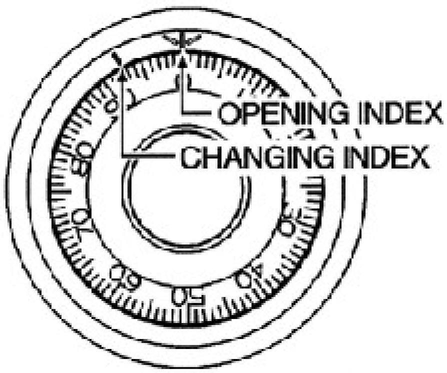
34_2.2.1 Mechanical Reliability

The modern mechanical combination lock is extremely reliable if produced to accepted industry standards. Established manufacturers such as S&G maintain extremely high tolerances to ensure consistent performance. Strict quality control procedures are implemented as well as extensive product testing. Sargent & Greenleaf, for example, will cycle their locks routinely for 30,000 - 40,000 openings without ever encountering a problem. The UL requirement contemplates a minimum of 10,000 openings.

If locks are routinely serviced, cleaned, and lubricated they will function without difficulty. The removal of debris and resetting of wheel-torque is critical to trouble-free operation. When a lock does malfunction, many indicators can provide the necessary information to determine the precise nature of the problem. Certain techniques are utilized by the safe technician to determine the cause of a lockout. These are discussed in **Chapter 36**.

34_3.0 Components and Principles of Operation

34_3.1 Introduction



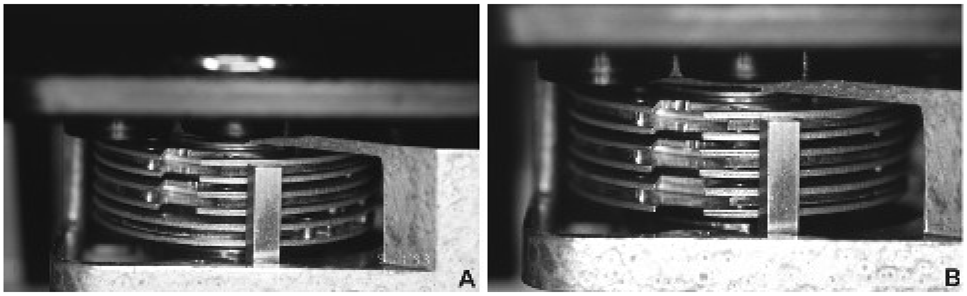
Our discussion will examine the theory of operation underlying the modern mechanical combination lock. We will focus on the three interrelated component groups that comprise the primary system:

- **Driver**
  Dial
  Spindle
  Drive cam
  Spline key

- **Wheel Pack**
  Wheels
  Wheel post
  Gate
  Tension washer
  Isolation washers
  Retaining ring
  Lock case (when wheel post is part of case)

- **Bolt works**
  Lever
  Fence
  Bolt
  Relocker
  Case

The operating theory for almost every mechanical wheel lock is identical and in many respects parallels that of the lever lock. They all contain a dial that performs the same function as a key. It is marked and subdivided into segments, using numbers or letters in the same way that a key has bitting corresponding to different depths. When turned, the dial allows the movement of critical locking components (wheels) much like the levers in a conventional lock.



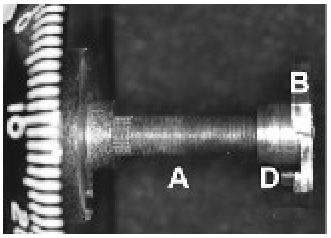
Wheels are equivalent to levers; the only difference is that they are rotated rather than lifted. Each wheel, like their counterpart, has a slot or gate that must be aligned with a fence or protrusion. The proper combination must first be entered. When this occurs, all of the gates are positioned just like all levers or pins are brought to shear line by the proper key. Upon proper alignment, the nose of the lever can enter the gates via the drive cam. The dial, as with the key in the lever lock, is used to mechanically retract the bolt.

34_3.1.1 Overview: Entering the Correct Combination

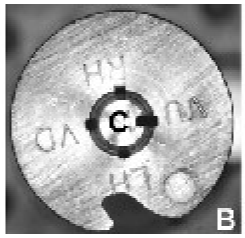
The mechanical theory and operation of the combination lock is actually quite simple in comparison to pin tumbler devices. Although Underwriters Laboratories requires a minimum of 1,000,000 unique combinations in Standard **UL 768**, this fact does not affect the relative simplicity of design. To open the lock, all discs must be arranged so that their gates are in precise alignment, thereby creating a recess into which the fence can drop. Movement of the wheels is accomplished through dial action in sequentially alternate turns; the drive cam links rotational energy using flys and carries each wheel to the correct position.

A wheel can be rotated without disturbing the other wheels, with drive pins and flys. These are precisely moveable protrusions on both faces of each wheel that are designed to contact and stop each other during one complete revolution, based upon the order that the wheels are turned. Thus, movement of wheel number-one will engage wheel number-two, which will then catch wheel number-three.

When the dial is first turned, all discs are moved together in the same direction, along with the drive cam (which is connected to the dial and spindle). This occurs because the drive pins and flys interact with each other. After three revolutions, the wheels are in effect linked together and moving as if they are one. Now the dial is stopped at the first number in the combination sequence, aligning the first wheel gate with the fence. The lock still cannot be opened because the remaining wheels have not created a complete recess for the fence. All gates are not perfectly aligned, so the fence still has nowhere to go.



The second wheel must be placed in a position where its gate is in the same position as that of the first wheel. To do this, the dial is turned in the opposite direction, carrying tumblers number-two and three (and four, if a four-wheel lock) in the reverse direction. Because of the design of the drive pins and flys, wheel number one will not be disturbed, but wheel number two will be brought to alignment.



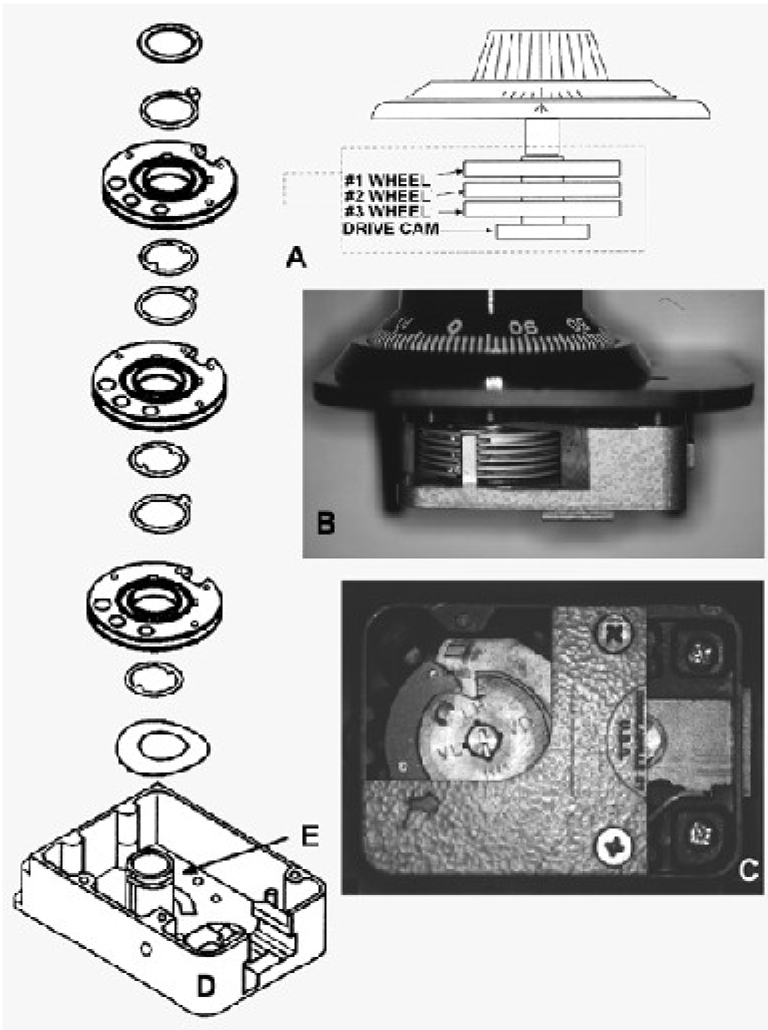
The dial is turned in the opposite direction in order to bring the third tumbler into alignment. All gates are now in the same position and create a vertical slot or recess for the fence. Once the nose of the lever is able to drop into all of the gates, the entire lever can pivot and allow the bolt to be retracted. The lock is now open. Extending the bolt to the locked position simply requires turning the dial in order to force the lever-fence out of the drive cam and gates.

34_3.2 Driver Group

The Driver group consists of the **dial**, **spindle**, **drive cam**, and **spline key**. These components control how each individual wheel is aligned and thus are perhaps the most critical. Usually, the **dial** is affixed to the **spindle** that is threaded into the **drive cam**. A groove (**spline**) in the threaded rod allows the drive cam

to be indexed to the spindle with a **spline key.** Together, the driver group is responsible for transferring information to the individual wheels regarding their positions with respect to the fence.

34_3.2.1 Spline Key



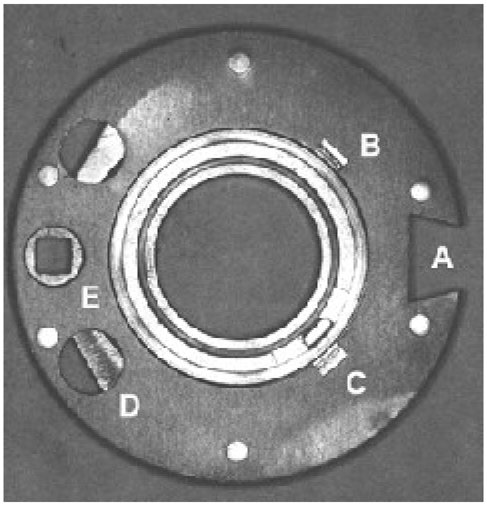
The function of the spline key is critical: it provides the mechanical link between the drive cam and spindle. Equally important, it sets the relationship between the position of the gate on the drive cam and the individual numbers on the dial. Any play between these two components will directly affect the combination. If the spline key should become dislodged, there is no way for the spindle (and dial) to cause wheel rotation.

34_3.2.2 Drive Cam

The drive cam makes contact with the first wheel through a fly and drive pin. It is moved by the action of the dial and linked by the spindle. As the wheels are turned, their gates will be brought into alignment with the fence. When all wheels are set to the proper position, the fence is able to drop into all of the gates simultaneously. At the same instant, the nose of the lever enters the recessed area of the drive cam.

34_3.3 Wheel Pack

The wheel pack determines the combination for a given lock. It is comprised of the individual wheels stacked in parallel, together with the wheel post, tension washer, isolation washers and retaining ring. Depending upon manufacturer, the wheel post may be part of the lock case or lock cover. The wheel pack is controlled by the action of the drive cam. Each wheel rotates freely within the pack; however, they do not change their **positional relationship** with each other once set. The drive pins and flys allow the drive cam to position each wheel.



34_3.3.1 Individual Wheels

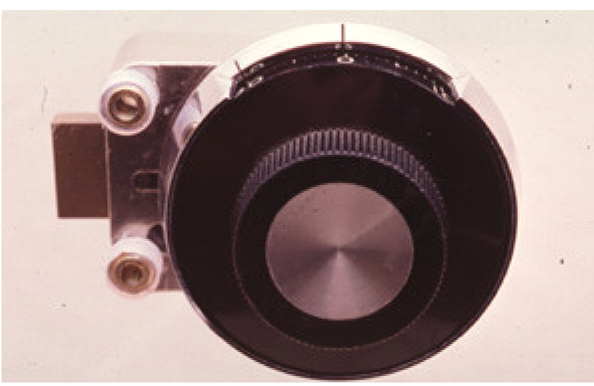
Wheels or discs are circular in design and made of metal or polymers. Each is perfectly round and has a precisely dimensioned recess in the form of a slot, called a **gate.** Each wheel is free to turn independently, is mounted on the wheel post and is separated by **"isolation washers".** Lugs within each isolation washer engage grooves in the wheel post to maintain their fixed position and stop them from rotating.

These washers prevent adjacent wheels from being "carried around" as the combination is entered. Convex thin metal **tension** washers provide spring bias to the components of the wheel pack to inhibit vibration or movement of other wheels while the

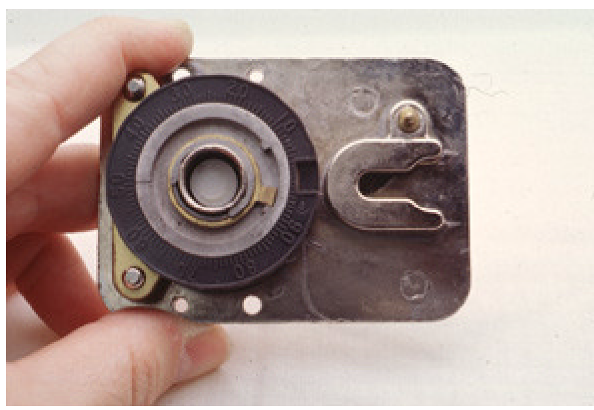
combination is dialed. The **retaining ring** keeps the wheels and isolation washers on the wheel post and works against the tension washer.

34_3.3.2 Development of the Wheel in Combination Locks

Many wheel configurations have evolved since Linus Yale produced the first combination lock. Major changes have occurred in the design of both the gate and method of changing the relationship between gate to the spindle position. Materials used in the production of wheels have undergone many improvements and have become more sophisticated. The following discussion analyzes the development of gates, wheels, materials, drive pins and flys, and the methods utilized to change the gate-wheel relationship.



34_3.3.2.1 Gate Design



The gate is a precise slot that is cut into the edge of each wheel. Its function is to provide a place for the fence when the wheel is in the proper position for the lock to open, based upon the number dialed. Many advances in the design of wheels, wheel packs, and gates have occurred since the first combination lock made its debut. Perhaps the most critical change was made by S&G engineers after burglars discovered that they could open a lock by vibrating the wheels so they would turn on their own accord and stop under the fence. Interestingly, a patent was granted to Jacobs in 1961 (**2974517(378)**) for a device to cause vibration to a safe lock to cause the wheels to rotate to a position where the gates were aligned with the fence.

From 1925-1954, the S&G wheel was solid with a square gate. In these early locks, the lever generally had a very limited pivot arc, or it entered the gate at the 12 O'clock position. Because the wheel was solid, it was heavier opposite the gate. Like the tire on a car, it was out of balance. If vibration was applied, the wheel would move to where its heaviest segment would naturally be positioned: at the bottom. This action would align the gate to the fence.

Consequently, both the lever and gate were redesigned. In the new configuration, the lever and fence entered the wheel off-center. The gate-slot angled to the right to match the pivot angle of the lever. In addition, small gear-teeth were added to the edge of the disc, with corresponding grooves on the fence. The theory was that the lever fence would hold the wheels in position. Unfortunately, the opposite occurred. The meshing of the teeth actually caused a ratchet effect, making it even easier to vibrate the lock to the open position. The design was discontinued in 1957. Balancing-holes were one remedy to inhibit vibration from rotating wheels. As lead weights are used for tire alignment, holes were placed in each wheel so that the weight might be perfectly distributed.

34_3.3.2.2 Changing the Wheel-Gate Relationship

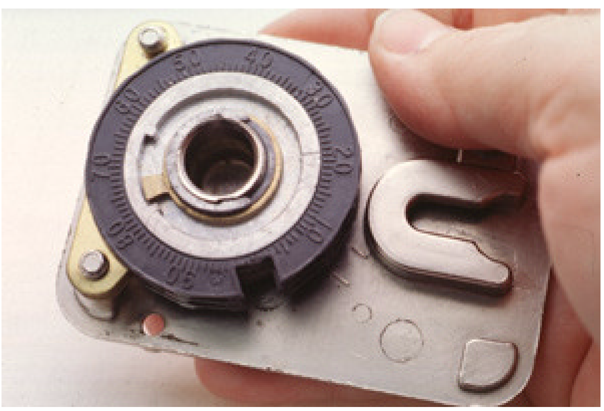


Figure LSS+3412 Changing procedure for hand-changeable locks. Shown is the Mosler CD302, which requires disassembly in order to change the relationship between the outer and inner wheels. Note that each disc has numbers that correlate to the dial markings. Courtesy of Mark Bates, The National Locksmith Guide to Modern Safe Locks.

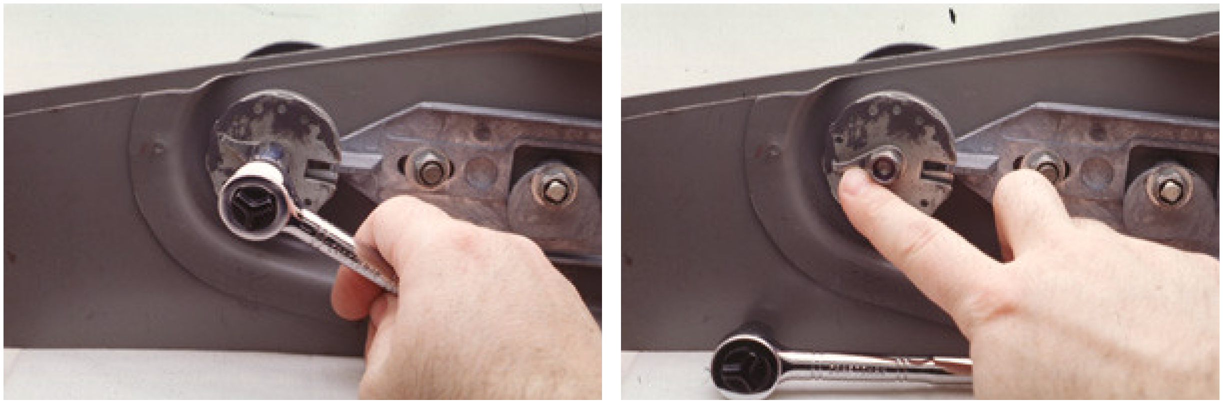

Figure LSS+3413 Changing procedure for hole-changeable locks. This lock is more primitive than the hand change model shown above. Shown is the Sentry safe lock, found on fire resistant containers. There is no lever or bolt. The rear wheel which constitutes the drive cam has an arm that connects into one of a series of holes on the wheel. To alter the combination, the wheels are loosened on the wheel post. The arm is then moved to a different hole, and the wheel tightened. Courtesy of Mark Bates, The National Locksmith Guide to Modern Safe Locks.

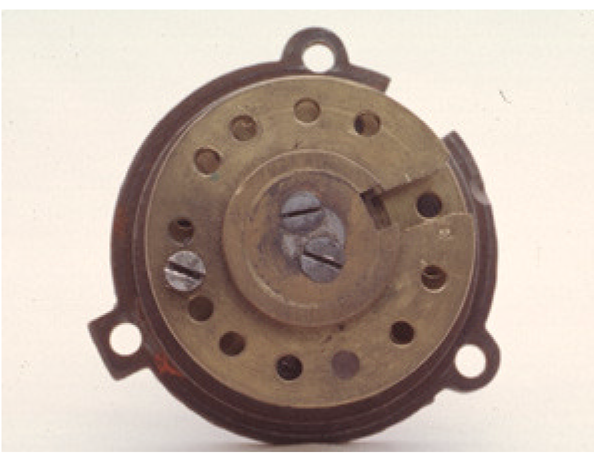

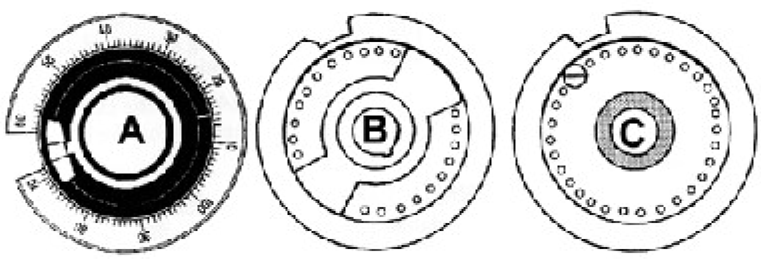

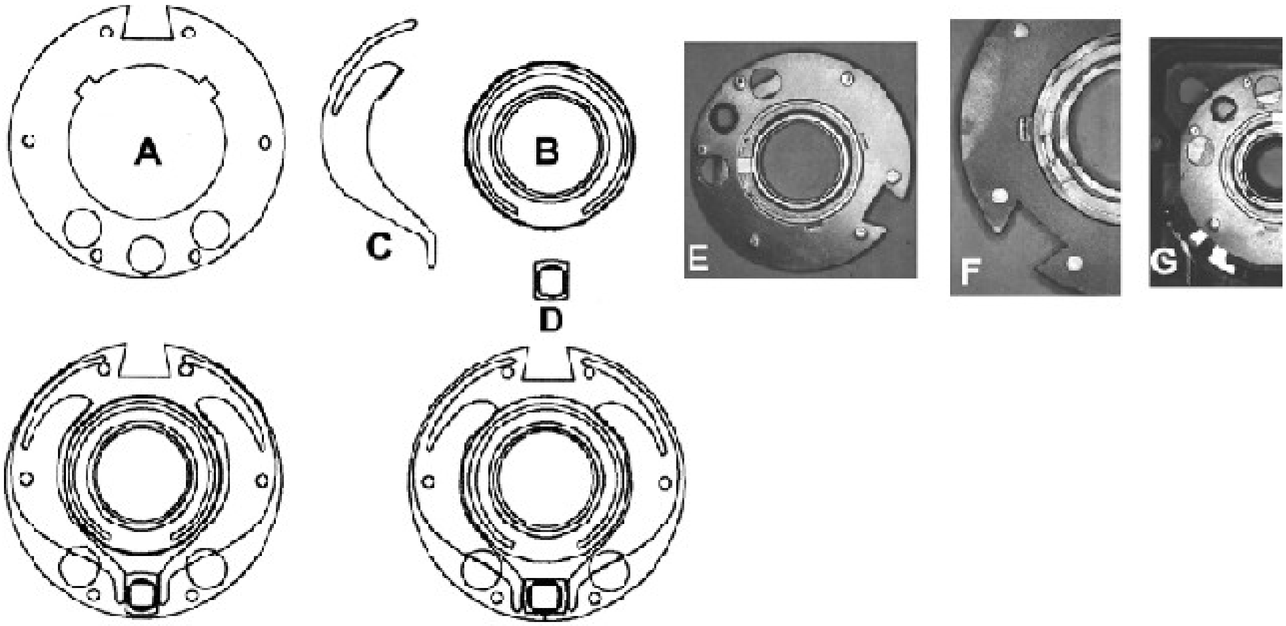

Figure LSS+3414 A screw-changeable lock is similar in function to a hole change lock. A screw is driven into a hole on the wheel. Each wheel will have its own set of holes. Courtesy of Mark Bates, The National Locksmith Guide to Modern Safe Locks.

From the beginning, it was recognized that some form of mechanism was required to permit changing the combination for a given lock. Although many different methods have been developed, they all must accomplish the same function: to alter the positional relationship between the gate and the index marker on the dial ring (or the spline key). In the early locks, this had to be done manually by disassembly of each wheel. Later, a key could be inserted and the wheel-gate relationship changed automatically.

At first, the technique was quite simple: a **hole-change** wheel was able to create a new combination by moving a pin or screw to a different position. A predetermined range of numbers would be available, depending upon where the pin or screw was placed. Then, the **mesh-change** wheel was introduced, together with a fly. This allowed all 100 numbers to be used for the combination. Still, the lock had to be opened and disassembled in order that each wheel be taken apart to effect the change.

In 1857, the **key-change** wheel was invented by James Sargent, one of the cofounders of S&G. This mechanism allowed the combination to be changed by the insertion of a key at the rear of the lock case. The key would pass through each of the wheels simultaneously and could alter the position of all of the gates, thereby changing the combination. Today, almost every lock utilizes the technique of dual mesh locking of the inner and outer sections of the wheel. In addition, the gate design allowed the wheel to be utilized in left and right-hand locks. Different designs have been described in U.S. patents (**1899739(379)**, **4375159(380)**) conventional locks (**3533253(381)**, **3983724(382)**, **2830447(383)**, **5109684(384)**) and padlocks.

34_3.3.4 Wheel Materials

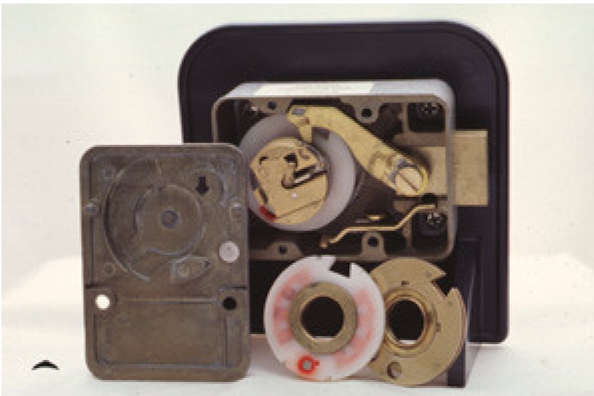

Figure LSS+3415 Metal and plastic wheels. Courtesy of Mark Bates, The National Locksmith Guide to Modern Safe Locks.

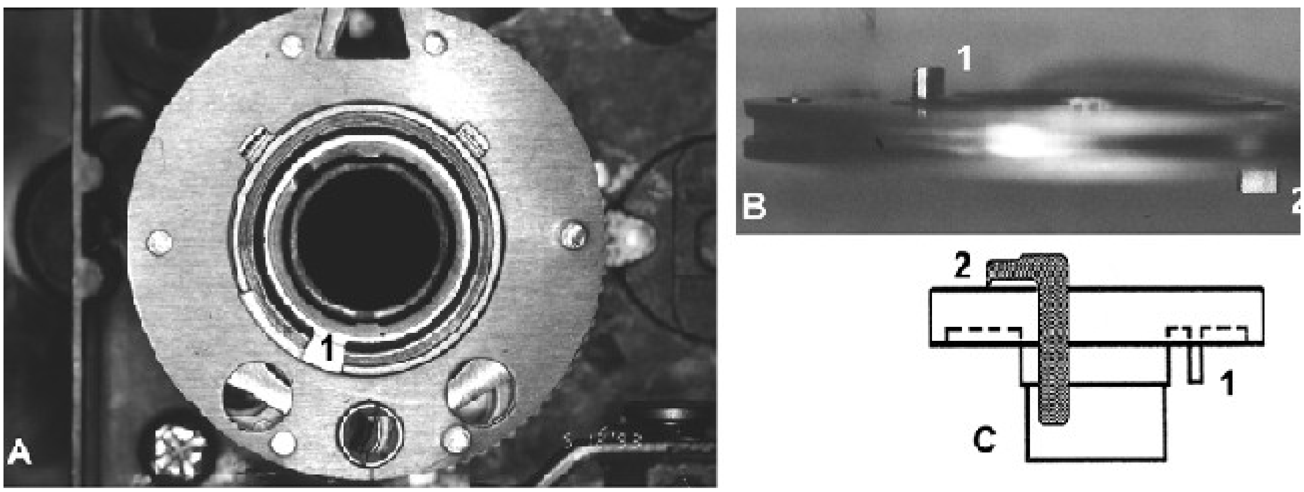
The materials selected for wheels are as important as their shape. Lock manufacturers must be concerned with non-electrolytic corrosion, radiographic attack, manipulation, vibration, microbiological growth (green film in wet climates), resistance to chemicals (such as oils, solvents and grease), self-lubrication, and conduction of electricity. Originally, wheels were made of brass, then steel or aluminum. In the 1950s, S&G made nylon wheels for the Group 1R lock, allowing the relock trigger to rest on a nylon button. Center Manufacturing then made an all-plastic wheel pack in their Model 100 that even had plastic moveable flies.



Plastics such as delrin, acetal, nylon, celcon, and polymeric materials are widely in use by manufacturers. Co-polymer fabricated wheels are light, self-lubricating, and do not require balancing. In addition, the materials can defeat radiographic attack and manipulation as well as the other problems associated with metal discs. They have excellent resistance to chemicals, corrosion, microbiological growth, and build-up of scale. Oils, grease, or solvents do not affect them.

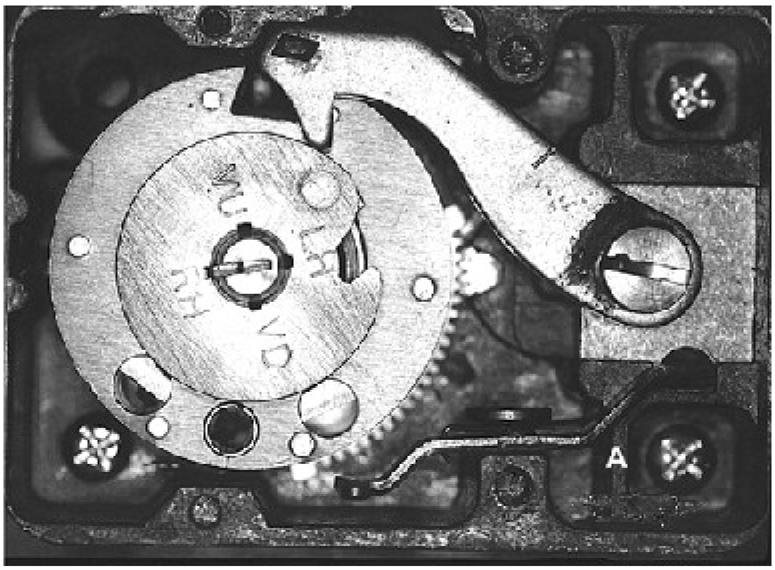
Plastic wheels such as the S&G celcon can be manufactured to a high tolerance. An added advantage is that they will retain their gate position even if they should become unlocked during normal use. Although some safe technicians to not like the feel of these wheels, they have a decided maintenance advantage in preventing lockouts.

34_3.3.5 Drive Pins and Flys

Drive pins and flys are the mechanism that transmits the

rotational information to each of the wheels as the combination is entered. They link each of the discs together in succession, so that once the position of each wheel is set it will not be disturbed as the others are moved. Each wheel contains a fly on one surface and drive pin on the opposite side. As each disc is rotated, the flys and pins catch at a specific point in the arc and will move the next wheel in succession. The system is designed so that direction of rotation will not affect the relationship between dial number and position of the gate.

34_3.4 Bolt Group



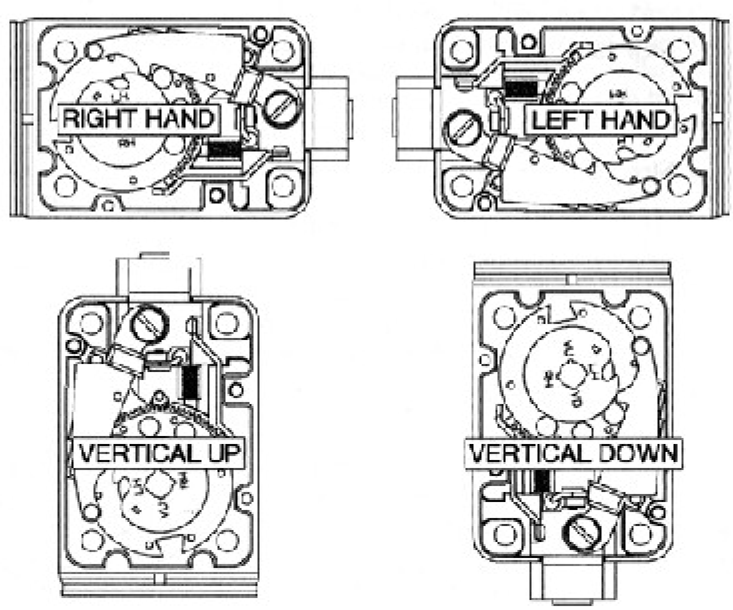
The bolt group includes the **lever**, **fence**, **bolt**, **relockers**, and **case**. The **fence** is the protrusion that must enter the gate of each wheel in order to be positioned properly. The **lever** carries the fence and engages the drive cam to actuate the bolt. **Relockers** are utilized to protect the lock case and wheel pack from forced penetration.

34_3.4.1 Lock Case Design

The case usually contains all parts of the locking mechanism, although in older safes this was not always true. It will usually consist of the body and back cover. The cover will hold the relocker, as well as the guide for the change key. The wheel post is usually an integral part of the case and performs the function of a bearing surface and guide for the drive cam. The wheels are generally affixed to the post with a clip and rotate around it.

34_3.4.2 Case Cover and Relocker

The cover is generally fabricated of the same material as the case and is utilized to seal the mechanism as well as provide a triggering mechanism for relockers. The design of a relocker depends upon the manufacturer; however, they are always released if the cover is altered or removed. They can take the form of breakaway parts, protrusions to hold down the relock trigger, weakened areas around mounting screws, or pin-depression schemes.



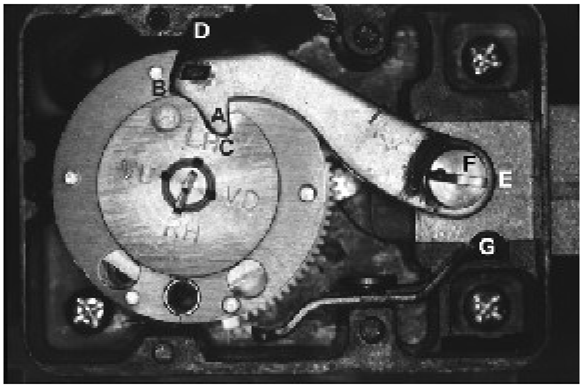
34_3.4.2.1 Materials

Cases that meet UL specifications must be fabricated with a corrosion-resistant material. Zamak, composed of aluminum and zinc, is the favorite, although older locks are made of brass, bronze, steel, or cast iron. Zamak exhibits good casting qualities allowing drilling, tapping, sanding, and filing. The material also has good tensile strength.

34_3.4.2.2 Mounting

Locks are mounted in one of four orientations, depending upon the design of the safe. This is known as "handing" and is referenced from the rear of the safe door, looking forward. Handing is significant when the safe is to be penetrated through drilling or manipulation. All mounting screws are now standardized at ¼-20 Allen head design. In some cases, the screws will be surrounded in a well to prevent one that is loose from falling into the

mechanism.



34_3.4.2.3 Case Size

The case size and hole patterns for mounting screws of almost all manufacturers are virtually identical.

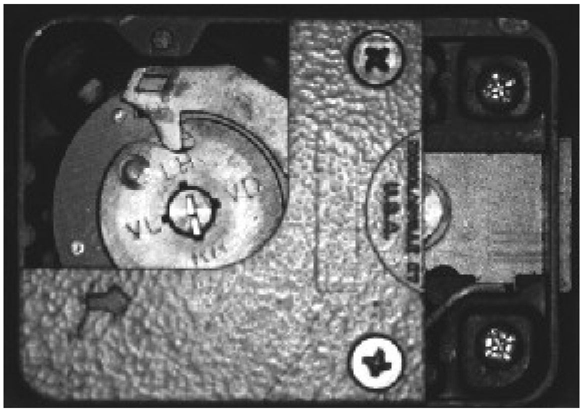
34_3.4.3 Lock Bolt

The bolt is generally made of brass or cast in zamak and coated with Teflon or other material. The lever is directly attached to the bolt. Its purpose, once extended, is to block movement of the boltwork or actuating mechanism (such as the handle-cam or carriage-bar) until the correct combination (or key) has been entered. Modern safes generally do not use the lock bolt as the actual securing mechanism for the door but rather link to a more sophisticated boltwork. This reduces the potential for lockout and minimizes stress on internal components.

34_3.4.3.1 Detent Ball

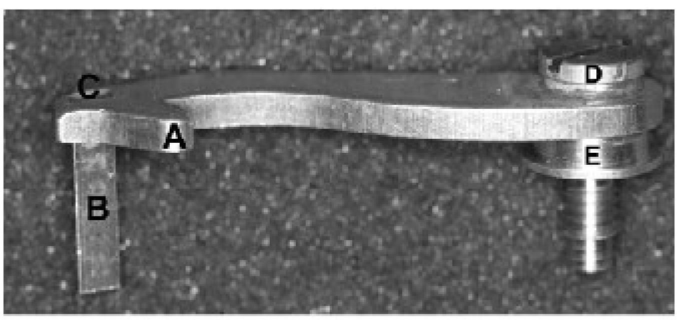
There is usually one detent ball and spring, known as a **timing ball**, located under the bolt within the case. LaGard utilizes two such balls, one for each bolt position (locked, unlocked). This mechanism performs several functions:

- **Holds the bolt in a fully extended or retracted position;**
- **Prevents bypass through vibration;**
- **Keeps the lever from binding against the lock case;**
- **Insures that the lever is in the correct position with the gates during opening.**

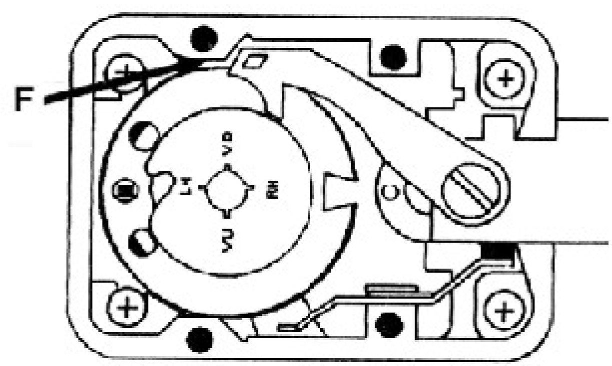


34_3.4.4 The Lever

The lever performs three critical functions:



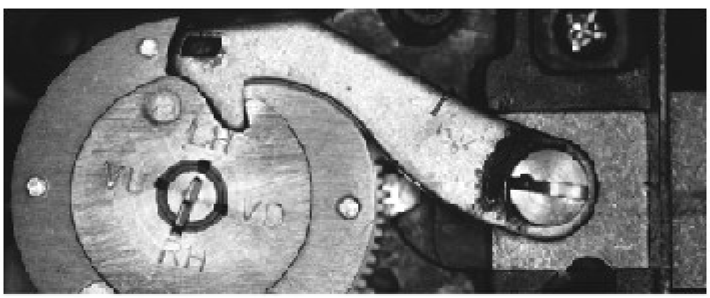
- **Positions the fence above and isolates it from the wheel pack;**
- **Engages the drive cam in order to extend and retract the bolt;**
- **It is blocked from movement once it reaches the lever stop. This prevents bolt retraction until the correct combination has been entered.**



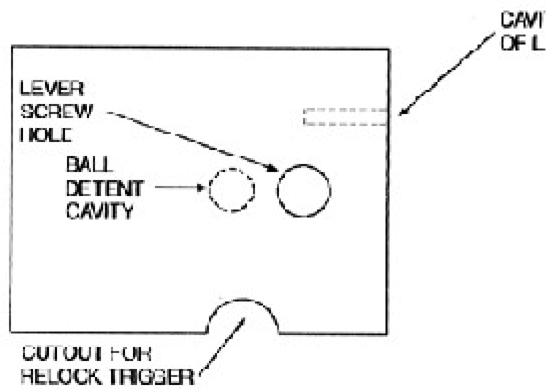
The lever is usually constructed of brass or zamak, although other materials have been utilized with limited success. Mosler, for a short while, used a cast black polycarbonate for the lever, fence, nose, and other components in the Group 1R lock for GSA containers. However, the design proved too brittle, resulting in

the nose breaking off and causing serious lockouts. It was soon discontinued.

A spring maintains downward pressure on the lever, forcing it to make contact with the drive cam. In manipulation-proof (MP) locks, the **accelerator spring** forces the lever to drop into the gate. Certain levers in MP locks are designed so that the dial or thumb-turn knob must be depressed. These control the spindle and opening of the drive cam gate.



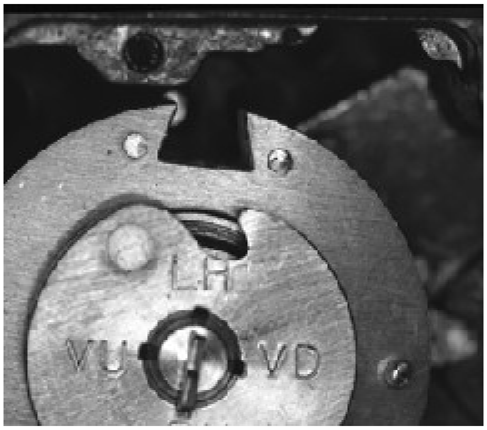
The lever has three primary components: the **fence**, **nose**, and **bushing**. The **lever stop**, **screw**, and **spring** are also part of the assembly. The **bushing** holds the lever screw, allowing the assembly to pivot as the bolt moves. The **nose**, at the opposite end from the bushing, rides on the ridge of the drive cam and drops into the gates when aligned. The **lever stop**, which is cast as part of the case, will prevent the lever from being forced to the unlocked position. The **lever screw** provides the pivot point and anchor for the lever assembly to the bolt; it is generally made of brass.



34_3.4.4.1 Nose of the Lever

The nose skirts the drive cam during rotation and keeps the fence from making direct contact with the wheels until they are properly aligned. It is designed to enter the drive cam gate and be "hooked." Once in this position, a turn of the dial will cause the lever to rotate **with** the drive cam, carrying the bolt to the unlocked (or locked) position.

34_3.4.4.2 The Lever Screw



Most locks contain a shouldered lever screw, usually made of brass. The screw holds the lever in place, and allows it to pivot. The shoulder guarantees freedom of movement, and prevents overtightening.

34_3.4.5 Fence

The fence is a metal protrusion that is soldered to the lever and is one of the critical components within any combination lock. It is constructed as a short horizontal stump or bar on the lever nose that extends in a perpendicular fashion laterally across the wheels. The fence is designed to precisely fit within corresponding slots (gates) in each individual wheel or lever when the lock has been set to open. The locking mechanism prevents actuation of the bolt until the fence is completely retracted into the aligned gates.

The fence will only make contact with each of the wheels when the proper combination has been dialed and the drive cam is in position to hook the nose of the lever and retract the bolt. When all of the wheels have been properly set, the lever assembly drops into the wheel pack and the bolt is withdrawn.

34_3.4.5.1 Fence Designs

There are four basic fence designs: **direct entry, gravity, friction, and spring loaded.** In each configuration, the fence is controlled or biased differently as it enters the gates. In a lock with a **direct-entry fence**, the bolt is part of the fence; it retracts into the gates upon opening. The wheel pack forms the obstacle, preventing entry except when aligned. If pressure is exerted upon the bolt by turning the handle, the location of each gate can be ascertained. Often, these locks will contain false gates to prevent this practice. In this type of mechanism, there are no contact points.

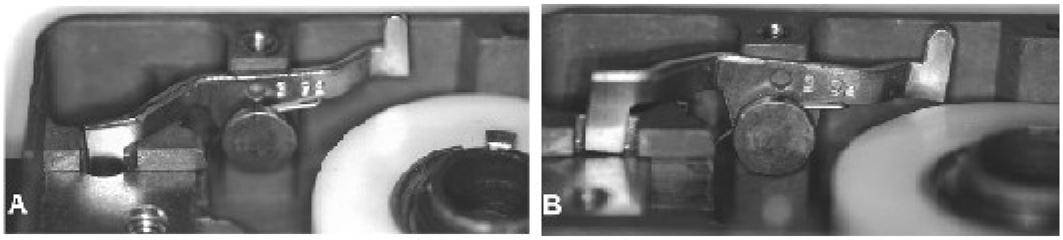
A **gravity fence** functions as the name implies. The weight of the bolt will cause the fence to drop into the aligned gates. A **friction fence** was utilized by Yale, and to a lesser extent, Mosler. It utilizes a gear drive to force the fence against the wheel pack when the gates are aligned. There will only be one contact point in these types of locks. The **spring-loaded fence** is the most common mechanical configuration. A spring will bias the fence to force it against the drive cam and wheel pack. This design is clearly distinguishable by the presence of contact points.

34_4.1 Relockers

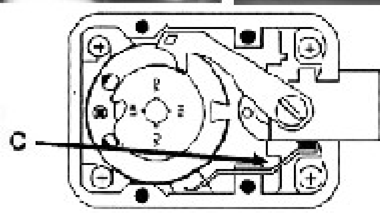
As described in **Chapter 33**, **active** and **passive** internal and external relocking devices are designed to permanently block the bolt when activated. They are incorporated within combination and key locks and throughout the boltwork mechanism of all modern safes. They are designed to protect against several forms of attack:

- **Punching the wheel pack;**
- **Drilling;**
- **Side pressure of the bolt;**
- **Thermal attacks;**
- **Vibration and concussion.**

When "fired," a relocker will lock the bolts, throw extra bolts, drop deadlock pins into place, or disconnect the links to bolts from an actuator.



34_4.2 Relockers on Safe Locks



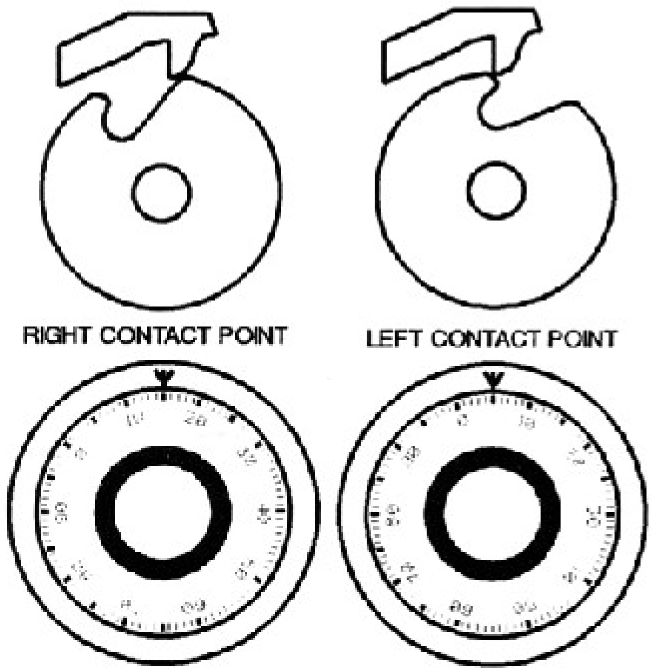
Internal relockers are mechanisms that deadlock the bolt, thereby isolating it from the wheel pack. The removal, distortion, or destruction of the lock cover or wheel pack usually activates them. Manufacturers will generally place lock case relockers in one of two positions:

- **Within the lock case. They are activated by the breaking or removal of the wheel pack or complete lock, or handle shear device;**
- **Within the door, triggered by breaking or removal of the lock case cover.**

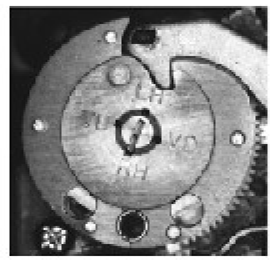
34_4.2.1 Relock Trigger Designs

Depending upon manufacturer, the relock trigger can take many forms. Although all are activated when the back of the case is compromised, the way in which the bolt, handle, or cam is blocked will vary. Although the term "relocker" is used for both safe locks and safes, the proper description is "relock trigger" when referring specifically to locks utilized in safes and vaults. The relock trigger is designed to function whenever the lock is attacked, when the cover becomes loose, or the spindle has been punched.

In early S&G designs, a spring-loaded pin or a one-piece arm protected the wheel pack from punching and deadlocked the bolt. This mechanism presented service problems and required that the trigger be removed in order to access the wheel pack. It was utilized until 1951, at which time it was modified to incorporate two components. S&G employed this system until 1962, and it was then returned to a single piece design. Currently, S&G utilize a single pivot arm to block the bolt. LaGard uses a spring wire; Mosler, a spring-loaded pin; Yale and Diebold, a spring brass tab.



Relock triggers will prevent a burglar from punching the wheel pack through the back of the lock case in an effort to gain clear and unobstructed access to the nose of the lever. Typically in this form of attack, the dial is broken off and the spindle driven into the lock case. The impact of the drive cam will generally result in part or all of the cover fracturing and breaking loose from the case. In the absence of a relock trigger, a burglar can move the wheel pack out of the way of the lever. It is then a simple matter to hook the nose and pivot the arm in order to retract the bolt. Techniques are described in U.S. patents (**4266488(385), 4470275(386)**) and in British patents (GB **2172931A(387),** GB **2069589A(388),** GB **2119011A(389),** GB 2114649A, GB 2179094A).

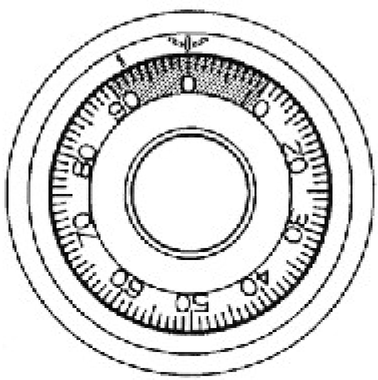


34_5.1 Physical Drop v. Dial Indication

The place at which the lever actually drops into the individual wheel gate is referred to as the **physical drop.** In contrast, the **dial indication** provides left and right contact points where the lever makes contact with the **drive cam gate.** This location will change depending upon the **handing** of the lock. The distinction

becomes important in drilling and manipulation.

The relationship between the spindle and drive cam will determine the physical drop location. The spline key is usually set at 50, although LaGard also places it at 44.



The physical drop location provides the absolute reference (with a dial index of zero) as to where the gates must be aligned in order for the lock to open. This location is calculated based upon the handing. For example, the S&G 6730 mounted RH has a physical drop of 97. If the lock is rotated to VU, 25 (1/4 revolution of the dial) would be added to 97, for a physical drop of 22. LH would be 47, and VD, 72. A dial revolution of a quarter turn of a 100 number index requires that 25 be added as the lock is rotated clockwise for each orientation.

The physical drop will be the same for all S&G 6700 and later series, as well as Federal, Diebold (800+ series), LaGard, and some imported models. Mosler locks have a shortened lever, and thus the drop is in a different position (RH 91, VU 16, LH 41, and VD 66). The Yale locks that use a roller-fence have different physical drops of (RH 80, VU 5, VD 55, and LH 30).

34_6.1 The "Forbidden Zone"

The forbidden zone refers to a mechanical problem inherent in all combination locks: the last number of the combination cannot be within the range of this area. It relates to the movement of the drive cam and the third or last wheel and their flys and drive pins. The problem is limited to mechanisms utilizing a pivoting lever and fence and cannot occur in a Yale roller fence (such as OC5) or a lock with a push-in dial.

The potential result of violating the "forbidden zone rule" is that the bolt cannot be retracted because the dial cannot be turned. Serious maintenance problems and lockouts will occur if the rule is violated. One result of the forbidden zone limitation is that the number of useable combinations is reduced. A block of numbers, generally ± 5 from the drop-in point, will be unavailable for use as the third or final number of the combination.

34_6.1.1 Violating the Forbidden Zone Rule

The forbidden zone rule only applies to the third or last wheel and its location with respect to the nose of the lever. If this wheel is positioned within the zone, it may still be possible to "run" the combination and open the lock. However, there will be no tolerance between the drive pin of the drive cam and the fly of the last wheel. When the dial is turned to retract the bolt, the last wheel is moved in order to rotate its gate to alignment with the fence.

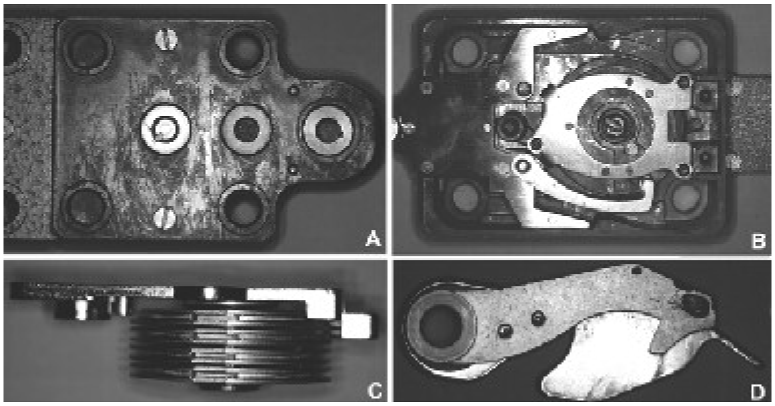
The fence is trapped in the gate before the nose can be carried by the contour of the drive cam gate, thereby blocking the extension of the bolt. This will prevent locking of the safe. Excessive wear occurs from this condition and will eventually lead to a lockout. The problem can be exacerbated when the customer tries to force the bolt to the locked position, causing

serious damage and a potentially difficult opening procedure.

If a combination is programmed that violates the forbidden zone rule, the problem can be corrected so long as the wheel pack is still accessible. The wheels are simply set to one number, the lock placed so that a change key can be inserted, and a new combination entered.

34_6.1.2 Relationship Between Physical Drop and Forbidden Zone

As with the physical drop, the zone will move in the same ratio, based upon handing. Thus, combination locks having a physical drop of 97, for example, will have a forbidden zone of zero through twenty. One exception is the S&G 8500 series with a push-in dial at zero. In this lock, the zone is 90-10. The newer LaGard locks with a spline located at 44 will have a forbidden zone of 94 through 14. The Mosler zone is 89 through 11.



34_7.0 Combination Lock Security

34_7.1 Introduction

Security, as it applies to combination locks, relates to two issues: surreptitious and forced-entry. All locks are designed to minimize their exposure to each of these threats. Mechanical considerations, materials, maintenance, and user convenience are all factors that determine the overall security of any lock. Underwriters Laboratories and many other world standards organizations have developed criteria for analyzing and rating the security of a combination lock. See **Chapter 37**.

34_7.2 Primary Security Ratings

There are two primary security classifications or groups for combination locks: **Group 1**, **1R** (a subgroup), and **2**. Group 1 listed locks are devices utilized by government agencies and entities that require the highest security, such as nuclear and missile facilities and federal law enforcement. Although the cost of Group 1 and Group 2 locks is about the same, their design is not. The public has no need for Group 1 devices.

Locks within the Group 1 category contain features specifically designed to prevent manipulation and radiographic imaging (1R). Group 2 locks such as the S&G 6730 provide a high level of security but not to the same extent as Group 1. The U.S. government, through the General Services Administration, promulgates the requirements for the use of locks on high-security containers.

34_7.2.1 Manipulation Resistance

A combination lock may be opened surreptitiously by externally sensing the position and dimensions of each of the wheel gates, thereby extrapolating the combination. The generic description of this process is known as **manipulation**. A more thorough examination of this technique is presented in **Chapter 36.**

Figure LSS+3416 S&G 6700 MP three wheel key changeable combination safe lock. Courtesy of Mark Bates.

Manipulation is possible because of imperfections in manufacturing processes and tolerances. Slight variations are encountered in the machining of parts and in mass production that allow certain locks to be opened by sensing the position of the gates.

Shortly after World War II, Harry Miller and others began developing anti-manipulation technology that was incorporated in the S&G and other locks (including padlocks) for use by the government. S&G actually copyrighted the term "manipulation-proof" in the 1950s. These locks are described in several U.S. patents (**2852928(390)**, **2814940(391)**, **2775112(392)**, **2625032(393)**, **2673457(394)**, 3045467, 3073145).

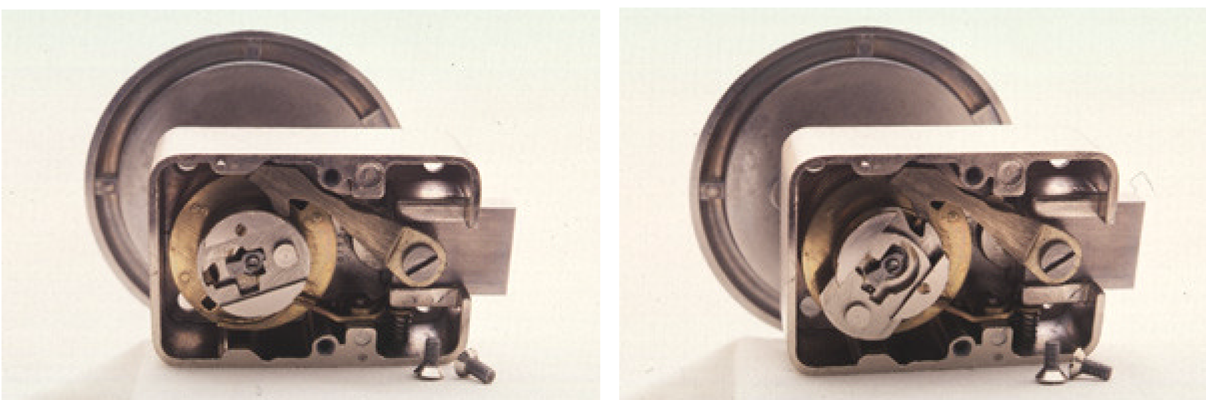


Figure LSS+3417 S&G M-6730 MP with drive cam closed and open. Courtesy of Mark Bates.

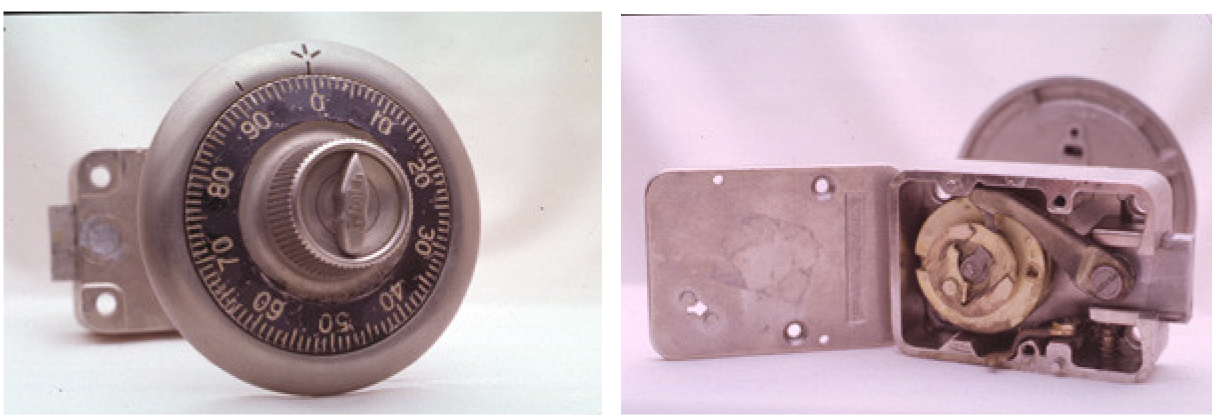

Figure LSS+3418 S&G 6700 MP lock. Courtesy of Mark Bates.

Manipulation can be accomplished manually by the operative

repeatedly turning the dial to derive the required information for the correct combination. A lock may also be opened automatically with robot dialers. These devices can be programmed to try every combination, can sense when the lock opens, and in some cases actually can hear or feel contact points. A dialer can open a three-wheel combination lock in as little time as forty-five minutes, depending upon a number of factors.

Auto dialers, such as produced by ITL, can dial up to one combination per second, depending upon the coefficient of friction in the wheels. Robot dialers will only function with Group 2 locks, although Mas-Hamilton has developed a unit for Group 1R mechanisms. These devices are programmed to take advantage of the inherent gate-fence tolerances so that a minimum number of attempts must be made in order for a successful opening. If one of the numbers of the combination is determined by manipulation before the dialer is activated, the time required to derive the remaining combination is greatly reduced.

Modern Group 2 locks are by no means manipulation proof, although some can be extremely difficult to open. Virtually all Group 2 locks can provide information (by using the dial) that will provide an indication of gate position. This is possible, even though almost every manufacturer isolates the fence from the wheels until the drive cam is in a position to allow an opening. Group 1 and 1R locks, by their very definition, cannot be manipulated now. Sensory access is denied with an **eccentric lever** that eliminates contact points by keeping the lever off the cam. It is anticipated that there will be a change in the rating criteria of Group 2 locks, or elimination of the classification altogether in order to increase resistance to manipulation. Mas-Hamilton and others have developed sophisticated technology that will defeat Group 1 locks. Electronic locks such as the X-07 cannot be opened with this technique.

Older lock designs prior to the 1950s and locks of inferior quality can be manipulated. This results from mechanical designs that allow the fence to ride on the ridge of the wheels. Sound, feel, and friction can provide the needed information to open the lock. The introduction of nylon wheels, sound baffles, secondary fences, and automatic random wheel rotation drastically reduced the potential for covert entry. Higher manufacturing tolerances, improved lubricants, and changes in mechanical design also contribute to increased security.

34.7.2.1.1 SARGENT AND GREENLEAF (S&G) 6600 SERIES COMBINATION LOCKS.

Note: The material in sections 34_7.2.1.1-7.2.1.7 has been excerpted from the **Intelligence Materiel Division Technical Data Handbook No. 2** **"Combination Locks,"** September, 1997.

There are at least three versions of Sargent and Greenleaf (S&G) combination locks in use bearing the 6600 series model number. The first version was a hand-changed lock introduced by S&G in the early 1950's. Although the lock has a spyproof dial and dial ring, the majority of them are equipped with a front-reading dial and dial ring.

The second version of the S&G Model 6600 series, also a hand-changed lock, was manufactured by S&G in the late 1960's for use on the Hillside Metal Products, now known as Art Metal, Class 6 Security Containers. This lock, as well as the earlier version, is no longer manufactured, nor are spare parts available from S&G.

The third version using the S&G 6600 series designation was a key-change lock manufactured in the 1980 to 1981 time frame, and bears no resemblance to the previous versions. This model was originally certified by Underwriter's Laboratories (UL) as a Group 1 or Group 1R, depending upon the material of the wheels. Subsequent tests of this lock by the Government revealed that the design should not be considered a Group 1 combination lock. All data in this Section is only relevant to S&G 6600 Series 1950 and 1960 version locks.

To Unlock:

Before operating the lock or changing the combination, read these instructions thoroughly. At the top of the dial ring, an opening index mark is provided for normal dialing and opening. This is a precision mechanism; therefore, extreme care must be used to align the combination numbers with the index mark.

Rotate the dial slowly and steadily. If, after turning the correct number of revolutions, any number is moved beyond the index mark, the entire series of combination numbers must be redialed. DO NOT ROTATE BACK TO REGAIN A PROPER ALIGNMENT WITH THE NUMBERS. Each time a selected number is aligned with the index mark, a revolution is counted.

CAUTION: Do not turn the Arrow Knob when the dial is set at any position other than "0", because the internal spring will be bent; this will require the mechanism to be replaced. All locks in this series are set on 50-25-50 after final inspection at the factory. Rotate dial to "0" and make sure the arrow knob is pointing to "0", then:

Figure LSS+3401 S&G Model 6600 Series (1950Version)

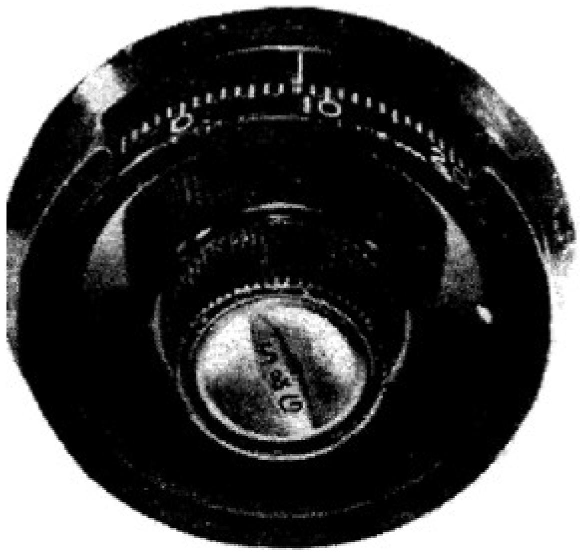

Figure LSS+3402 S&G Model 6600 Series (1960Version)

(1) Rotate dial to the LEFT, stopping when "50" is aligned with the index mark, the fourth time around;

(2) Rotate dial to the RIGHT, stopping when "25" is aligned with the index mark, the third time around;

(3) Rotate dial to the LEFT, stopping when "50" is aligned with the index mark, the second time around;

(4) Rotate dial to the RIGHT, stopping when "0" is aligned with the index mark, the first time around;

(5) On the 1950's version, hold the dial with "0" aligned with the index mark, and turn the small arrow knob to the RIGHT as far as it will go. NOTE: On the 1960's version turn the arrow knob to the LEFT as far as it will go;

(6) Rotate the dial to the RIGHT until it stops. The bolt is now

fully retracted and the safe or cabinet may be opened. The above procedure is used with any three number combination substituting the selected numbers for the example numbers 50-25-50.

To Lock:

To lock, rotate the dial to the LEFT, stopping when "0" is aligned with the index mark. Hold the dial in alignment and turn the arrow knob as far as it will go opposite to the opening direction, then continue to rotate the dial to the LEFT for at least four complete revolutions.

Changing to a New Combination:

Make up a new combination, selecting three numbers that meet the criteria for a secure series. Do not use numbers between 0 and 20 for the last number (e.g., 46-82-13). For maximum security, do not use numbers ending in 0 or 5, and do not use numbers in a rising or falling sequence (e.g., 35-50-75 is not as good a combination as 54-38-72).

(1) Make sure lock is in locked position with dial set on 50 before removing lock cover;

(2) Remove two cover screws and lift cover from lock;

(3) Remove spirolox washer or retainer clip from wheel post and remove three wheels and two washers and lay out in order of removal. CAUTION: Wheels must be replaced in the same order after changing;

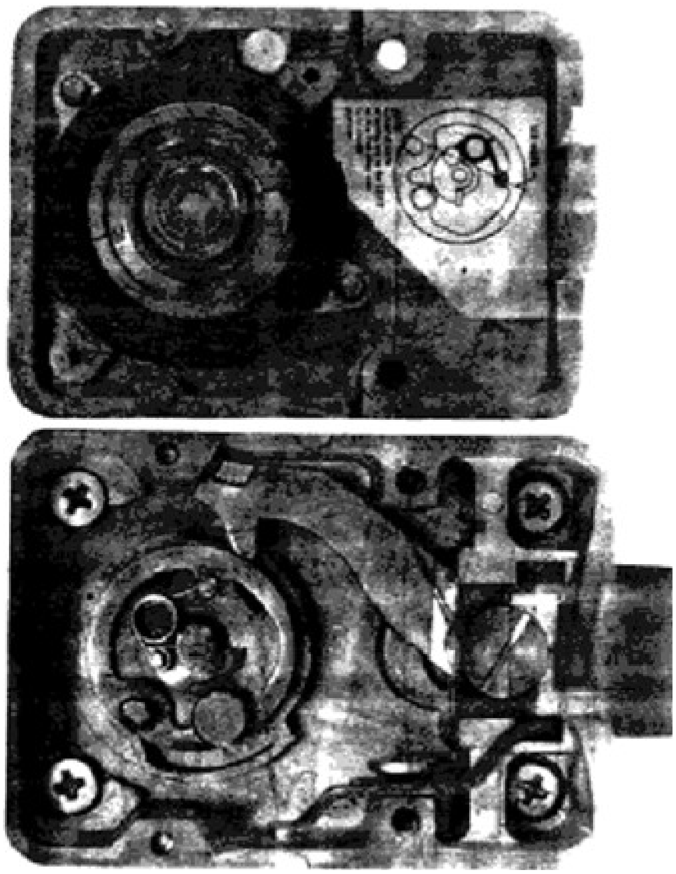

Figure LSS+3403 S&G 6600 SERIES (1960 VERSION) DISASSEMBLED

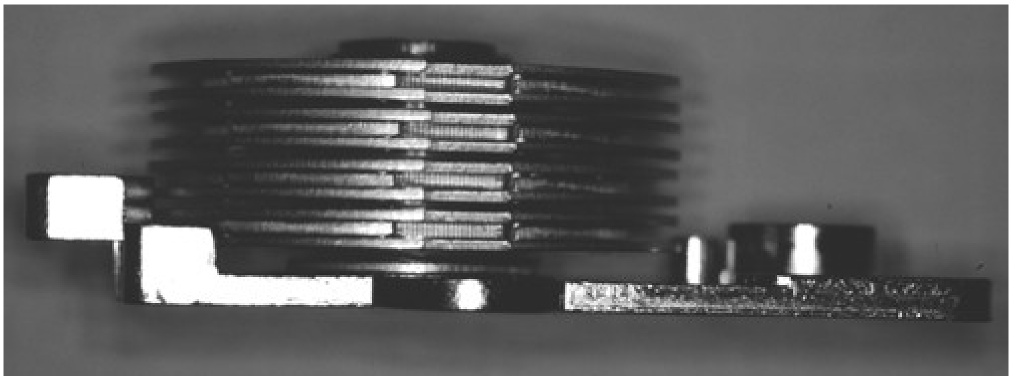
(4) Take the last wheel removed with numbers facing you, and press up the inner disc separating it from the outer ring;

(5) Reset the inner disc in the outer ring with the index mark on the metal insert opposite the number selected for the first number of the new combination. Replace the wheel on the post with numbered-side UP. Replace washer. CAUTION: Observe that the numbers increase counterclockwise on the wheels;

(6) Repeat the above process with the middle and top wheels. To help identify the wheels, observe the middle wheel gate (cutout) is approximately 180 degrees opposite the number, 92;

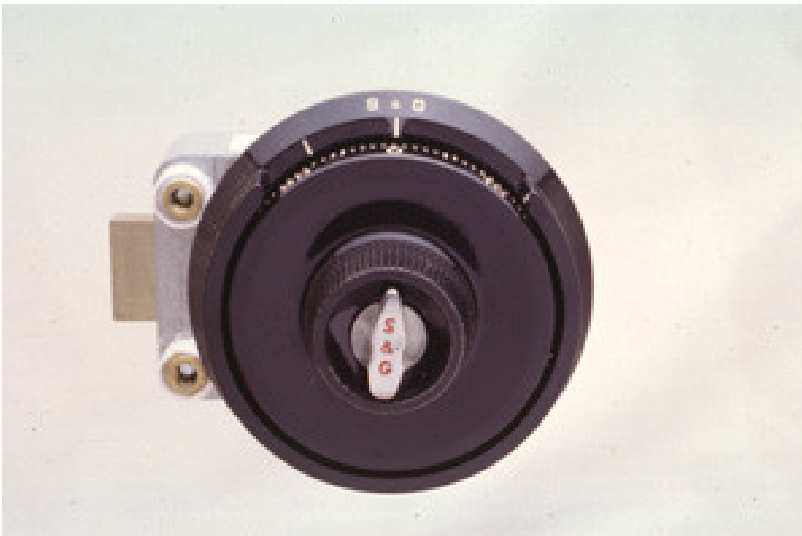


(7) Replace the spirolox washer or retaining clip. Cover is now ready to replace on lock;

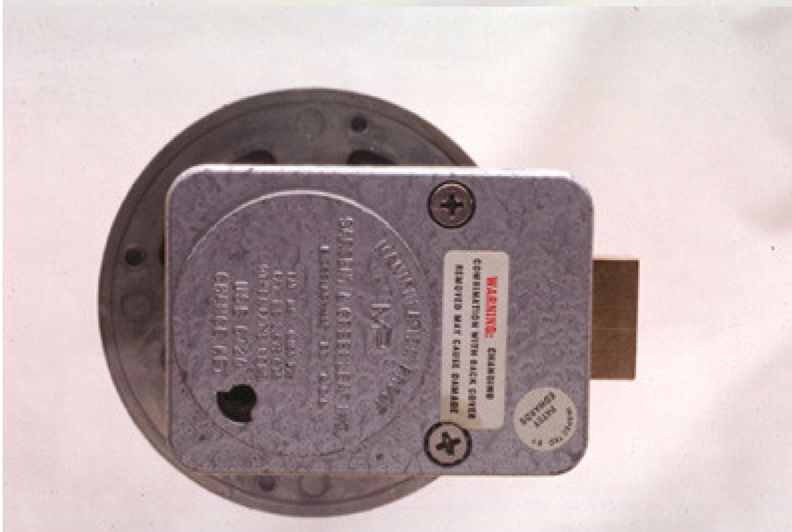
(8) Before closing the door, operate the new combination several times to test it.

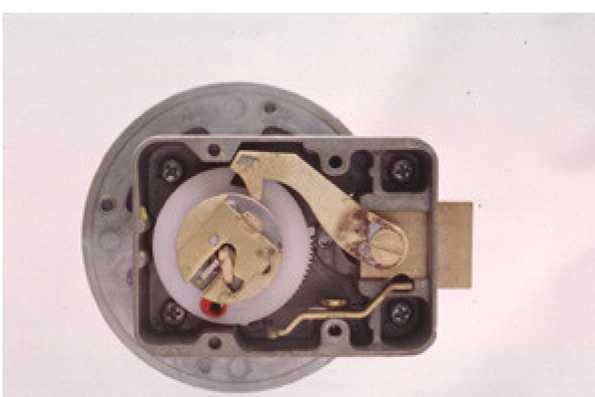
34_7.2.1.2 S&G 8400 SERIES

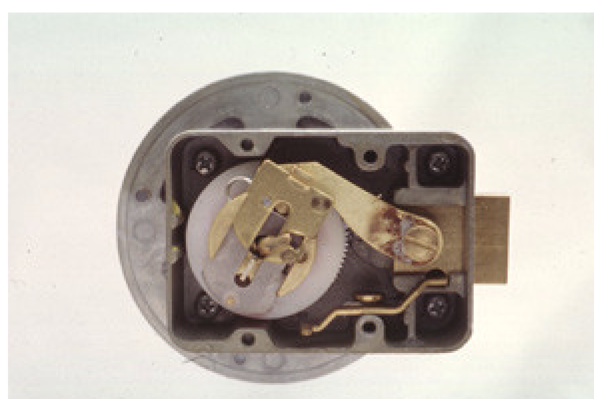
The **8400 Series** S&G Combination Locks are key-changeable Group 1 and 1R "Manipulation Proof" (MP) identified with the typical S&G arrow knob (butterfly) in the center of the dial knob. The drive is **gear** indirect type to increase **manipulation resistance.**



Opening the 6730 MP and 8400 Mp, by Harry Sher







Unlocking Procedure:

At the top of the dial ring, an opening index mark is provided for normal dialing and opening. This is a precision lock, therefore, extreme care must be used to align the combination numbers with the index mark. Rotate the dial slowly and steadily. After rotating the correct number of revolutions, should any number be rotated beyond the index mark, the entire series of combination numbers must be redialed. DO NOT ROTATE BACK TO REGAIN A PROPER ALIGNMENT WITH THE NUMBERS. Each time a selected number is aligned with the index mark a revolution is counted.

WARNING: CHANGING
COMBINATION WITH BACK COVER
REMOVED MAY CAUSE DAMAGE

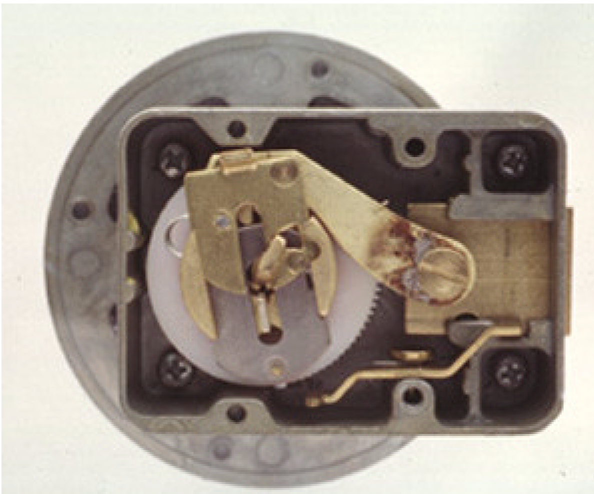


Figure LSS+3419 The S&G 8400 series lock. Notice the distinctive back cover for this MP lock. The photographs show the drive cam closed (left), open (center), and retracted (right). Courtesy of Mark Bates. Courtesy of Mark Bates.

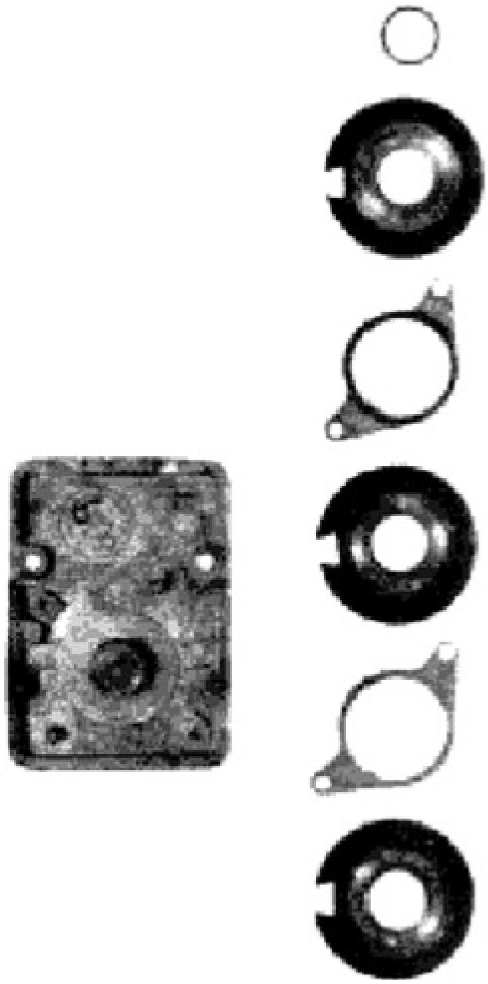

Figure LSS+3404 Disassembled hand change wheel pack; Spirolox Washer, No. 3 Wheel, Cover Plate Spacer, No. 2 Wheel, Spacer, No. 1 Wheel

CAUTION: Do not turn the arrow knob when dial is set at any position other than "0", because the internal spring will be bent, requiring the lock to be replaced. All mechanisms in this series are set on 50-25-50 after final inspection at the factory. Rotate dial to "0" and make sure the arrow knob is pointing to "0" then:

(1) Rotate dial to the LEFT, stopping when "50" is aligned with the opening index mark, the fourth time around;

(2) Rotate dial to the RIGHT, stopping when "25" is aligned with the opening index mark, the third time around;

(3) Rotate dial to the LEFT, stopping when "50" is aligned with

the opening index mark, the second time around;

(4) Rotate dial to the RIGHT, stopping when "0" is aligned with the opening index mark, the first time around;

(5) Hold the dial with "0" aligned with the opening index mark, and turn the small arrow knob to the RIGHT as far as it will go;

(6) Rotate the dial to the RIGHT until it stops. The bolt is now fully retracted and the safe or cabinet may be opened. The above procedure is used with any three-number combination, substituting the selected numbers for the example numbers 50-25-50.

Locking Procedure:

Rotate the dial to the LEFT, stopping when 0 is aligned with the index. Hold the dial in alignment and turn the arrow knob one quarter turn to the LEFT (as far it will go), then rotate the dial to the LEFT for at least four complete revolutions.

Changing to a New Combination:

Select three new numbers that meet security guidelines for combinations,as defined earlier. CAUTION: Use Change Key 6720 (unless otherwise specified on back of lock) on this series lock, other keys will not function properly.

(1) Using the changing index, dial the existing combination as previously explained;

(2) Hold the dial with the last number at the changing index found 8 1/5 numbers to the left of the opening index. Insert the change key in the keyhole in the back of the lock until the wing is entirely inserted and comes to a positive stop;

(3) Turn the key one-quarter turn to the LEFT. With the change-key in this position, turn the dial four complete turns to the LEFT, stopping when the first number of the newly selected combination aligns with the changing index, the fourth time;

(4) Rotate dial to the RIGHT, stopping when the second number is aligned with the changing index, the third time;

(5) Rotate the dial to the LEFT, stopping when the third number is aligned with the changing index, the second time;

(6) Holding the dial in this position, turn the change-key back to the RIGHT and remove it. The new combination is now set in the lock;

(7) Before closing the cabinet, try the new combination several times, using the opening index.

WARNING: Never insert the change key in the lock when the cover is removed. Always be certain that the wing of the change key is entirely within the lock before turning the key.

If an error has been made in setting a new combination, it is suggested that local Facilities Engineers or supporting Military Intelligence (MI) personnel be notified. Caution dictates that a new temporary storage facility be found until competent assistance arrives. DO NOT shut control drawer or vault door when this error occurs.

S&G MODEL 8470 MODIFICATION:

S&G now manufacturers a new "Locked-Open Latch" which is used on their Model 8470. The back cover plate can be retrofitted on existing 8470's. The latch is designed so that passersby cannot spin the dial when the combination has been dialed, or use back-dialing to recover the combination.

SARGENT & GREENLEAF Model 8470 Combination lock with dead bolt:

The diagram below shows an S&G Model 8470, formerly SM50 Pinch-proof combination lock. It is a reversible, surface-mounted lock for use on locally fabricated doors constructed of either wood or metal. The lock features an automatic deadlock tripper, and an inside release knob allowing the lock to be opened from the inside in the event the door is closed and the combination is spun off. The 8470 can be ordered with either the S&G Model 8400 or 8500 Series Combination Lock; Spyproof Dial (TOP READING) should be specified. In the event the 8500 Series combination lock has been specified, ensure the proper handing of the lock (i.e., left or right) is also designated. In addition, ensure that the lock is equipped with a tube for ease of installation.

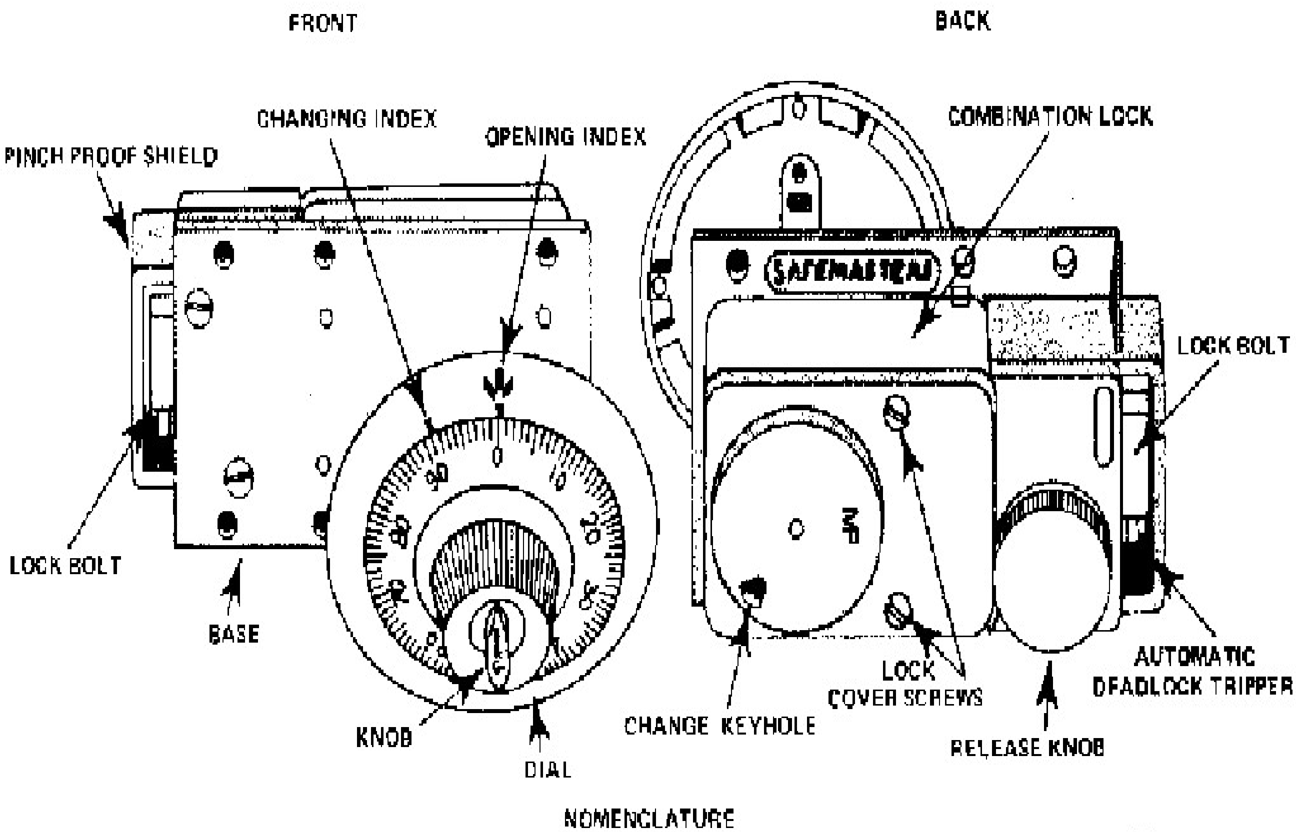

Figure LSS+3420 S&G Model 8470 combination lock with dead bolt.

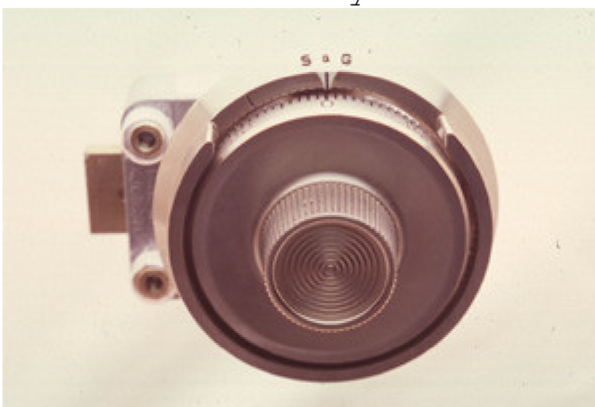
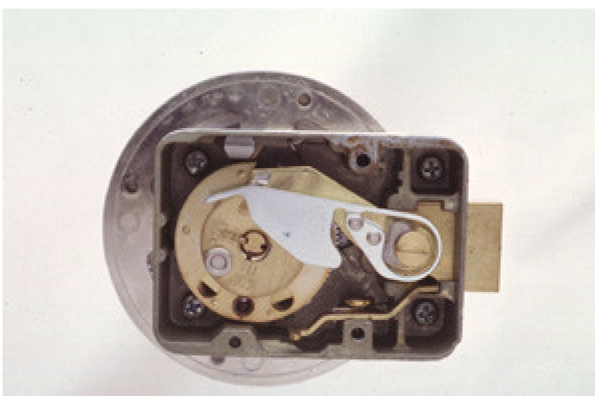
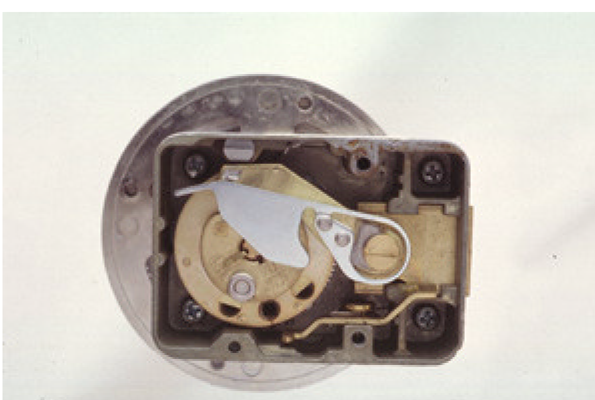


Drill resistant hard plate: A 1/8 inch drill-resistant hard plate should be installed between the S&G Model 8470 and the locally fabricated door. In certain regulations and manuals, this hard plate is a requirement that should not be overlooked. The drill-resistant hard plate should be installed at the same time that the 8470 is installed.

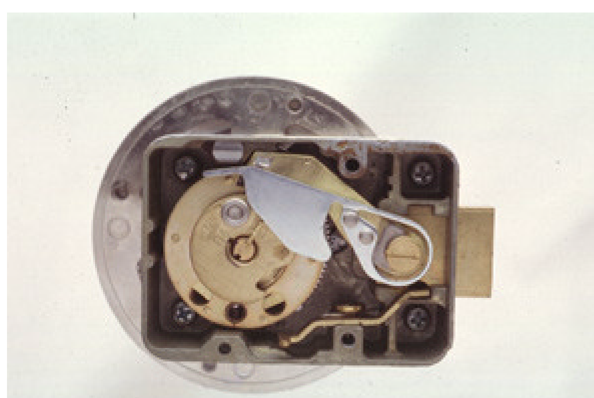
34_7.2.1.3 S&G 8500 SERIES COMBINATION LOCKS



There are several methods of attack to penetrate combination locks. Manipulation Proof (MP) locks produced by Sargent and Greenleaf offer far greater protection than any other lock. The 8500 Series MP locks have been designed to give added security against penetration in light of new scientific instruments and methods of attack. The security offered conforms to UL Groups 1 and 1R.



This Series does not have the typical inner spindle thumb turn knob (arrow knob or butterfly) on the dial as used in previous



S&G Group 1 and 1R MP combination locks. The 8500 Series may be identified by a plain center dial that can be pushed in at the zero location. This action is spring loaded and causes a definite click to be triggered. It is important to that installation and service personnel appreciate the 8500 Series MP locks' features. A satisfactory installation, requires that these instructions to be followed closely.

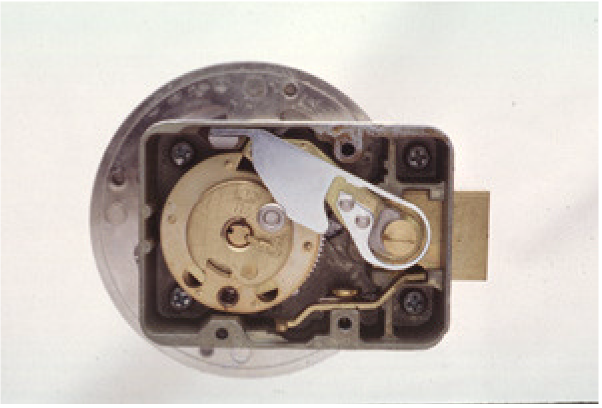


Figure LSS+3421 The S&G model 8550. Photographs show the wheels aligned and the dial at zero (top center), dial has been pushed in, allowing lever to drop (top right), the bolt may be retracted (bottom left), when the dial is rotated to extend the bolt, the roller on the drive cam contacts the accelerator spring (bottom center), and lifts it back onto the shelf (bottom right). Courtesy of Mark Bates, Modern Safe Locks.

IMPORTANT: Tolerances must be maintained and related components must be used to achieve overall satisfactory performance. The lock is designed for right-hand, vertical-up or vertical-down use. Left hand operation was originally achieved with a true left-hand model. A Universal Model has superseded these, and is the present model offered. All locks feature a relock trigger as a standard security feature. The 8500 Series Combination Lock is available in four models. They are:

8550: Three brass wheels, no tube
For: Universal: 8550-UNI (Present Model)
For: Right Hand Vertical Up or Vertical Down: 8550-COM Obsolete (ref. only)
For: Left Hand: 8550-OLM Obsolete (ref only)

8555: Three brass wheels, with tube
For: Universal: 8555-UNI (Present Model)
For: Right Hand Vertical Up or Vertical Down: 8555-COM Obsolete (ref only)
For: Left Hand: 8555-OLM Obsolete (ref only)

8560: Three x-ray Proof Wheels, no tube
For: Universal: 8560-UNI (Present Model)
For: Right Hand Vertical Up or Vertical Down: 8560-COM Obsolete (ref only)
For: Left Hand: 8560-OLM Obsolete (ref only)

8565: Three x-ray Proof Wheels, with tube

For: Universal: 8565-UNI (Present Model)
For: Right Hand Vertical Up or Vertical Down: 8565-COM Obsolete (ref only)
For: Left Hand: 8565-OLM Obsolete (ref only)

Dialing Combination to Unlock:

On the dial ring, there are two indices. The index at the top is for normal dialing and opening. The index to the left is provided for use only when changing the combination. Rotate the dial slowly and steadily. After turning the correct number of revolutions, should any number be turned beyond the index mark, the entire series of combination numbers must be redialed. Do not turn back to regain proper alignment with the numbers. Each time a selected number is aligned with the opening, index a revolution is counted. To unlock on a factory setting (50-25-50):

(1) Rotate the dial to the LEFT, stopping when "50" is aligned on the opening index the fourth time around;

(2) Rotate the dial to the RIGHT, stopping when "25" is aligned the third time around;

(3) Rotate the dial to the LEFT, stopping when "50" is aligned the second time around;

(4) Rotate the dial to the RIGHT, stopping when "0" is aligned the first time around;

(5) With "0" aligned in the index, push dial in to activate lever assembly, release dial;

(6) Rotate the dial to the RIGHT for a right hand and Universal lock and LEFT for a true left hand lock, until the bolt is fully retracted. Then the combination lock can be opened. NOTE: True left hand locks are no longer made, but early 8470 deadlocks used these for left opening doors. This procedure is used with any three number combination selected. CAUTION: Dial should not be pushed in and released at "0" until all three numbers have been dialed.

Procedure to Lock:

Rotate the dial LEFT or RIGHT at least five complete revolutions in one direction.

Changing to a New Combination:

Select three numbers. Do not use digits between 90 and 10 for the last number.

NOTE: Only use Change Key 6720 on these locks; others will not function properly. When using new locks and new change keys, the change key may be difficult to turn at first. This situation may be eliminated by removing the lock cover, inserting the change key through the hole in the cover and turning it several times. Then remove the key and replace the cover on the lock.

WARNING! Never insert the change key into the lock itself when the cover is removed. Also, always be certain that the change key is entirely within the lock before turning.

(1) Using the changing index, dial the existing combination as explained previously, substituting charging index;

(2) Leave the dial with the third number at the changing index, insert the change key in the key hole in the back of the lock until the wing is entirely inside the lock and stops;

(3) Turn the key one quarter turn counterclockwise. With the change key in this position, dial your newly selected combination to the change index;

(4) When the third number is aligned with the changing index the second time, hold the dial in the position, turn the change key one quarter turn clockwise; this will relock the wheels with the new combination set;

(5) Before closing the container, try the new combination several times using the opening index.

NOTE: Read complete instructions on each style of lock before installation.

General Installation Instructions for S&G 8500 Universal (UNI) Series Locks to be followed when replacing locks in security containers.

(1) Remove the lock cover. Put the lock bolt in the extended position and the accelerator spring in the loaded position.

CAUTION: DO NOT remove the drive cam;

(2) Mount the lock in place with four 1/4 x 20 attaching screws;

(3) Attach the dial ring, lightly tighten the attaching screws to hold the dial ring in place for alignment. The dial ring opening index should be at 12 O'clock center position. Before installation of the dial ring, the plastic bearing insert should be pressed into the opening in the back of the dial ring. The insert must fit flush with the dial ring;

(4) To install dial, hold the drive cam in place with one hand and thread the dial into the cam until the dial comes to a stop against the surface of the dial ring;

(5) The alignment of the dial and dial ring is critical to the operation of the lock. Perfect alignment must be obtained. The dial should be flush and centered with the surface of the dial ring for true center;

(6) Measure the excess spindle that projects beyond the drive cam;

(7) Remove the dial, cut off excess spindle and remove burrs;

(8) Tighten the dial ring screws;

(9) Place a washer, compression spring and washer on hub of dial;

(10) Insert the dial into the lock. Holding the drive cam in place (to receive the nose of the drop lever) with one hand, thread the dial into the cam until the dial stops;

(11) Rotate the dial counterclockwise a MINIMUM of one full turn until the spline in the spindle is aligned with the proper spline in the cam, the cam is positioned to receive the nose of the drop lever, and the dial is on zero. NOTE: If the lock is mounted in the vertical-up or vertical-down position the properly aligned spline should be marked VU/VD on the drive cam. For right or left hand mounting RH/LH should be aligned;

(12) Insert the spline key with lip toward edge of cam. Tap in lightly. The dial must turn freely with no rubbing or interference. (NOTE: Before attaching the cover to the lock,

check for proper in and out travel of dial for operation of accelerator spring.);

(13) Rotate the dial at least one complete revolution and stop at "0". The accelerator spring should now be in the loaded position;

(14) Hold the cover in place on the lock and push the dial in at "0". Release the dial. Remove the cover and check the position of the accelerator spring (the spring should be in the released position). If the accelerator spring is not in the released position, the dial has not been backed out of the cam far enough. This condition must be corrected;

(a) Repeat step (11);

(b) Rotate the dial at least one complete revolution and stop at "50". The accelerator spring should not release. (If the accelerator spring does release, the spindle must be turned clockwise into the cam one revolution and this step repeated.);

(c) Hold the back cover in place on the lock and push the dial in at "50". The accelerator spring should not release. (If the accelerator spring does release, the spindle must be turned clockwise into the cam one revolution and this step repeated.);

(15) Dial the set combination (50-25-50) on the lock and observe the drop lever falling into the drive cam at least three times;

(16) When the accelerator spring is opening properly, the cover may be attached to the lock and the new combination set;

Special Instructions for S&G 8500 Series Tube Locks:

(1) Fasten the lock to the mounting plate. Place the dial ring on the tube;

(2) Measure the tube excess. Remove the lock and cut off excess. Leave 3/16" to insert in dial ring;

(3) Remove any burrs from end of tube. Replace the dial and ring on the door.

Torque Adjustment:

The torque adjustment feature allows the feel of the dialing of the combination to be adjusted for individual preference. With the cover removed, insert an Allen wrench into the adjusting screw. Turn clockwise to tighten or counterclockwise to loosen. NOTE: Adjustment should not be less than eighteen inch-ounces of dialing torque, i.e., slight drag on the dial.

Disassembly for Servicing:

Periodic servicing will extend the life of the lock and is essential for maintaining proper security. To do a proper servicing job, follow the disassembly carefully (see Diagram of Disassembled Lock).

(1) Remove lock cover;

(2) Remove lever screw and lever assembly. Be sure to remove the lever control tension spring so it is not misplaced;

(3) Using a pair of side cutters, grip the head of the spline key as close as possible to the surface of the drive cam. Lift straight up, being careful not to bend the head. The edge of the case may be used for leverage;

(4) Unscrew the dial from the lock. Remove cam;

(5) Remove Spirolox washer from wheel pack carefully with a sharply pointed instrument;

(6) Remove wheels and associated parts and place them in sequence so that they can be replaced in proper order;

(7) Remove the lock bolt, do not misplace the detent ball or ball spring;

(8) Remove dial and spindle assembly from dial ring;

CAUTION: Remove the washers and spring from the dial ring and carefully place them in sequential order for reassembling later. The lock is completely disassembled and ready for servicing.

Service and Reassembly:

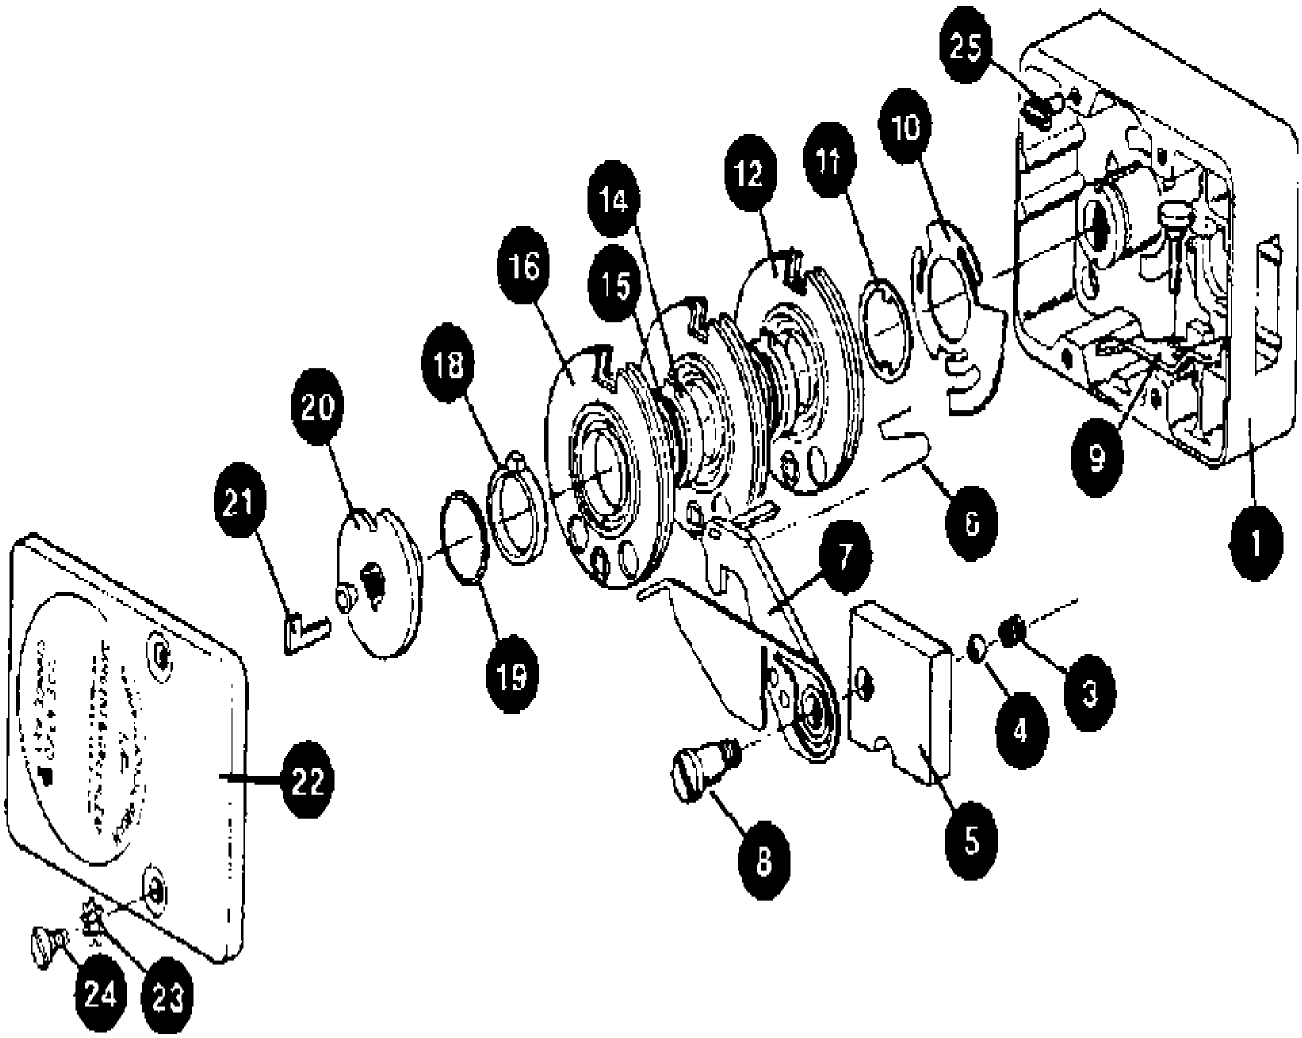

Figure LSS+3405 Diagram of disassembled lock

(1) Tighten the attaching screws on the dial ring and lock;

(2) Wipe each wheel, the wheel post and other bearing surfaces clean. Wipe complete interior of the lock case clean;

NOTE: S&G recommends that GE-322L Lubricant be used. If this lubricant is not available, use a thin film of white petroleum jelly;

(3) Lightly grease the bolt holding up the relock device and insert the bolt;

(4) Be sure to examine each wheel part, the cam, and lever

assembly carefully to make sure nothing is worn or damaged. Replace the wheels and parts exactly as they were before disassembly;

(5) Lightly grease the bearing surfaces of the wheel post and drive cam bearing, then screw the dial and drive cam together until snug. Hold the cam and turn the dial back one complete turn, then align the spline keyway. Insert the spline key. IMPORTANT: It is recommended that a new spline key be used each time the lock is serviced;

(6) Grease the lever bushing and install the lever. Tighten the lever screw snugly, and carefully position the lever control tension spring. Be careful not to bend the actuator spring;

(7) Install the lock cover. Make sure the cover screws are tight and secure;

(8) Reset the combination;

(9) Check the combination at least three times before locking the safe.

Errors:

The most frequent error during the changing procedure is dialing the number on the wrong index. Occasionally, all the numbers may be dialed to the opening index rather than the changing index. More often, dialing part of the combination to the changing index and part to the opening index occurs. As long as the container or door is open, the error is easily corrected.

Recovery Procedure in the Event of Error:

(1) Remove the back cover of the lock;

(2) Insert a straightened paper clip or similar instrument in the square keyways in the wheels;

(3) Rotate each wheel until all keyways are in perfect alignment directly over the small hole in the bottom of the case. There are two holes in the case, the keyway in the cover generally tells you the correct location;

(4) Replace the cover and screws, then insert the change key. NEVER INSERT THE CHANGE KEY INTO THE LOCK WHEN THE COVER IS REMOVED. Always be certain that the wing of the change key is entirely within the lock before turning the key;

(5) Turn the change key one quarter turn and dial the new combination using the changing index;

(6) Remove the key with the combination now set;

(7) Try the combination at the opening index at least three times before closing the door.

34_7.2.1.4 Mosler Model 300-400 and 301-401 MR Series Locks

There are four models of the Mosler combination lock. Although the detailed instructions in this text only deal with the 302-402 MR and MRK series, the following series of locks might also be encountered in the field:

The Mosler Model 300-400 hand-change combination lock is the forerunner of the Manipulation Resistant (MR) series that Mosler currently manufactures. The wheel pack is constructed of a light gray plastic material, which includes the inner disc that is employed to set the combination. This lock was usually supplied with a bright chrome dial and dial ring.

The Mosler Model 301-401 MR is also a hand-change lock and was usually supplied with a bright chrome dial and dial ring. The wheel pack consisted of the same light gray plastic material as the Mosler Model 300-400. The inner disc of each wheel is constructed of metal.

34_7.2.1.5 Mosler Model 302-402 MR and 302-402 MRK Series Locks

The Mosler Model 302-402 MR is the current model of the Mosler Hand Change Combination Lock. This lock can be identified from the exterior by a brushed chrome dial and dial ring. The wheel pack is constructed of a black plastic material with a metal inner disc. The Mosler Model 302-402 MRK is the newest combination lock that Mosler manufactures. The "K" in the model designation signifies that this lock is a key-change variety. When the MRK was first introduced, the dial and dial ring

remained the same as the 302-402 MR hand-change lock.

Because these dial rings did not have a separate changing index, the operator had to use the opening index as the changing index to change combinations. This was accomplished by adding 10 numbers to the selected combination. The 302-402 MRK now has both a changing index and opening index inscribed on the brushed chrome dial ring.

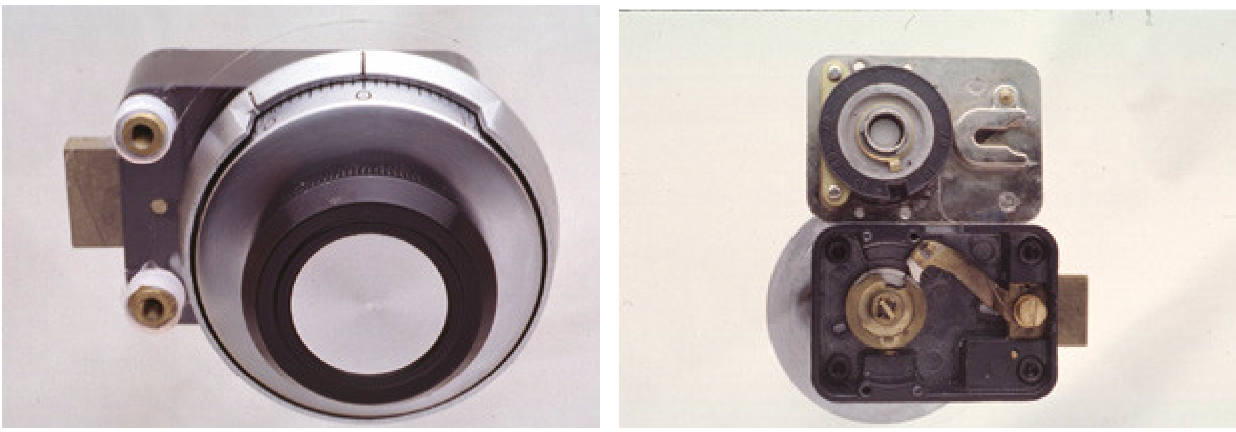

Figure LSS+3406 Mosler 302 MR Hand Change Lock

(1) Rotate the dial for a minimum of four times to the LEFT. This clears all previously dialed numbers. Stop EXACTLY at the opening index mark the fourth time that the first number of the combination has reached the opening index mark;

(2) Rotate the dial to the RIGHT. Stop EXACTLY at the opening index mark the third time that the second number of the combination has reached the opening index;

(3) Rotate the dial to the LEFT. Stop EXACTLY at the opening index mark the second time that the third number of the combination has reached the opening index mark;

(4) Rotate dial to the RIGHT, pausing a moment at zero, and then continue rotating to the RIGHT until the dial stops. The locking bolt is now retracted. This enables the handle of the drawer or door to be "thrown", thus allowing it to be opened. Always rotate the dial slowly and evenly. Spinning the dial is unnecessary, and may cause loosening of component parts which could cause a lockout.

To Change Combination MOSLER MRK 302 Series (Key Change):

(1) Open the drawer or door and release the bolts to the locked position. (If unit is equipped with a locking bolt interlock, it will be necessary to depress the interlock plunger before the bolts can be thrown.) Dial the old combination exactly as normal in the opening instructions; however, stopping at the changing index mark, which is (approximately 10 digits) left of the opening index mark;

(2) Insert the proper change key in back of the lock. Be sure it is inserted all the way up to the shoulder. Turn the key to the limit of its travel in the direction indicated by the arrow marked on the lock cover;

(3) Select the new combination within the parameters given below, and write it down;

(a) Keep numbers above 13,

(b) Below 90, and

(c) Ten digits apart.

(d) Use high-low-high or low-high-low.

(4) Dial the new combination on the changing index mark (using proper turns), being certain of preciseness when stopping at the index. When uncertain of the correctness of the dialing, start over again. This will save time in case of error. After dialing the last number of the combination, do not disturb the dial;

(5) Turn the change key to the limit of its travel in the direction opposite to arrow. REMOVE CHANGE KEY;

(6) Try the new combination, using the opening index at least twice before closing the container in order to be certain that the combination is set properly and operates smoothly;

If New Combination Fails to Operate:

If the lock cannot be opened on the new combination, it can be assumed the new numbers were not set properly. It will then be necessary to remove the cover from the lock case. Proceed as follows:

(1) Remove two screws and the back cover plate. This will expose the wheels on the back plate;

(2) Rotate the dial until the fence disengages from the gate of the drive cam;

(3) Turn the wheels so that all change keyholes line up. Keeping holes in line, turn wheels until the change keyholes in the wheels align with the change-key hole in the lock cover;

(4) Carefully replace the cover to the lock case so as not to disturb the wheels. Before attaching the cover to the lock case, check to see that the change-key holes in the wheels are aligned with the change-key hole in the cover;

(5) Insert the change-key and proceed.

To Change Combination, Mosler MR 302-402 Series (Hand Change).

When selecting numbers for the new combination, use recommended method as listed in 302 MRK Key Change procedure.

(1) Open the container as previously described. The locking bolt must be extended to the locked position to remove the cover. Turn the dial several revolutions, stopping at approximately the number "50";

(2) Remove the cover plate screws from the rear of the lock and detach the cover plate from the case. (On some containers, it may be necessary to remove a panel or small circular cover from the inside of the door to expose the lock.;

(3) Remove the retainer clip from wheel post. Remove the wheels and spacers. Wheels are numbered on outer plastic ring in order that they can be replaced on the post in the proper sequence. The number-one (1) wheel is set at the first number of the combination, and is the first wheel on the post;

(4) Hold number one (1) wheel assembly with numbers up and push the center disc upward until it is removed from the outer ring. Rotate center disc until the setting mark on the metal insert is opposite the desired number on the ring. Press the center disc back into position until it's flush with the outer plastic ring.

Observe that numbers increase counterclockwise on wheels. Change the combination numbers on the remaining wheels in the same manner. Remember to keep numbers above 13 and below 88.

(5) Replace parts on the post in the proper sequence. To help identify wheels for proper reassembly, each Mosler wheel has a number 1, 2 or 3 molded next to one side of the gate (cutout). Further confirmation is gained by observing that the gate (cutout) of the middle wheel is 180 degrees opposite zero. There may be more than one tension washer at the base of the wheel post. The numbered side of the wheels are to face up. When the retainer clip is replaced, check to ensure that it is properly seated in the groove on the post, and that all wheels and spacers are properly mounted on the wheel post;

(6) Replace the cover and screws. Tighten screws firmly;

(7) Try to lock at least twice on the new combination with the CONTAINER OPEN to be sure that the lock is set properly and operates smoothly.

34_7.2.1.6 LaGard 1980-ARL Group 1R Combination Lock

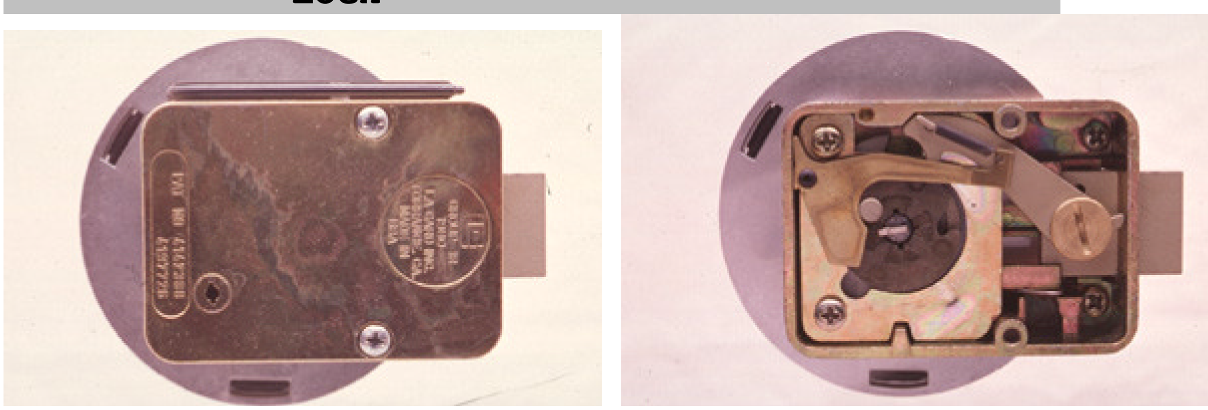

Figure LSS+3422 LaGard model 1980. Courtesy of Mark Bates.

The LaGard Model 1980-ARL has been certified by Underwriter's Laboratories and approved by the General Services Administration as a Group 1R Combination Lock. It may be found as original equipment on Art Metal GSA Approved Security Containers and is only available in a key-change configuration. Combination changing procedures for the Group 1R LaGard are identical to that of the Mosler Key Change Model 302 MRK. Therefore, when combination changing is desired, refer to the procedures listed

for the Mosler 302 MRK. The LaGard Group 1R is easily identifiable by its unique dial and dial ring. You must use the LaGard change key.

34_7.2.1.7 Mas-Hamilton X-07 Group 1R Electromechanical Lock

Opening the X-07:

The X-07 lock has been shipped preset in the Single Combination Mode with the combination set to 50-25-50. Practice opening the lock several times before setting a new combination. The X-07 uses sophisticated computer security and makes dialing much easier than that of traditional combination locks. The X-07's computer recognizes a number as being part of a combination when you stop dialing on that number and then reverse the dialing direction. If at any time the dial remains stationary for more than forty seconds, the computer will reset (LCD will go blank) requiring the operator to redial the entire combination.

The X-07 has protective software that detects robotic dialing. If robotic dialing is detected, the X-07 will not open even if the correct combination has been dialed. The user should dial with complete full wrist turns. This helps the X-07 distinguish between human and robotic dialers. The X-07 may mistake a human for a robot if the user:

- Dials more than 1.3 revolutions in either direction with no pauses in dialing activity;

- Dials with very short, quick repetitive turns, producing very short pauses in dialing activity;

- Dials the combination in less than fifteen seconds (ten seconds in newer version).

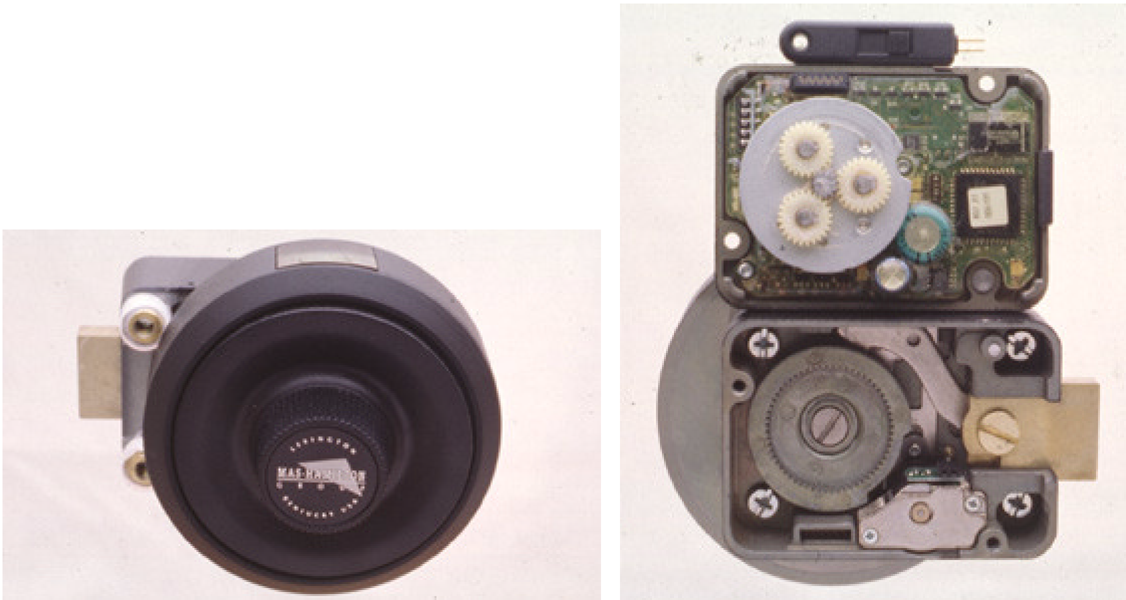

Figure LSS+3407 Mas-Hamilton Group X-07 Electromechanical Lock. Courtesy of Mark Bates.

Opening the X-07 using the Preset Combination:

(1) Dial left (counterclockwise) 4-6 turns to "power up" the lock. Numbers will appear on the LCD display screen;

(2) Continue dialing left to the first number in the combination (50). Stop; the number 50 will be displayed on the screen;

(3) Now dial in the opposite direction (right, clockwise) to (25). Stop;

(4) Now dial left (50). Stop;

(5) Now dial right. After "OP" (Open right) appears on the display screen, continue dialing slowly to the right to pull the lock bolt.

NOTE: If you pass your target number by four or more numbers, continue to dial, but if you pass the target number by no more than three numbers, you may reverse direction slowly and the display will "jump back" four numbers. Now you may dial slowly in the original direction to the target number. If at any time you see a Lighting Bolt, you have made an error in dialing the combination. At this time you must allow the X-07 to "go to

sleep" and redial.

Setting the Operating Mode and Changing Combination:

Before a new combination can be set, select and set a mode of operation.

(1) The X-07 has three modes of operation:

(a) SINGLE COMBINATION MODE: The X-07 will open when one three-number combination is successfully dialed;

(b) DUAL COMBINATION MODE: Two separate combinations are required to open the X-07. Either combination may be dialed first; however, the operator must begin entering the second combination within forty seconds of entering the first combination;

(c) SUPERVISORY/SUBORDINATE MODE or SUPER/SUB MODE: Two separate combinations are required to open the lock, with the Supervisory Combination controlling access of the Subordinate Combination. The Supervisory Combination must be entered first. There can be unlimited delay between entering the Supervisory Combination and entering the Subordinate Combination. There can also be unlimited openings by the holder(s) of the Subordinate Combination until the Supervisory Combination is redialed;

(2) Retract the bolt by entering the correct current combination(s). In Dual Combination or Supervisory/Subordinate modes, both combinations must be entered simultaneously;

(3) Insert the Change Key into the slot on the back of the lock;

(4) Dial to the left (counterclockwise). The Change Key Symbol will appear in the display. The lock is designed not to open when the Change Key symbol is displayed. (Technique when the drawer is locked with the key inserted.;

(5) Enter the current combination(s) again;

(6) Dialing right, the symbol "SL" (for Select Mode) will be displayed. Now dial left to select mode of operation:

1 -for Single Combination Mode

2-for Dual Combination Mode

3-for Supervisory/Subordinate Mode

(7) Stop on the number of the selection. Now dial right to set the mode. The symbol "EC" (Enter Combination) or "E1" (Enter First of Two Combinations) will be displayed depending upon the mode selected;

(8) If Single Combination Mode (Selection 1):

(a) The symbol EC will be displayed. Enter the desired combination by dialing the numbers in the correct sequence. LEFT (counterclockwise) to the first number. Stop. RIGHT (clockwise) to second number. Stop. LEFT (counterclockwise) to third number. Stop. RIGHT (clockwise) until display flashes new combination;

(b) The display will flash the new combination three times and then display the symbol PO (for Pull Out Change Key). Remove the Change Key. This will cause the Change Key symbol to disappear. The display will show the symbol CC (Confirm Combination(s));

(c) To confirm the combinations, redial the new combinations. When the OP (Open right) appears on the display, continue dialing to the right to retract the bolt. The combination is now set;

(9) If Dual Combination Mode (Selection 2) or Super/Sub Mode (Selection 3): (NOTE: For Dual mode, either combination may be entered first; for Super/Sub mode, the Super combination must be entered first.);

(a) The "E1" symbol will be displayed. Enter the first new combination. Dial: Left to the first number. Stop. Right to the second number. Stop. Left to the third number. Stop. Right until display flashes new combination. The display will flash the new combination three times then show the symbol "E2" (Enter second combination);

(b) Dial the second new combination in the correct sequence, in the same manner as the first combination was entered. The display will flash the new combination three times, then display the symbol "PO" (Pull Out Change Key);

(c) Remove the Change Key. This will cause the Change Key symbol to disappear. The display will show the symbol "CC" (Confirm

Combination(s));

(10) To confirm the combinations, redial the new combinations:

(a) In Dual Combination Mode: dial either of the new combinations. The symbol "E2" (Enter second combination) will be displayed. Enter the remaining combination;

(b) In Super/Sub Mode: dial the Supervisory combination first. The "E2" (Enter second combination) will be displayed. Dial in Subordinate combination;

(c) When "OP" (Open right) appears, continue dialing right to retract bolt. The new combinations have now been set.

Alternate Method of changing the Combination:

This alternate method replaces steps 1 - 4. If you have lost or forgotten the current combination and have access to the back of the lock, you can select a mode of operation to set new combination(s) using the serial number found on the inside cover of the lock. This serial number will not open the lock, it will only allow you to set a new combination.

(1) Dial an incorrect combination to obtain the Lighting Bolt error symbol;

(2) Insert the Change Key into the back of the lock;

(3) Enter the serial number as the current combination. Dial:

(a) Left to first 2 digits of the serial number. Stop.

(b) Right to second 2 digits of the serial number. Stop.

(c) Left to third 2 digits of the serial number. Stop.

(d) Right to "SL" (select mode will be displayed continue with Step 5 from above.

Lockout Prevention:

If the door of the container is shut and the X-07 accidentally locked with the Change Key still inserted in the Change Key slot:

(1) Allow the lock to power down. (After forty seconds the display will go blank; wait an additional minute for full power down.);

(2) Turn the dial to the RIGHT until power-up occurs (numbers appear);

(3) Dial the current combination in correct sequence;

Using the Audit Feature of the X-07:

The X-07 keeps count of the number of successful openings. It will also alert the user if there have been three or more unsuccessful attempts to open the lock.

TO CHECK THE NUMBER OF SUCCESSFUL OPENINGS: Dial RIGHT when the lock is powered down (screen blank and no dialing for two minutes). After the lock is powered up, it will alternately flash two pairs of numbers. The number with the arrow flashing left represents the first two numbers of the successful opening count. The number with the arrow flashing right represents the last two numbers in the opening count. The successful openings count does not reset. The number will reflect the total number of times the X-07 has been opened since it was manufactured. When the X-07 has been opened 9,999 times, the count will begin again at 0 and continue to increment.

TO CHECK UNSUCCESSFUL ATTEMPTS COUNT: Dial LEFT when the lock is powered down (screen blank); or Dial left after checking successful openings count. The count will be represented by a two digit number with a Lighting Bolt symbol. When the count is displayed, stop. After you have seen the count continue dialing left to enter combination. The unsuccessful attempts count will be displayed only when three or more incorrect combinations have been entered. The count resets to 0 whenever the correct combination is entered. If the number of attempts exceeds 99, the count will remain at 99 until reset.

34_7.2.2 Radiographic (X-Ray or Gamma Ray) Attack

Radiographic analysis of combination locks is more thoroughly discussed in **Chapters 32** and **36**. It is a technique developed by the intelligence services of the United States and the Soviet Union that allows the extrapolation of gate position for each wheel. The process relies upon the production of an image using electromagnetic waves that are directed at the wheel pack.

Harry Miller was the first to conduct experiments using x-rays to open locks in 1947 at the University of Rochester. The prime focus was to learn if a manipulation-proof lock was subject to this method of attack. The government was not concerned about the problem until 1953 when an isotope became generally available that made portable x-ray machines practical. Group 1 locks that contained low-density delrin wheels were patented about the same time.

In order to prevent the use of radiation to read wheel packs, Harry Miller patented (**3024640(395)**) the integration of lead bearings at the back of the dial. These had the effect or deflecting and absorbing energy from the source. Miller conducted tests by setting a camera seventeen feet from the radiation source to expose a box containing film. Each of the wheels were rotated individually and synchronized with the film to determine gate positions. Since the original work by Miller, there have been many studies conducted by the National Laboratories in the U.S., including Livermore and Argon. Russia has also been involved in radiographic imaging for a very long time.

Traditionally, a source is placed at the back of a safe and film at the front. A series of exposures are made in order to determine individual gate positions. Today, radiation imaging can be accomplished with computers and liquid crystal displays for real-time output. Portable x-ray devices are now available that can be carried in a briefcase and operated without danger of exposure to radiation. They will produce a real-time image of the internal mechanism of locks and explosives. Harry Miller also designed a neutron- resistant lock for which he received approval from the government.

34_7.2.3 Mechanical Security

Today, almost every combination lock provides 100 segments or divisions per wheel. This allows for theoretically 1,000,000 different or unique permutations to which a three-wheel lock can be set. Many locks have four, five, or six wheels, thus reducing the potential for deriving the combination to 1:1,000,000,000,000. Modern locks are highly reliable and require little maintenance. Depending upon whether they are Group 1 or Group 2, their internal tolerances will vary, which in turn directly affects their security. S&G and other manufacturers have implemented strict quality control and testing procedures to

insure reliability.

They utilize robot dialers to study how the consumer operates a lock and the method of entry of combinations. The speed of entry, motion, and delays can all be factored into dialing programs to detect and predict failures. Locks also incorporate devices and safeguards to overcome the natural tendency of employees to ignore security procedures and guidelines in favor of convenience. Thus, day locks, time locks, and scramblers have been integrated into standard combination mechanisms.

Day locking systems prevent the dial from being turned by unauthorized individuals without a key. Medeco and other keyed cylinders are built into the face of the dial to accomplish this purpose. The problem with this enhancement is that employees will utilize the low-security cylinder as a substitute for fully activating the combination lock. S&G introduced a “timbination” lock that triggers a programmed time delay and opening window once the correct combination is entered. This feature is designed to prevent robberies because the safe cannot be opened until the delay period has expired. Additionally, the lock will reset if it remains in an unlocked state longer than a predetermined period.

The S&G Scrambler (**2625032(396)**) will randomly turn each wheel when the dial is spun to a locked status. This is intended to prevent the practice of rotating the dial slightly past the last number of the combination. Unfortunately, many employees do not completely spin the dial to reset all wheels when the safe is locked. Rather, they move the dial slightly so as not to reenter the entire combination. It is convenience, rather than security. Although the Scrambler partially solves this problem, numbers can often be read back within a few digits after the mechanism triggers. Kromer has attempted to solve this problem by requiring that all wheels be turned before the bolt can be thrown.

Spyproof dials are also utilized to prevent others from viewing the numbers as they are entered into the lock. Their design provides for a perpendicular view of the index marker.

Dust covers are another popular security feature. They prevent the interpretation of fingerprints on the dial. A clear plastic shield fits over the dial and ring, and will obliterate any indicia of finger position and dial rotation (**4404823(397)**).

Clear Plastic Dial Covers: Certain regulations and manuals require clear plastic dial covers be placed on all combination locks. Plastic dial covers are generally supplied with each new security container for the appropriate lock installation.

34_7.2.3.1 Number of Permutations

Although a manufacturer may represent that their locks have from one million to one trillion permutations, such representations are not accurate but only theoretical. Unless the lock utilizes a computer to derive each combination, the number of permutations does **not** equal the total dial segments multiplied by the number of wheels. Only in computer-based mechanisms such as the Mas-Hamilton X-07 will the computation of total possible permutations equal or exceed the theoretical limits of their mechanical counterparts. In the X-07 there are at least 1,000,000 unique and useable codes when the lock is set for a three-digit combination. Depending upon programming and supervisory control options, this number can actually be one trillion or more.

34_7.2.3.1.1 Permutations in Mechanical Combination Locks

The number of theoretical permutations is computed by multiplying the number of wheels by the total number of divisions available for each wheel. Thus, a three-wheel lock having 100 positions per wheel would have 100 times 100 times 100, or 1,000,000 different combinations (100^3). A four-wheel lock would have 100 times 100 times 100 times 100 (100^4), or 1,000,000,000 theoretical combinations. A substantial difference exists between

the number of theoretical and actual permutations. In reality, a 1,000,000-number lock may have only 240,000 useable combinations. This results from the unavailability of some numbers in the forbidden zone, the use of closely spaced combinations, the use of duplicate numbers, and fence-gate tolerance.

34_7.2.3.2 Mechanical Design Parameters

The critical design parameters that ultimately determine the actual number of available combinations relate to the **fence-gate interface** and **fence-gate tolerance**.

34_7.2.3.2.1 Fence-Gate Interface

The fence-gate interface relates to how and where the fence enters the gate and directly affects tolerance of components. In S&G locks, the fence must be centered precisely above the gates. Although the fence can be vibrated into alignment if close to the proper position, this technique becomes harder as the gate angle grows more acute. A tight window will make the job of an auto dialer more difficult and time consuming, because the number of actual combinations that must be entered will increase. Dialers are programmed to take advantage of the “overlap” of unique gate positions; in high tolerance locks, this number is reduced.

34_7.2.3.2.2 Fence-Gate Tolerance

The fence-gate tolerance is determined by the size and shape of the gate, the position of the fence upon entry, and changes in mechanical tolerances occasioned by wear. If the width of the gate is diminished, then the wheels must be more precisely positioned at the drop in point. Wear, resulting from use of the lock, will affect the play between spline and drive cam. When this condition occurs, the lock may be difficult to open because the fundamental relationship between dial marker and gate has slightly changed.

In a Group 1 lock, the tolerance or overlap between the gate and fence is 1.5 - 1.75 divisions, or **±**.75-.875 from center of the gate. In a Group 2 lock, it is up to +-1.25. UL calculates this tolerance from the edge of the gate; S&G from the center.

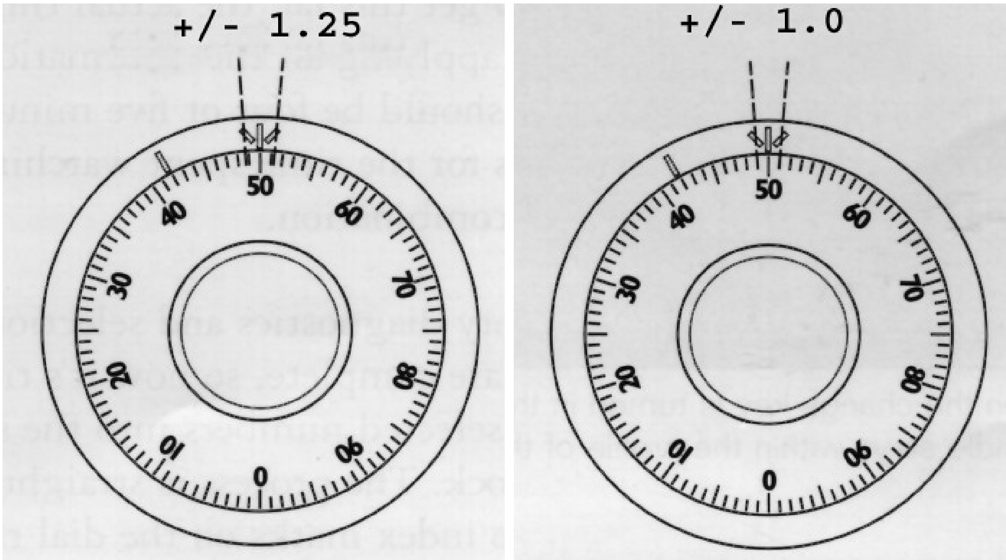

Figure LSS+3424 UL provides for a maximum of +- 1.25 dialing tolerance in Group 2 locks, and +- 1.0 for Group 1 devices. S&G claims it obtains 0.9 for its Model 6730.

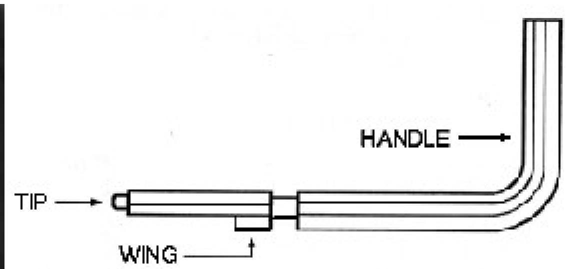
Overlap, or fence-gate tolerance, means that the position of the fence can be offset by this number and still is in alignment. An automatic dialing program takes full advantage of these tolerances. In a three-wheel lock, the probability percentage of opening increases as more numbers are dialed. With tolerances factored into the equation, as few as 100,000 unique numbers must be dialed to open the lock. Although there is a very low probability of opening with the first combination, the curve is linear as the dialer progresses. In a Group 1 lock, for example, there is a probability that the lock can be opened in twenty hours.

An example illustrates how fence-gate tolerance can reduce security of the lock. The actual combination, in a Group 2 lock, is 10 20 30. With a tolerance factor of ±2.5, the following numbers within the defined ranges **will** open this lock:

FIRST NUMBER	**SECOND**	**THIRD**
8.75-11.25	**18.75-21.25**	**28.75-31.25**
#1	**#2**	**#3**
9	**19**	**29**
9	**19**	**30**
9	**19**	**31**

9	20	29
9	20	30
9	20	31
9	21	29
9	21	30
9	21	31
10	19	29
10	19	30
10	19	31
10	20	29
10	20	30
10	20	31
10	21	29
10	21	30
10	21	31
11	19	29
11	19	30
11	19	31
11	20	29
11	20	30
11	20	31
11	21	29
11	21	30
11	21	31

A minimum of 27 permutations of the original combination will open the lock, based upon whole integers. If fractions are included, then that number will be increased significantly.



34_7.2.3.3 Electronic Combination Locks

Electronic combination locks such as the X-07 do not suffer from any of the limitations of conventional mechanical devices. They can provide true 1,000,000 single-sequence entry permutations without any restrictions. If dual or sequential control is implemented, then this number can exceed one trillion different useable numbers. Later in this chapter, a detailed discussion of the X-07 is presented because of its uniqueness and wide-ranging patent claims. It was the first electronic lock approved for high-security containers and remains the premiere computer controlled lock in the world.

34_8.0 Combination Changing

Every lock must provide the means to alter the relationship between wheel position and gate in order to facilitate combination changing. A special change key is employed for this purpose. The number sequence used to open the lock is often entered to a **change index marker** on the dial ring, rather than the standard marking. This will cause the discs to align to a different position, allowing the entry of the change key into openings in each wheel. Some locks utilize a **zero change** index system, whereby the same marking is used for both opening and combination change. In such cases, the number sequence can be changed whenever the lock is opened.

The change key is inserted into the rear of the lock and turned. This will release the inner and outer portions of each wheel, thereby allowing the gate location to be altered with respect to the spline key position. Most wheels are designed so that the inner and outer portion of the discs mesh together like a gear. When the spring bias is released, the outer wheel is free to move in direct relation to the turning of the dial to a new combination. When the change key is removed, the spring bias on each disc is reintroduced, thus locking the two segments of the wheel together and fixing the wheel- gate relationship.

CHANGE KEYS: The manufacturers of Mosler and Sargent & Greenleaf locks have advised that their keys are available through sources listed below. However, Bode-Panzer no longer manufactures the change key necessary for their lock.

34_8.1 Procedures for Changing Combinations

Each manufacture specifies different procedures for changing the wheel-gate relationship within their combination locks. However, there are certain basic principles that must be adhered to in order to successfully alter the wheel-gate relationship without causing maintenance or lock-out problems.

There are four actions that must be accomplished:

Determine the combination;
Select a new combination;
Set the new combination;
Test the new combination with low and high numbers.

In order to properly set a new combination, the technician must:

1. **Have the proper change key;**
2. **Have knowledge regarding dialing tolerance, forbidden zones, wheel pickup for the specific lock;**
3. **Perform routine maintenance at the time of change;**
4. **The lock must be in good working condition; there should be no end-play.**

The technician must determine certain preliminary information prior to changing the combination:

1. **Obtain the current combination from the customer;**
2. **Wiggle the lock case to make sure there is no play;**
3. **Insure that the dial ring is tight against front of safe;**
4. **Determine the dial end play by pushing and pulling on the**

dial.
There should be no more than .050"; preferable is .025."
5. Be certain the dial ring is properly aligned;
6. Determine the number of wheels within the lock;
7. Ascertain the level of friction in wheel pack;
8. Determine the condition of moveable flys;
9. Determine the amount of rotation from wheel pickup to wheel pickup;
10. Ascertain the location of the contact points;
11. Determine the location of forbidden zone.

The lock must be first tested by the technician before proceeding to change the combination. This is accomplished by moving all wheels left for five turns, stopping at 50. This will park all wheels in the same position.

Then turn the dial to the right. During first full revolution, only the dial, spindle, and drive cam will actually be moved. The technician will detect any binding between the dial and ring. There should be no friction.

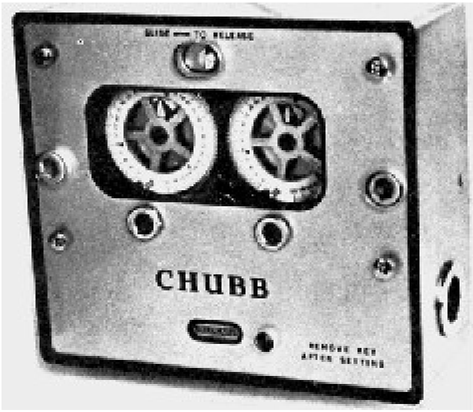
As the dial is turned right from 20 to 0, two subtle bumps should be felt. These are the contact points. Although they are not always between 20-0, this is the most common area.
Keep dialing right. More resistance should be encountered near 50, as one of the wheels is picked up. This will occur from 1.0 to 1.5 numbers from 50, based upon the tolerance of the lock.
Note: if pickup occurred several numbers **before** 50, then there is a stuck fly on that wheel.

Continue to rotate the dial in order to pickup additional wheels. After three revolutions, there should be no change (unless it is a four wheel lock). If the lock is in proper mechanical order, the dial should never drag during rotation. Two contact points should be identified. Each wheel should pickup within +- 1.5 of its marker. There should be no significant binding if the dial is riding within the dial ring. There should be no stuck flys.

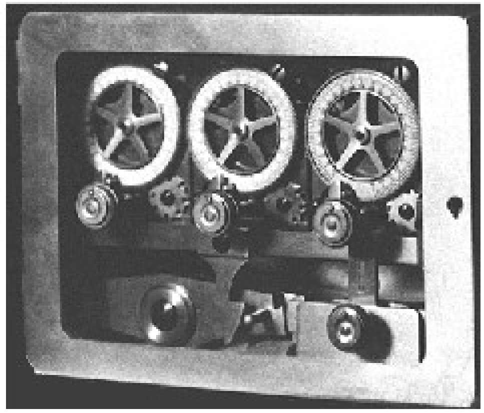
Specific rules should be followed for picking an acceptable combination:

1. The last number must not be in the forbidden zone;
2. The numbers should be +- 5 from the contact points;
3. No easily guessed numbers should be used;
4. Do not use numbers that all end in 0 or 5;

5. Do not use ascending or descending sequences;



To change the combination, the following guidelines should be followed, after **covering the opening index** to avoid errors in alignment. Be certain that parallax errors are eliminated by viewing the dial straight-on.



1. **Dial the number to the change index;**
2. **Insert change key;**
3. **Turn change key;**
4. **Dial new combination to the change index;**
5. **Turn the change key, then remove it;**
6. **Check the combination;**
7. **Test the combination by subtracting and adding 1 digit to each number. In Group 2 locks, the permutations should open the lock. This provides assurance that the wheels are meshed properly and that no parallax error in viewing the combination has occurred.**
8. **Verify that there is not a manufacturing error between the change and opening index on the dial ring, by insuring that the markings coincide with the dial position.**

34_9.0 Time Locks

The time lock is a mechanical or electronic device that is integrated into the bolt works of a safe or vault to block actuation except during a designated window of time. The time lock consists of a case, locking mechanism, and one or more chronometers. They operate independently of the combination lock and provide for no external controls.

They were developed over 150 years ago in response to the drastic increase in armed robberies.

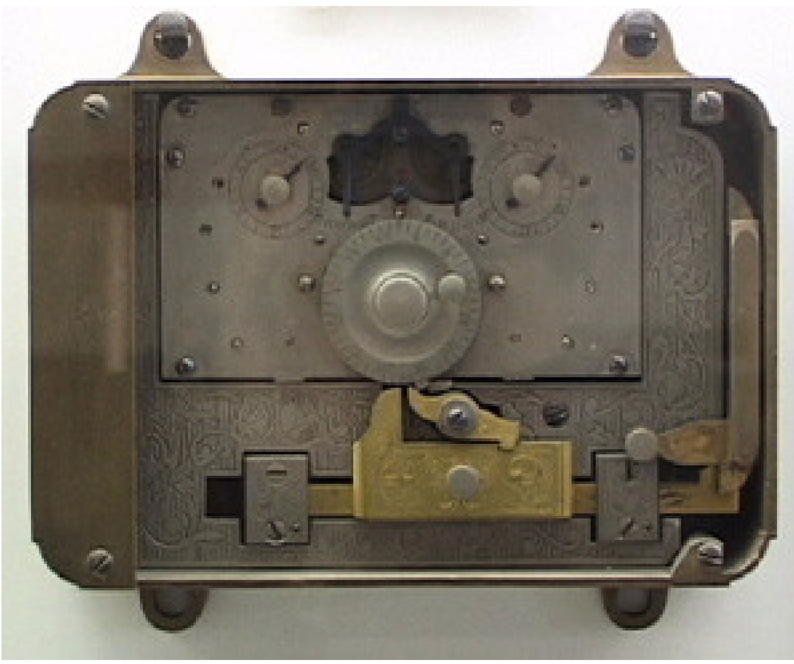


Figure LSS+3423 The Pillard time lock

In the 1870s, a new form of bank robbery became popular. Masked intruders would attack and kidnap bank cashiers, often within their homes, and force them to divulge the combination for the bank vault. Failure to provide this information often led to their death.

Prior to the introduction of time locks, the safe or vault was ineffective as a device to protect valuables because one person with a gun could bypass the most secure enclosure. After the time lock was introduced, the armed robber could not force an opening. Once set, the device would render futile any attempt at bypass. Even with the correct combination, the safe would not

yield until the predetermined time. Although William Rutherford (in Scotland) patented the initial design and concept in 1831, it would not be implemented for another fifty years. The original mechanism consisted of a disc with a notch, driven by one or two clocks. The notch would prevent access to the bolt mechanism until it rotated to the correct position after the specified time had elapsed.

In response to the new wave of crime, James Sargent, a famous American manufacturer and lock picker, invented and patented a new time lock. Sargent & Greenleaf (S&G) began to manufacture the invention in 1873. The inventor fit the original device to the vault door of the First National Bank in Morrison, Illinois, in 1874 for the sum of $500. Thereafter, banks everywhere adopted them, almost eliminating the crime that caused their introduction.

All time locks are set for the number of hours that the container is to remain locked, precisely as the inventor had envisioned. They characteristically contain three independent running chronometers that are either wound or powered. Usually the movements can delay opening from 120-244 hours, and operate in parallel. Some of the newer electronic time locks provide for an audit trail. If there is a failure of one device, the others can still allow the lock to open. The conventional time locks will generally provide a window of approximately forty-five minutes. If the safe is not opened during this time, then it will remain locked until the full delay period expires.

TIME LOCK DEFINITIONS

There are a number of specific terms associated with time locks, to describe their internal components.

Accelerated Active Movement

This component allows power from the spring at "0" hour to accelerate the rotation of the display wheel. This will move the unlocking pin rapidly, thereby forcing the carrier to the unlock position.

Actuator Control Button

Moves snubber to locked position.

Carrier Trigger

Case

Display Wheel (dial wheel)

This displays the numbers for timing.

Escapement

A device that controls the speed of the gear train.

Front Cover

Gear Train

There are a series of different sized gears through which energy is transferred and stored.

Jewels

These provide a bearing surface for frictionless operation.

Main Spring

This is the method of energy storage.

Mainspring Barrel

This provides a housing for the spring.

Mounting Table

This platform secure the clocks.

Movements

Plate

This provide place for movement to be mounted.

Reserve Power

This energy is stored as energy by the mainspring.

Reset Movement

This allows a reduction of time. A clutch on the third wheel allows back winding.

Standard Movement

A time lock with no extra features.

Unlocking Pin

This piece is mounted on the display wheel between the 90-100 hour mark.

Winding Arbor Assembly

This is the winding arbor.

Winding Key

Snubber Locking Bolt

This component blocks the movement of the snubber.

34_9.1 Electronic Time Locks

Electronic time locks will ultimately replace their mechanical counterparts because of reliability and ability to offer complex timing options. These microprocessor-controlled systems, using high- technology, mirror the basic options offered in the older mechanical time locks. They provide the ability to regulate access to the container. All of these devices contain real-time clocks that allow programmed openings and closings for an entire year, if desired. They can account for both holidays and special conditions. One or two-employee entry of the combination can also be required, and a detailed audit log can be generated.

A modification was introduced by S&G, which was called the **Timbination** Lock. This is a time-delay device that provides an opening window of three minutes. The countdown time can be changed in the non-UL listed version from four to thirty minutes. This lock provides a backup if the operator forgets that the combination has been entered and a safe remains unlocked. The mechanism will automatically lock after the timing window expires. Originally, UL specified a fifteen-minute window but has now modified that to five minutes.

34_10.0 Definitions

Discs: See Wheel pack

Anakin Relocker: Once triggered, this type of mechanism causes a bar to pivot that will block the movement of the carriage linkage used to retract locking bolts in a safe.

Arbor: A generic term for a shaft used in handles and dials spindles.

Balance Hole: Wheels in combination locks must be balanced or trimmed in order that their mass is precisely distributed. One or more holes are placed in the outer ring, much like weights on an automobile tire. Balancing is required to prevent induced vibration from slowly rotating the disc to the position that the gate is aligned with the fence. This had been a recurring problem aboard naval vessels, where constant vibrations caused safes to open.

Case: The shell that contains the internal components of a combination lock.

Change Key: A device that is utilized to alter the combination or lever configuration of a lock. The key is inserted into the **change-key hole**, an opening in the lock case. Each wheel contains a **change-key cam** that is a finely geared outer ring that is linked to each of the wheels in the wheel pack. The positional relationship between cam and wheel will determine the location of the gate. A small **pilot hole** in the base of the lock case will provide seating for the tip of the change key. Protrusions or **stops** around the change- key hole will control the amount of key rotation allowed.

Changeable Lock: A mechanism that allows programmable alteration of the fence-gate relationship in wheels or levers in order to effect an immediate change of combination. A change key is inserted into the lock for this function. A **hand change** lock must be partially disassembled for reprogramming.

Changing Index: A marker on the dial ring that provides a reference for gate position. It is used when changing a combination.

Click Lock: A combination lock that provides user feedback in the

form of clicks rather than numbers on a dial.

Combination or Code: The sequence of digits, letters, or symbols that when entered, will open a lock.

Contact Points: The precise location is referred to as the **contact area**, where the nose of the lever touches the left and right side of the drive cam gate. The position of the left contact area is critical when the lock is manipulated open.

Counterspy Dial (Spy proof Dial): The numbers appear at the top rather than facing outward, in order to restrict visibility only to the operator.

Cover: The cover is the removable portion of the lock case that allows access to the internal mechanism.

Curb: In older combination locks, this is the round cover to which the wheels are attached.

"C" Retainer: A C-shaped clip that retains the wheels to the wheel post. Also known as a **Circlip**. A **Truarc** ring is a modified version of the C retainer. A **Spirolox** retainer, in contrast, is a flat ring with overlapping ends.

D.A.T.(Delayed Action Time Lock): A safe lock mechanism that requires a **delay period** before it can be opened and then provides a brief window for activation.

Dead Zone: Older combination locks had areas on the dial where no numbers or increments were printed. These were referred to as dead zones.

Detent Ball (Timing Ball): A spring-biased bearing is placed under the bolt to retain it when in a fully extended position.

Dial Ring: A round plate that is mounted immediately behind the dial and surrounds it to provide an index for dial number and change-key markings. It is also known as a **flange**.

Dial: The round, exterior control mechanism of a combination lock. The dial is utilized to transmit rotational motion to the wheel pack and drive cam to align each gate in sequence as it is turned. The dial, spindle, and drive cam may be referred to as the **dial knob aassembly** (Mosler).

Direct Drive: The action of the dial, spindle, and drive cam are said to be linear, or directly linked.

Double-Bitted: A key with bitting on two opposing surfaces.

Double Dots: The presence of two raised dots between the bolt and top mounting hole in the bottom of the lock case indicate the use of a Spirolox type retainer on the wheel post in S&G locks.

Drill Point: The precise location to drill a hole in order to open a combination or lever lock.

Drive Cam: The drive cam is a modified wheel. It is directly linked to the spindle in all but high-security combination locks. Its function is to transmit rotational energy to each of the wheels (through **flys and drive pins**) and to provide a recess (**drive cam gate**) into which the fence is retracted when all wheel gates are properly aligned.

Drop: The physical location where the nose of the lever actually drops into the gate of the drive cam and wheel pack. The position is usually referenced to a dial position of zero. In the S&G 6730, for example, the drop is at 97.

Escutcheon Plate: A decorative or protective plate that surrounds the dial ring or handle.

Factory Combination: A universal code that is programmed during production that will open the lock. Once the lock is installed, the code should be changed.

Fence: A metal protrusion shaped in the form of a stump or bar that is designed to precisely fit within corresponding slots (gates) in each individual wheel or lever within a lock. The mechanism is designed to prevent retraction of the bolt until the fence is completely contained within the aligned gates. There are several different fence designs. An example is the Yale OC5 **geared roller**. This pivoting arm is allowed to rotate into the gate and is driven by a geared drive cam.

Flys and Drive Pins: Flys and drive pins are the components that form part of the wheels; they are used to receive (**flys**) and transmit (**drive pins**) motion as the individual discs are rotated.

Forbidden Zone: Within every combination lock, there is an area

that cannot be utilized for the third (or last) wheel gate position. This zone encompasses the physical area that is required for the drive cam to retract the bolt. If the last wheel is set to a number within the forbidden zone, unreliable operation will result. A lock with a physical drop of 97, for example, would have a forbidden zone of 0 - 20.

Gate: The corresponding slot in each wheel or lever to which the fence is mated. See **Fence** above.

Handing: The direction to which the bolt extends and retracts from a safe lock with the door open. There are four standard positions: Right hand (RH), left hand (LH), vertical up (VU), and vertical down (VD). Some locks are **true right** or **true left** handed and are made to be mounted in one specific orientation.

Index: A marking is provided on the dial ring as a reference point for the numbers on the dial when entering a combination. This mark is called the **opening index**. A **changing index** is a separate reference that is used for altering a combination.

Inspection Window: An opening is provided in lever locks to view the interaction of the levers with the fence.

Key Changeable: See **Changeable Lock.**

Key Locking Dial: A pin tumbler or wafer lock that is mechanically integrated into the dial to prevent it from turning.

L.O.B.C., "Locked On By Combination," or "Locked On Back Cover": Certain locks require that the correct combination be entered (often to a special index mark) before the back cover can be removed.

Lever: The portion of the lock's mechanism that contains the fence. When all of the wheels are aligned properly, the entire assembly enters the drive cam gate to retract the bolt. The **nose**, which is the protruding portion of the lever, rides on the edge of the drive cam. There are many different designs of the lever assembly, depending upon manufacturer.

Listed Locks: Combination locks that have received a UL security rating are said to be "listed." The 1R manipulation proof is such a device. Many locks are also said to be non-listed.

Manipulation: A technique to determine the combination of a lock,

through interpretation of data from the contact points on the drive cam.

MR: Manipulation-resistant designation

MRK: Nomenclature for a manipulation-resistant lock with a key-change operation.

Nose: See **Lever**.

Physical Drop: See **Drop**.

Relocker: One or more mechanical devices that are integrated into the lock body and boltwork in order to block the bolt in case of forced-entry attempts. A **relock trigger** is a device within the lock case to deadlock the bolt.

Retainer Washer: See C-clip. These devices are utilized to retain the parts of the wheel pack to the wheel post.

Shutter Cam: Within a Mosler manipulation-proof lock, a spring-loaded shutter is engaged while the dial is moved through the drop area. This makes manipulation virtually impossible.

SMNA Labels: The "Safe Manufacturers National Association," was a testing and certification facility until the mid-1950s for burglary and fire containers. SMNA labels can still be found on older safes (see **Chapter 37)**.

Spacer Washer: A flat washer is placed between discs within a wheel pack to prevent friction, touching, or dragging between components. They will also dampen the effects of vibration that can cause wheel movement.

Spindle: The threaded rod that physically connects the drive cam and the dial. A **punchproof** spindle is tapered or shouldered to prevent punching or driving of the shaft into the lock.

Spirolox Retainer: A flat ring with overlapping ends that is used to affix the wheel pack to the wheel post (see also, **C-clip)**.

Spline: The longitudinal groove or slot that runs the length of the threaded portion of the spindle and correspondingly into the drive cam, which allows the spline key to lock them together.

Spline Position: The relative placement of the spline with respect to the rotational position of the dial. Most manufacturers spline the spindles at "50."

Tenite: A synthetic material used by Mosler for dials.

Time Lock: A locking mechanism that is controlled by one or more precision timepieces. The clocks will provide an **opening window,** during which the lock can be activated. It is also known as a delayed action time lock (See D.A.T.).

Timing Ball (Detent Ball): A metal ball and spring are located beneath the bolt to retain it in a locked or open position.

Torque Adjuster: An alignment feature provided by S&G to adjust the amount of torque on the wheel pack.

Tube: A shroud that surrounds and protects the spindle from insulation and contaminants. It aligns the dial ring for proper installation.

UL Rating: A designation relating to many aspects of security and established by Underwriters Laboratories. UL is a private testing organization.

VdS Rating: Verband der Sachversicherer is a designation for safe locks.

Wheel (Disc): A group of rotating parallel discs, together with drive pins (pegs) and flys, that comprise a wheel pack within a combination lock. Each disc will individually prevent the bolt from retracting until the fence has entered its corresponding gates. The relative position of each gate will determine a lock's combination. Wheels can be made of metal or plastic and are connected by the spindle.

Wheel Pack: The wheel pack is comprised of three or four individual wheels that form the critical operating components of the combination lock. Each of the parallel rotating discs is connected to the others and the **drive cam** through the **spindle.** Their actions are mechanically linked through interconnecting **flys** and **drive pins**. A wheel pack is said to have an **indirect drive** if the spindle and drive cams are not directly linked. Generally found in high-security locks, gears are employed to transmit motion in such mechanisms.

X-Ray-Resistant Gate Patterns: Radiographic imaging can be frustrated by a raised pattern of gates on the bottom of a lock case. This technique will cause shadows to appear on the film, making the determination of gate position difficult and unreliable.

Zamak: An alloy of zinc and aluminum that is utilized for lock cases and components. The material has good casting qualities and tensile strength and can be sanded, filed, drilled, and tapped.

Zero Change: Changeable combination locks that do not require a separate changing index mark.

34_11.0 Computer-Controlled Combination Locks

Computer-based locking systems are gaining wide acceptance in many diverse industries. They can meet any security requirement and have been certified by the United States government for use on containers holding top secret information. They are also quite prevalent in the hotel industry in both door locks and in-room safes (**4745784(398)**). The utilization of electronic locks is widespread; they can be found in many military, government, and business requirements as well as residential, recreational, automotive, and vending. Motor vehicles, gun cabinets, lockers, storage containers, safe-deposit vaults and hundreds of other applications utilize the technology.

These locks began to appear in the 1980s. Since then, they have taken many forms during their rapid evolution. The original devices were quite simple but quickly gained sophistication as the technology of microprocessors virtually exploded. While the conventional combination lock has been evolving for the past one hundred years, the relatively short life span of its counterpart has been remarkable. Harry Miller was the first to patent what can be identified as an “electronic lock.” Although these early devices could really be classified as electromechanical in nature, nevertheless they relied upon crude “digital” data to perform their tasks. Actually, similar electromechanical devices were utilized in conjunction with cryptography during World War II and the Korean War.

Since the introduction of the Mas-Hamilton X-07 in 1992, a new standard in security, functionality, and reliability was

established for electronic locks. The integration of electronic combination locks is inevitable for all but the most rudimentary of containers. These devices are immune from normal maintenance problems, such as mechanical wear and changing tolerances, and all of the limitations inherent in mechanical components. The locks are secure if properly engineered and are virtually immune from traditional manipulation techniques.

34_11.1 Comparison of Electronic and Mechanical Locks

There are critical differences between conventional and electronic locks. These distinctions relate to:

- **Overall theory of operation;**
- **Mechanical reliability;**
- **Fence-gate relationships;**
- **Wheel packs;**
- **Drive cam;**
- **Lever and bolt actuation;**
- **Security and manipulation resistance;**
- **Theoretical and actual permutations;**
- **Audit control and accountability;**
- **Optional configurations.**

34_11.2 Theory of Operation: An Overview

Electronic locks replace the wheel pack and associated lever and fence with a microprocessor. The computer is utilized to perform the functions normally associated with conventional mechanical hardware. Specifically, the processor accomplishes the following tasks:

- **Provides a method for the entry and programming of numbers that constitute the combination of the lock;**
- **Stores, in non-volatile memory, one or more sequences of numbers that must be input by the operator to open the lock;**
- **Provides a sensing mechanism to allow the entry of numbers by the operator;**
- **Processes the information as entered by the operator and determines if:**

- **The entered numbers match those of the combination;**
- **Incorrect numbers were entered as part of the sequence;**
- **More than a specified number of attempts were made to enter numbers;**
- **Manipulation was attempted;**
- **A defined timing parameter was met;**
- **The correct sequence was entered and whether it shall actuate the bolt mechanism.**

Within the computer-based lock, there is no wheel pack, lever, fence, drive cam, or flys. Rather, there is an entry device (dial or keypad), a processor to store the reference and input data, and an output solenoid or similar mechanism to control retraction of the bolt.

34_11.3 Mechanical Reliability

The mechanical reliability of electronically based locks is superb because there are few moving parts. Generally, they are the dial or keypad, bolt, and solenoid control. Most common failures are electronic contacts, cable interconnections, memory batteries, displays, and solenoids.

34_11.4 Fence-Gate Relationship

Electronic locks do not have fences or gates; the processor replaces their function. Number sequences are programmed when the lock is installed or subsequently and can be set to any value. As will be detailed in the description of the X-07, multiple combinations can be entered to enhance security and control. Virtually all microprocessor-based locks are instantly programmable.

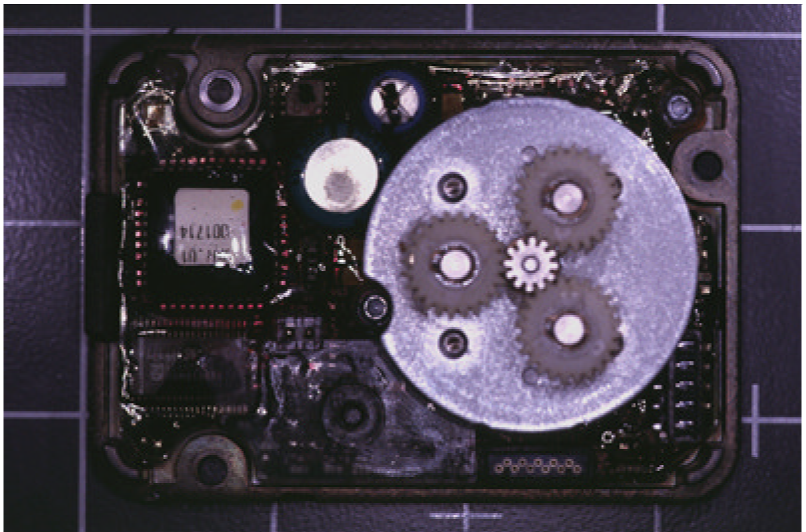
34_11.5 Security and Manipulation Resistance

There is a wide diversity of security and manipulation resistance of electronic combination locks and their susceptibility to countermeasures. Security is a direct function of the sophistication of the processor and the amount of research and development upon which the lock is based. The author has been able to compromise some of the solid-state locks presently on the market, either electronically or through mechanical means. The

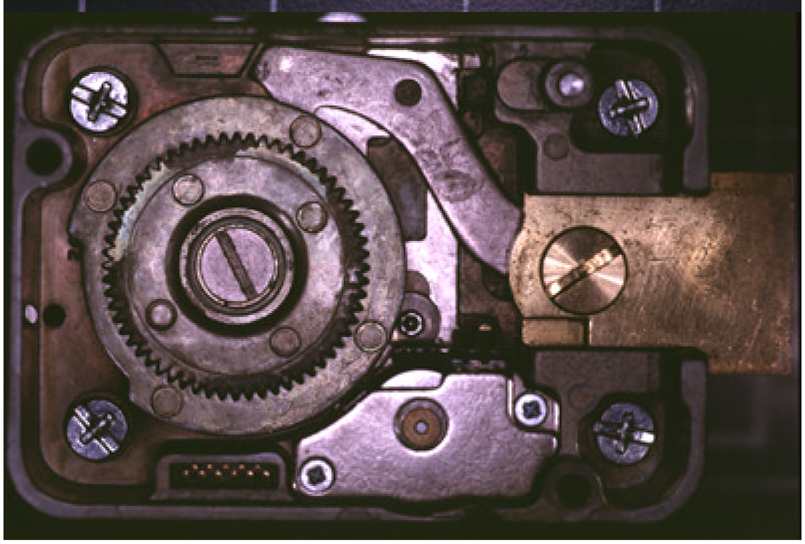
ability to bypass is dependent upon many factors involving both the mechanical configuration and circuitry.

Even the X-07, probably the most secure and sophisticated lock in the world, required certain redesign. The author, other technicians, and a government testing and research laboratory independently determined that there was the potential for bypass using certain techniques. This, even though eleven government security agencies could find no defect in the lock prior to certification by GSA. If properly designed, the electronic combination lock, such as the X-07, will offer superior manipulation and surreptitious entry protection. Extremely high reliability and sophisticated audit control will guarantee that these locks replace their conventional counterpart in the future.

34_11.5.1 Theoretical and Actual Permutations



Electronic locks do not suffer from the problems associated with the "forbidden zone" and "drop in" or "contact points." Thus, they can offer true 1,000,000 permutations that are not diminished by mechanical limitations. These locks can also require two different sequences to be entered simultaneously for supervisory control. Thus, one trillion actual different combinations can easily exist for one lock.



34_11.5.2 Audit Control and Accountability

Audit control and accountability is not possible in the conventional combination lock but is standard in computer-based systems. The X-07 will store and display invalid attempts and the fact that certain manipulation techniques were employed. These locks will shut down for a predefined window of time if successive manipulation attempts are sensed.

34_12.0 Mas-Hamilton X-07 Electronic Combination Lock

34_12.1 Introduction

LSS101: Discussion of the X-07 and X-08 with Joe Cortie

The Mas-Hamilton Group in Lexington, Kentucky set out to create the worlds most sophisticated electronic combination lock. The design team consisted of the brightest engineers from IBM, together with a world-renowned security expert from the government. In 1991 after almost three years of development, the X-07 made its debut in government service. The X-07 was the first self-contained lock to be certified by GSA to protect top secret containers. The device, which appears in a standard footprint, meets UL 768 and Federal Specification FFL 2740. See **chapter 37** for the full text of this specification. The inventors were granted over thirty patent claims (**5061923(399)**).

The critical and extraordinary functions included a computer-controlled lock and magneto power system. Although the system is microprocessor-based, the lock contains no batteries or other power source.

As with all high-security government locks, the X-07 relies upon the safe manufacturer to protect it from attack. The primary advantage of this system is the sophisticated functionality to prevent surreptitious entry through manipulation. A second generation of the Mas-Hamilton system made its debut within three years of the introduction of the X-07, and since the printing of the hardbound edition of this text. The X-08 is also described here. The X-07 set the standard by which all microprocessor-based locks will be measured for many years to come. This is in part due to the patent claims that will preclude other manufacturers from implementing the same innovations. For this reason, a detailed description of the X-07 is provided here.

There have been other patents granted for electronic combination locks, but none of these devices have attained the security and sophistication of the X-07, X-08, and derivative Mas-Hamilton products. See the Gartner electronic combination lock that was patented in 1994 (**5307656(400)**).

34_12.2 Design of the X-07

The X-07 comes in a standard footprint and can easily replace most conventional combination locks. Actually, the configuration comes in two parts: the dial with LCD, and the lock body that contains the electronics and bolt mechanism. A ribbon cable interconnects the two components. The dial has no markings but rather uses a liquid crystal display. It shows numbers as it is turned, together with rotation direction. The operator moves the dial in a left-right-left sequence, stopping as the correct number is displayed for each segment of the combination. When all three numbers are entered correctly, the microprocessor causes a magnetic pin to release, allowing the bolt to be retracted. If an incorrect digit is selected, the lock will not open and certain security traps are set. These are discussed subsequently.

Within the lock case is housed the magneto power system, Intel designed microprocessor, and bolt-release system. The lock body and case cover are mated through an integrated connector. The dial, containing the liquid crystal display, is connected with a ribbon cable to the processor. All systems are potted with Dymax,

a high-dielectric material (1800 volts/mm) for environmental protection and security. The special compound is impervious to moisture, fungus, and electrostatic shock and incorporates a reddish material randomly scattered in the compound. This provides a unique luminescent fingerprint when exposed to a UV light source. This signature will provide evidence if the lock has been tampered with or replaced.

34_12.3 Power System

Perhaps the most unique aspect of the X-07 design is the power generation and storage system. The lock requires no external electricity and will never go dead regardless of the interval of inactivity. The dial is gear-linked to three stepper-motors that act as alternators to provide power to the processor. These charge a capacitor upon being rotated.

Once the capacitor is fully charged, the microprocessor is initialized. This causes numbers to display on the LCD, beginning in a random sequence. Turning the dial as the combination is entered keeps the processor alive. Sufficient energy is generated to power the CPU, display, memory, and the bolt-release magnetic assembly.

The function of the power system is to generate alternating current that is rectified and stored. This power (up to 3.2 volts) will initialize the system, power the memory, processor, and all active components. The lock will actually operate at 2.5 volts. The alternator is actually a three-phase motor that computes direction of rotation and will tell the microprocessor what speed to display numbers.

34_12.4 Testing Standards

The X-07 was probably subjected to the most rigorous testing protocols ever for a combination lock. Eleven government security labs as well as UL evaluated the Mas-Hamilton design for almost a year. The result: the lock could not be manipulated by any known means. Because the X-07 was to be utilized to protect data of the highest sensitivity, tests involving electronic countermeasures, spectrum analysis, random number generation, atomic particle saturation, electromagnetic bombardment, and radioscopy were performed together with the more traditional forms of attack. Some of the procedures that were conducted to insure the reliability, integrity, and viability of this lock included:

- **The lock case and dial was subjected to static electricity of repeated strikes of up to sixty times at 250,000 volts without effect. Eddy currents were created on the potting compound to test for the skin effect;**
- **UL salt test, simulating 40 years of exposure on the deck of a battleship in a 100 percent salt environment;**
- **UL life test required 10,000 cycles. Actually, the lock was tested for 430,000 cycles;**
- **No adjustment or calibration during life cycle testing;**
- **Magnetic disturbance utilizing 1000 amps through a coil; no effect;**
- **Spray, temperature and humidity: -25C-+70C (UL is 0C-50C; Federal is -23.4C-70C). Storage temperature, -40 to +90 with all electronics operating -40C to 85C;**
- **Relocker temperature threshold: 70C will trip;**
- **EEPROM memory one 100-year test or 100,000 write cycles;**
- **EMI tests to determine effects of radio frequency and electromagnetic interference;**
- **Spectrum monitoring in order to determine if any useable information is radiated from the lock. Based upon Tempest specifications, no useable emissions were present and all noise transmission was under -100 dbm.**

34_12.5 Standard Features

There are certain standard features incorporated into the X-07 that are not available in any conventional combination lock. These were implemented to correct problems associated with mechanical designs. They include:

- **Dial direct to the number in the sequence. It is not relevant how many times the correct number is passed so long as the proper digit is correctly entered;**
- **No dialing tolerances or contact points resulting**

from the design of conventional wheel packs and lever fence;

- **No index lines;**
- **Display indicates direction of rotation of dial;**
- **Commands and prompts provided to user through the display;**
- **Allow back dialing of up to three digits if the correct number is inadvertently passed;**
- **Allow three user modes:**
  - **Sole responsibility (three numbers in sequence);**
  - **Dual responsibility (two three-number different combinations within forty seconds);**
  - **Supervisory/subordinate mode (toggled) requires each combination to be entered in sequence;**
- **Eliminate back dialing for day use;**
- **Automatic combination reset after forty seconds;**
- **Day locking;**
- **Audit features;**
- **Successful opening count (cannot be reset);**
- **Display of invalid digit-entry sequences and number of occasions. Attempts are defined as a dialing sequence with two changes of direction without entry of the correct combination. This number count is reset every time there is a successful opening. Tracking will not exceed 99 attempts.**

34_12.6 Security Features of the X-07

In a conventional lock, there is no way to learn about unsuccessful opening attempts, nor the capability to capture information regarding the fact that an attempt was made or how often such an event occurred. The Mas-Hamilton design team considered many security deficiencies in mechanical locks, as well as how they could be remedied in their electronic counterpart. The following critical problems were identified in traditional locks that would ultimately be corrected in the X-07:

- **The relationship between the dial position and number displayed is always fixed. Therefore, once a lock case was opened, it could be examined to determine the combination;**

- **Tolerances of moving parts substantially reduces the actual number of combinations;**
- **Only one number sequence can be set for a given wheel pack: sequential combinations are not available to enhance security;**
- **Robot dialing is impossible to detect;**
- **Locks are not user-friendly with respect to the number of turns required and direction or rotation (L-R-L or R-L-R);**
- **It is impossible to determine if the lock has been exchanged.**

The X-07 has been designed to thwart every known form of attack. Consequently, there are many advanced security features integrated into both the hardware and software of the X-07. These include systems to prevent robot dialing, audit trail functions, and to thwart interception or extrapolation of the combination. Because this lock was primarily designed for use in top secret containers, the most important criteria is the knowledge that an attempt or surreptitious entry has been accomplished. In the X-07, several safeguards have been implemented to make known any unauthorized occurrences. These include:

- **Failure to complete the entry of a combination within 40 seconds will reset memory and require the reentry of all digits;**
- **Day-locking is impossible;**
- **Continuous movement of the dial at a speed of over 600 RPM, caused by the use of a robot dialer, will cause a zener diode to blow. There is a 5:1 gearing ratio between the dial drive cam and power generation system. Thus, if 3000 RPM is applied to the dial, then 600 RPM will appear at the internal generator. Once the zener is triggered, it will cause a permanent short circuit and deprive the super capacitor of the ability to charge;**
- **Total scramble of random-number generation and display, making back-dialing impossible;**
- **Provide audit feature to record and report the number of opening attempts;**
- **Impossible to observe the combination while it is being dialed;**

- **True one million permutations; no dead numbers resulting from tolerance of moving parts as in conventional lock;**
- **Single and dual combination mode entry for a possible one trillion unique combinations;**
- **Prevent robot dialing;**
- **Each time that the user enters a digit, a new series of random numbers are generated to make manipulation impossible;**
- **Each dialed number is stored in memory;**
- **Processor can operate from 3.5 MHz.-25 MHz and is not affected by temperature;**
- **Redundancy in electronics (70%) to eliminate failure potential of component and to allow close tolerance in timing parameters;**
- **Potting compound is utilized to prevent access to the electronics. There is no way to read or write the device without the correct software;**
- **Eleven data lines connect the dial with the microprocessor. No useable information can be derived from these circuits;**
- **Relockers are incorporated to deadlock the bolt. If the lock cover is moved 1/10" or the case is heated to over 158 F, a magnetic pin will be drawn into the bolt.**

34_12.6.1 Anti-Manipulation Features

The fatal design parameter of every Group 2 mechanical lock is the ability to attach a robot dialer and open the lock in thirty hours or less. If one of the numbers is determined through manipulation, then the process can be reduced to forty-five minutes. As detailed in **Chapter 36,** a Group 2 (and perhaps some Group 1) mechanical locks can always be manipulated with an automated dialer because of the following inherent design parameters in all wheel packs:

- **There is always a constant physical correlation between the position of the dial and the location of the left and right contact points;**
- **There is a definable mechanical tolerance or play in all locks that will allow a wide latitude (up to**

±1.25 numbers) of variance from the index marker to the actual combination digit;

- **The manufacturing tolerance for every lock is known;**
- **A three-number 100-segment lock with a theoretical 1,000,000 combinations may actually have 240,000 or less useable permutations.**

The X-07 cannot be manipulated open, because sophisticated programs have been integrated into the operating system to insure that the lock does not function like its conventional counterpart. The following security programs have been implemented to insure that robot dialers are totally ineffective:

- **The data representation of the number sequence is changed each time the dial direction is reversed;**
- **The number generator seed is encrypted and the key is changed each time the dial is turned;**
- **There is a free-running counter in the processor that is re-encrypted each time the lock is opened;**
- **The seed for the algorithm changes each time the lock is reprogrammed: it is random and free-running;**
- **The memory location for the seed changes when the lock is reprogrammed;**
- **The serial number of the lock is utilized in generating the seed. This will prevent the use of a logic analyzer to sample memory locations of different locks in an effort to determine the algorithm;**
- **It is impossible to decipher any data stored in the memory to learn the combination.**

The profile of a robot dialer will be met and appropriate countermeasures initiated if the following conditions occur:

- **Continuous dialing without a pause of at least .250 seconds every 1 1/3 turns will cause the combination to be ignored;**
- **If an entire combination is entered in less than 15 seconds;**
- **If continuous dialing occurs for more than five minutes without letting the lock power-down;**
- **Dialing ten incorrect combinations in sequence**

requires a two-minute power-down and blanking of the display until power reset.

A robot dialer utilizing the most sophisticated sensing technology, including optical character recognition, sound, and video, would be expected to accomplish an opening based upon half of the combinations, in 190 days. In dual-combination mode, the robot dialer would not know if one of the combinations had been entered incorrectly until both were dialed. In reality, there is no such thing as surreptitious entry of an X-07. If one statement can summarize the security of the X-07, it is this: "if you do not have the combination, you will not open the lock."

34_12.6.2 Future Security Enhancements

Later models of the X-07 are expected to contain a clock to provide greater audit detail and increased functionality, with respect to entry control. Remote control for alarms as well as authorizations for opening and changing of combinations will also be incorporated. It is also expected that future locks will store up to 50 or more different combinations, one for each employee. With additional memory, every opening and closing can be retained. Expect memory size to increase to 1,000 or more bytes (from the present 100 bits) and stored data to be encrypted.

34_12.7 Programmability (Changing Combination)

The X-07 is field programmable for all options and number sequences, including supervisory control functions. To change a combination, the user places a two-pronged plug into the back of the lock that short-circuits the contacts. When the proper combination is dialed, the lock will display (SL) for change-key mode. The lock will not open in the change mode, so the bolt cannot be withdrawn nor can the door be shut.

A series of commands will allow the operator to enter and verify a number sequence for single or dual-combination modes. If the lock cover is accessible and the combination has been lost, the serial number may be entered through a specific sequence to place the lock into programming mode. This security feature will prevent someone from covertly obtaining the combination. Presently however, there is no audit trail with regard to removing the back cover, although such a feature is planned for later models, together with different code change procedures.

CHAPTER THIRTY-FIVE: FORCED ENTRY OF SAFES

Destructive Entry of Safes: Tools and Techniques

35_1.0 Introduction

This chapter describes the accepted methods for penetrating safes by force that are used by professional technicians. The traditional and modern techniques utilized by criminals are also described, together with the evidentiary aspects of safe and vault burglary. In the experience of the author, any safe can be opened; this chapter explores those methods. The wide array of tools, both general and specialized, is described together with guidelines for their use. Particular emphasis is placed on drilling technology of hard plate barrier materials. See **Chapter 5** for a more technical discussion of metallurgy as it relates to locks and safes. Covert and non-destructive-entry techniques, including manipulation, are described in **Chapter 36.**

The subject of safe and vault penetration is quite complex and involves many disciplines. As the reader will learn, opening a security container is both a science and an art, and can be hazardous. Successful penetration requires the correct equipment, coupled with accurate information and knowledge of the art. Patience and extreme attention to detail are essential if the mission is to be accomplished without danger to the technician.

Remember that safes in a perfect world are **designed so that they cannot be opened by anyone who is not authorized to do so**, regardless of the methodology employed. In the real world, most safes **can** be opened, either covertly or through force. Depending upon one's point of view, this is either good or bad. Whenever a safe must be opened by other than normal means (combination or key), it is usually because the lock or boltwork is inoperative due to mechanical malfunction of critical components, including relockers. The cause may also be a failed burglary, complex maintenance problem, obstruction in the doorjamb, triggered relocker, sabotage, or a previous penetration attempt that was unsuccessful. An opening may also be required for a security or intelligence operation or for evidence.

Although television and the movies portray techniques of safecracking as a relatively simple task, the process is anything but that. In fact, penetrating a high-security safe can be likened to battlefield surgery: you only do it after all other methods have failed. Safes are not meant to be opened except by the use of a key or combination. Any other procedure entails risks. It is not a simple decision to drill or apply any form of force to a secure container to effect an opening. It is a technical procedure that requires extensive information about the lock and the construction of the safe. All other methods of entry must first be exhausted.

Statistically, few safes are attacked and fewer actually opened. Most customers believe safecracking to be a rare crime; thus, any money spent on quality containers is wasted. In reality, the only reason that a safe is not successfully compromised is due to quality in its design and construction. Drills, hammers, levers, thermic lances, torches, and explosives are the tools of the trade. Their use will be described in order to provide a detailed summary of proper procedures.

All safes are normally secured and opened through a mechanical or electronic combination lock, a lever lock, or both. As described

elsewhere in this text, these locks can provide an extremely high level of security against manipulation. The container, however, always has the job to protect the lock from physical compromise. In some cases, safes are penetrated through surreptitious means. The term "surreptitious" is often misunderstood and is therefore defined here. It is "a means of entry which would leave evidence, but would not be detectable by a user during normal use, but would be detectable during inspection by a qualified person." The General Services Administration (GSA) in 1989, in A-A-F-358G, Paragraph **6.4.3**, promulgated this definition.

35_1.1 The Art of Safecracking

The history of safecracking is rich with examples of innovation, initiative, and ingenuity upon the part of burglars. One axiom always has held true with regard to security containers: “If there is a way that they can be opened, they will be, and often.” See the discussion in **Chapter 33**. Criminals and technicians have always sought to develop methods to circumvent all of the mechanical design innovations, engineering talent, and production technology that could be incorporated into a container to keep its contents secure. A tremendous reservoir of knowledge has been gathered since the Industrial Revolution relating to container security, and all that that concept entails. Every time a safe is to be penetrated or a lock manipulated, two centuries of experience is placed as an obstacle to one attempting that which is supposed to be impossible. The reader may also wish to review the discussion by Alfred Hobbs regarding this subject in **Chapter 14** of his book.

35_1.2 Container Security: Early Problems and Solutions

Safecracking has been going on for hundreds of years and has always been a contest between manufacturers, technicians, and burglars. Safe makers have sought to produce containers and locks that could not be compromised by anyone through any means. Every part of a safe has been designed in response to some form of attack or threat. The shape, design, mechanism, metals, and even the paint is a product of security.

Manufacturers have gone to extraordinary lengths to protect their containers. Great advances in metallurgy, chemistry, physics, and manufacturing processes have combined to produce the most secure locks and containers on earth. Likewise, methods of

attack that were once primitive and rudimentary are now sophisticated. They include the use of high- tech tools and computers.

Burglars began with crude tools, such as jimmies, levers, pickaxs, sledgehammers, pry bars, and wedges. The use of drills, torches, lances, and explosives soon followed. Safe makers responded to each method of attack with various enhancements that contributed to safe and vault technology today. Manufacturers have logically focused their design efforts to barrier materials, bolt works, locks, hinges, and construction techniques. In response to each new method of entry, they have refined their products and processes. The more relevant advances can be found in technical specifications in the Chubb archives:

- **The methods of fixing steel plates together to form the body of a container;**
- **The construction of comb and dovetail joints with extra fillets at the corners;**
- **The development of sophisticated metals to act as barrier materials, with Rockwell C ratings exceeding 90;**
- **Changes in bolts and locks to protect against drilling, manipulation, temperature, and explosives;**
- **The development of complex and fail-safe relocker systems, utilizing mechanical, thermal, vibration, and glass materials to prevent compromise of locks, bolt works, and barriers;**
- **Introduction of many enhancements in mechanical and electronic combination locks;**
- **Introduction of time locks, time-delay locks, and automatic scrambling locks;**
- **Isolation of wheel pack from the bolt. In older safe designs, the discs were directly connected to the boltwork. This allowed feeling and hearing the fence-gate positions as pressure was applied to the bolt;**
- **Implementation of reinforced lock mounting and protection of the keyway, in order to prevent the practice of pushing a strong steel threaded rod into the keyhole and driving it backward with a sledgehammer;**
- **Sealing of cavities to prevent gunpowder from being**

directed into the safe with a bellows or straw, allowing the safe to be blown apart;

- **Reduction or elimination of sharp, square edges on walls and doors. Only safes with rounded, welded edges would resist lever or wedge attack;**
- **Advances in riveting, attaching, dovetailing, and welding of metal plate to increase strength;**
- **Prevent ripping and peeling through the use of steel bands and supplemental enforcement;**
- **Use of manganese steel and other sophisticated alloys to prevent cutting;**
- **Reduce the tolerance gaps in square doors to prevent the use of nitroglycerine to seep into these areas. The round door in the Corliss safe was a direct result of this practice;**
- **Develop a crane hinge to provide closer tolerances than was possible with traditional hinges that required rotation around the radius of the pin. The crane hinge provided for a direct straight-in fit, much like a bath plug fills a drain;**
- **More secure door and door mating designs to reduce tolerances and make them more secure. Locking and sealing was accomplished in one motion, borrowed from the design of the breach locks of big guns. For a time, the doors were designed as a large plug with interrupted threads that actually constituted a screw thread with slots cut into the frame. To engage these doors required a partial turn to lock secure. They were extremely effective but eventually were compromised;**
- **The thickness of walls and barrier materials was increased. Steel that is less than ¼" thick will provide no resistance to attack from drilling, ripping, and explosives because it cannot resist pressure;**
- **Sophisticated barrier materials have been developed to resist drilling, especially around the lock. More than one inch of material may be considered as drillproof. Several layers of different metals may be employed to protect against the effects of drilling, temperature, and pressure;**
- **The physical weight of safes was increased for**

structural integrity, rigidity, and protection from concussion. Over 800 pounds is considered the minimum requirement.

35_1.3 Terms of Art: The Original Safecrackers

Many terms came into the lexicon in England and then America almost two centuries ago to describe the tools and techniques of the **Peterman** or **Boxman.** This jargon attests to the uniqueness and mystique of the craft. Some of the terminology is included here to preserve the tradition, and provide a flavor of the art for the reader:

Bellmen: Users of explosives;
Bellows: Device utilized to create a pressurized airflow to force explosives into a safe;
Blower: Safecracker;
Box: Safe;
Boxmen: Safecracker;
Dets: Detonator for explosives;
Grease: Nitroglycerine;
Gut Box: The locking mechanism

Gutshot or Spindle Shot: Nitro can blow a lock after the dial has been removed and the safe is laid on its back. An eyedropper is employed to drip the nitro onto the dial, where it will follow a path into the lock. A detonator is required to set off the explosion.

Jam Shot: This method of opening a safe requires some skill. Nitro is poured into the crack around the edge of the door, allowing the fluid to trickle in and fill the doorway. It will blow the door open and allow it to remain on its hinges once detonated. To accomplish this technique successfully, two critical items were required: a bar of kneaded soap and a strip of cellophane tape ½" wide. The tape was first pressed into the crack around the door and then the soap was used to create a sealed track over the cellophane. The tape was then removed and the nitro poured around the door. Manufacturers have since introduced tighter tolerance and a small lip around the door to catch the nitro and stop the practice.

Jimmies or **Jemmies:** Levers;

Kiester: Smaller safe within a larger one;

Knocker: Detonator;

Mit: Handle of the safe;

Nitro: Nitroglycerine. This is actually glyceryl trinitrate, which is used for the treatment of angina in cardiac patients. It expands blood vessels and reduces the work load of the heart;

Peter Cane: A lever that is used to open a jammed or distorted safe door after an attack that succeeded in creating a gap between the door and frame;

Peterman: Safecracker;

Powder: Gunpowder;

Punching a Cam: Forcing the lock mechanism away from the bolt by driving a rod into the lock case, then applying pressure to release it from its anchor;

Rag Shot: This involved boring a small hole directly above the dial. Then, a rag was saturated with a solution of nitro, pushed into the hole, and covered with kneaded laundry soap. A wire connected the detonator to a battery;

Shooting for Space: Introduction of nitroglycerine into crevices and tolerance gaps within a safe;

Space Shot: This involved dropping a safe on its back, then building a soap cup on the center of the door and detonating an explosive contained in the cup. The aim was to “dish the door”;

Yeggs: Traveling safecrackers;

35_1.4 About Opening Safes: Things You Should Know

Experienced safe technicians who have spent many years learning the craft open most safes. A competent "safe tech" is invaluable because without his skill, the safe will either not be opened or it and the contents will be destroyed in the attempt. Time is generally a critical factor in most openings: the professional safe technician will require the minimum amount of time to do the job right. Finally, when the safe is opened it will be restored

to its original security rating. It will not be left vulnerable to future attacks that have been made simpler by the previous penetration procedure.

Most professionals in the world are members of both the **Safe and Vault Technicians Association (SAVTA)** and the **National Safemans Organization (NSO).** Many have attended schools on safe penetration and manipulation conducted by either Mark Bates or Lockmasters. Information regarding NSO and SAVTA, specialized schools, and a master index of articles and bulletins can be found at **security.org**. Opening a safe, especially for the first time, can be an awesome experience. It is usually remembered for quite some time by the technician, often with accompanying nightmares!

35_1.4.1 Reference Material and Courses

Many books on the subject of penetration contain a great deal of valuable data. Hopefully, this will be one of them. However, no text or school can properly prepare the technician to open a difficult container. Only experience and making many mistakes can do that. There are so many variables, unexpected circumstances, and conditions that can occur that every opening is a challenge and fraught with peril.

Courses in safe penetration may be valuable. A knowledgeable instructor with a recognized curriculum must teach in a facility capable of properly demonstrating various techniques. Basic and advanced classes, manufacturer seminars, and resident classes may all be helpful. In the first instance, be certain of the accuracy of the reference material that is being relied upon as the basis for drilling or other forced-entry techniques. If the diagram or drill point template was not drawn by Ed Willis or a craftsman with similar competence and experience, then the data may not be reliable. Information published prior to 1970 regarding drilling procedures should be read quite critically. Prior to the mid-1980s, carbide-tipped drills were not available for penetrating hard plate, and thus some of the procedures that were published were slightly different than today.

35_1.5 Remember the Basics

Always remember that the lock controls access to the safe. Open the lock, and the safe will follow. The manufacturer of the container is largely irrelevant and of secondary importance if the lock can be bypassed. The vast majority of malfunctions that

require that a safe be penetrated are lock related. See the discussion below about lockout diagnostics.

In almost every penetration, drilling is accomplished within the dial ring area, although this may not be the case in high-security containers with glass relockers. Do not be easily intimidated by the size, complexity, or security of a container. Simply respect it. To do otherwise will ultimately occasion errors in judgment and lead to failure. Remember that every manufacturer touts its products in technical terms, calculated to act as a deterrent to anyone contemplating penetration.

Most design engineers working for safe manufacturers are not particularly clever, and few think as a burglar does. In the author's view, they have little understanding of how to “break” a safe, only to design it. Quality during production and the proper research and development make a safe secure. A UL rating simply confirms the security level of a container and provides an index as to the difficulties that may be encountered in an opening. It does not guarantee that the safe cannot be opened.

Other basic guidelines for safe technicians that are often forgotten or misunderstood include:

- **Do not be intimidated by any safe. Have respect for the potential difficulty of the task and the engineering that is incorporated into the container. It is designed to keep from being opened without the key or combination;**
- **A safe or vault lock is no more complicated than a pin tumbler or lever device;**
- **The proper knowledge of the design of the container is essential and can compensate for a lack of confidence;**
- **Safe manufacturers require that their products can be serviced. They are generally cooperative with a professional safe technician and law enforcement agency in providing information about opening their product;**
- **Possess all of the correct tools to do the job, understand their function, and know their limitations. An opening should not be undertaken without the proper implements;**
- **Tools are expensive, and there is no substitute for**

quality. A serious safe tech should spend the required amount on the finest tools after careful research to determine what best meets his requirements.

35_1.6 Hazards in Opening Safes and Vaults

Many hazards can be encountered in the process of opening a safe. They may cause physical danger, legal liability, economic loss, and injury to reputation.

35_1.6.1 Documentation: The First Step

It is important that the proper documentation be maintained regarding the opening of any container. This includes:

- **Any impact upon security;**
- **Cause of the lockout;**
- **Complete description of the work performed;**
- **Complete identification of the safe: color, make, model, generic type, and serial number;**
- **Date and time;**
- **Information regarding repairs, including drilling, for insurance claims and UL certification of the container. This data can be used to rebut claims of negligence should burglars using the same drill point compromise the safe;**

- **Information regarding the specific job, which includes:**
    - **Insurance coverage for negligence, property disappearance, and business interruption;**
    - **Maintenance data for future service;**
    - **Maintenance records regarding service and combination change, including documentation of details regarding the job. (This may be very important in the case of a lockout that occurs shortly after the work was performed);**
    - **Method of opening;**
    - **Parts installed;**
  - **Services performed;**
- **Signature of individual in authority, both prior to**

and after acceptance of the work performed;
- **Verification of the authority of individual requesting the services of a safe technician, so that charges of theft and conspiracy cannot be lodged against the technician;**
- **Warranty data regarding work performed;**
- **Witness to opening, in order to verify that contents have not been removed by the technician;**
- **Written contract for work to be performed.**

35_1.6.2 Dangers to Life or Property

Although rare, there are dangers that can occur while working on safes and vaults. An assessment should always be made prior to any opening or performance of service. This should include:

35_1.6.2.1 Explosives

If a safe was burglarized using explosives, extreme caution must be exercised because active non-detonated charges may be present. This is especially true where nitro was employed. If nitroglycerine is present, it can be detected by the presence of a soapy substance. In fact, soap is actually used to contain the "grease." Safes may also be booby-trapped with other forms of explosives.

35_1.6.2.2 Tear Gas

Tear gas was first introduced in 1871, and was developed by Graebe. Its chemical composition can take several forms, the most common of which are chloroacetophenone, phenacyclchoride, Chemical Mace, and CN. Perhaps the most popular was chloroacetophenone, which is a solid crystallization produced by chlorinating acetophenone and benzene.

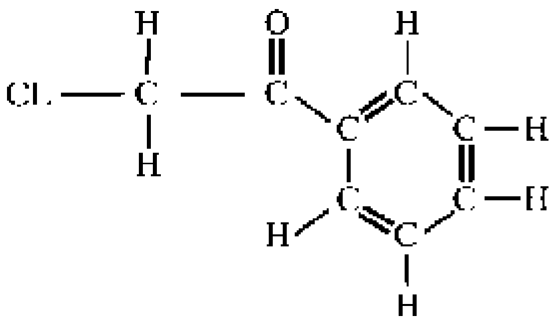

Figure LSS+3501 Chemical composition of the most common form of tear gas.

The presence of tear gas can be lethal, especially if the material was produced and installed many years ago. Tear gas was routinely placed in safes and vaults used in federal buildings and banks, between 1935-1970. Discharge can cause evacuation of a building and be dangerous to those with heart or respiratory conditions.

If the safe is quite old, the tear gas may have deteriorated and can become toxic or even deadly. This is especially true if cyanide was utilized as a primary ingredient. Companies that produced tear gas systems for safes included Badger Safe Guards (New Jersey), Detour Safe Protector (Minnesota), Night-Hawk (Oregon), Chicago Tear gas Company, Pro-Tex Laboratories (Chicago), and Lake Erie Chemical Company (Cleveland).

Tear gas may be released during a failed burglary attempt. Glass vials containing the chemical can be exposed to breakage during the search for evidence and present an additional risk. The use of a torch to open a burglarized safe after the fact can also trigger tear gas relockers.

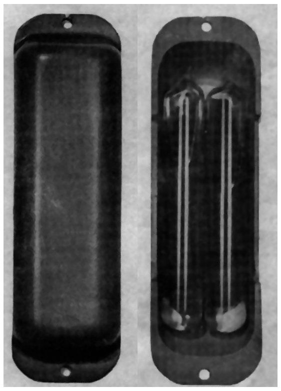

Figure LSS+3502 A typical tear gas container with two glass vials containing the active material. Upon the triggering of a relocker, shock, or vibration, the vials are broken and the gas released.

35_1.6.2.3 Smoke Bombs

Smoke bombs were popular in safes produced at the end of the nineteenth century. They were contained in a metal canister mounted within the door and activated by a tensioned relocker.

35_1.6.2.4 Dangerous Contents

Safes can contain dangerous materials that may cause injury or death. If the safe is opened by grinding, hammering, prying or with a torch, the problem can be more pronounced. This is especially true if blasting caps, ammunition, fuel, or explosives are contained within. The safe may also be booby-trapped with a bomb.

35_1.6.2.5 Burglarized Safes

There are several hazards associated with opening a burglarized safe. The search for evidence must be preceded with an investigation into possible dangers relating to contents and physical condition, including:

- **Electrical wires, conduit, or outlets that are in contact with the container;**
- **Stability and anchoring of the container. Pay particular attention to broken casters or mounting pads;**
- **Door and hinges are secure and will not fail when dislodged or opened;**
- **Temperature of the container;**
- **Corrosive chemicals on the surface of the container;**
- **Sharp edges;**
- **Explosive residue, especially nitro.**

35_2.1 Security of Safes and Vaults

There are many ways to compromise or penetrate a safe. In addition, certain very basic measures will help to prevent losses from fire and burglary.

35_2.1.1 Buy a Quality Safe

There is no substitute for quality. Manufacturers such as Chubb, Mosler, and Diebold have been in business for over a hundred years and have developed extremely sophisticated technology to protect valuables. There is a reason why good safes are expensive. Research, development, and precision construction come at a price. Safes can be subject to many quite sophisticated forms of attack; advanced metallurgy, chemistry, and physics are required to insure a high-security rating and effective resistance to such measures.

35_2.1.2 Access to the Safe

Hide the safe or encase it in concrete or other barrier material to prevent access. In commercial establishments, place the safe where it can be observed from the outside. Utilize reliable internal and external alarm systems including door trips, motion detection, and proximity sensors. Alarm devices should protect against movement, temperature, and vibration.

35_2.1.3 Obtaining the Combination

Prevent anyone from obtaining the combination by using spyproof dials and obstructing remote viewing. Do not leave the combination where it can be found, and do not utilize predictable sequences of numbers such as birth dates or telephone numbers.

35_2.1.4 Locks

Utilize high-tolerance combination or key locks. Electronic locks such as manufactured by Mas-Hamilton have set the world standard for computerized high-security control. Mechanical locks should have at least 1,000,000 theoretical permutations, with a maximum of ±1.0 number tolerance for fence and gate. False notches should be incorporated to deter manipulation. Group 1 locks are generally required for military, government and high-security installations. Time locks should be utilized on vaults to control access, especially whenever holdup or hostage taking is a potential threat.

35_3.0 Methods of Entry for Opening Safes and Vaults

There are many techniques for opening safes and vaults and for

bypassing safe locks. The procedures can be divided into non-destructive (covert or surreptitious) and destructive means. Within each classification, there are several options. These depend upon a complex array of factors based upon the lock, safe, or vault to be opened. Several alternatives may be applicable for any job and are in part dependent upon the skill of the technician, tools available, window of opportunity, and conditions at the time of the opening. Non-destructive entry involves the bypass of locks and other mechanisms in a manner that cannot be detected. Such techniques do not cause any alteration or damage to a component. An entry that causes damage or a change to any mechanical component of the lock or safe is said to be destructive, regardless of whether the change is fully repaired.

Although there are many approaches described in this text, drilling is the primary method of destructive entry. Major emphasis will be placed on that technique and all of its facets. The following summary analyzes and categories the available options for effecting an entry by both non-destructive and destructive means.

35_3.1 Summary of Non-Destructive-Entry Techniques

Non-destructive entry occurs by obtaining useable information about critical locking components without their disassembly or destruction. Nine primary methods for obtaining such information will ultimately lead to an opening.

35_3.1.1 Combination Deduction

The original factory combination or number sequence is deduced by using tryout numbers or other means. Numbers can be obtained from a variety of sources if the proper security measures have not been implemented. Perhaps the easiest approach is to test the lock using known factory-default combinations. Many times, locks are replaced and never reprogrammed. Using a list of test numbers from the manufacturer, the lock can be opened.

Unfortunately, convenience can take precedence over security. Selection of combinations based upon birth dates, social security numbers, telephone numbers, easily remembered sequences, or patterns are too often used. The burglar can sometimes guess these. Combinations are often written on pieces of paper and left

in desk drawers, on bulletin boards, blotters, in notebooks, or on the container itself. In one bank theft investigation worked by the author, the combination to the main vault had been written on a file card in the security director's desk. It had been missing for nine months without the combination having been changed. There should have been no surprise when the money finally disappeared!

35_3.1.2 Employee Compromise

Information regarding combinations may be obtained from employees, with or without their knowledge. Numbers may be written down and recorded by employees for safekeeping or to facilitate recollection. If an unauthorized person such as a janitor or coworker locates that information, then the contents of a container can be compromised without the ability to identify the perpetrator. Employees may unwittingly provide information about a combination to third parties through innocent conversation. They may also sell the information or provide it while in collusion with criminals.

35_3.1.3 Surveillance

The combination sequence can be derived through surveillance while the container is being opened. This can occur through direct or remote observation. Techniques for obtaining information through surveillance include:

- **Secrete persons or cameras in ceilings;**
- **Observe safe being opened at close range;**
- **Audio or video plants in order to derive the combination or information about it. Devices will include video, film cameras, or audio recorders. Some older locks emit clicks for each number division. These can be recorded and deciphered later;**
- **Long-range lenses, telescopes, or binoculars;**
- **Simulated burglary in order to force maintenance of the safe. This can lead to information being obtained or overheard from locksmiths or safe technicians about the problem;**
- **Paper under safe dial to record rotations.**

With the availability of extremely small video devices, a camera

can be placed in such a position as to afford a direct view of the dial. This information can be recorded, or directly seen. The results of surveillance can yield partial or complete data regarding the combination. Obtaining one of three numbers in a combination sequence can reduce the time required to open a lock to less than forty-five minutes.

35_3.1.4 Manipulation

Extrapolation of the combination through the manipulation of the dial can be accomplished on most Group 2 and non-listed locks. Manipulation is not detectable once it is performed. It is a precise process and thoroughly described in **Chapter 36**. Although manipulation has traditionally been a manual process, Mas-Hamilton has introduced an extremely sophisticated computerized system to automate the task for certain popular combination locks. The Soft Drill is detailed in **Chapter 36**.

35_3.1.5 Vibration

Older combination locks can be opened with vibration. As has been noted previously in **Chapter 33**, this design problem in certain mechanisms was particularly prevalent on ships where constant engine tremors were transmitted to wheel packs through the metal of the vessel. In the older designs, no balancing mechanism was integrated into the wheel structure. Because there was less material at the top of the wheel (where the gate required the removal of metal), there was a corresponding imbalance or weight difference.

If the wheel vibrated, the heavier portion at the bottom would find its natural position based upon the action of gravity. All that was required was to introduce enough vibration so that all three wheels would align their lightest portion (gates) at the twelve O'clock position beneath the fence. Vibration could cause the lock to be opened without a trace that an entry had been made. This was such a pervasive problem that safes would open themselves on some ships.

35_3.1.6 Day-Locking

Safes are often day-locked using a second locking mechanism integrated into the dial. This provides little protection from picking or other methods of compromise. Day-locking may also be accomplished by turning the dial a few divisions past the correct number to expedite the opening process. Employees will often

engage in this practice in order to eliminate the requirement for entering the entire combination.

Obviously, a thief can also back dial the number to open the safe without having any direct knowledge of the combination. In certain cases, the number sequence in locks using wheel pack scramblers can be derived.

35_3.1.7 Robot Dialers

Robot dialers can be an extremely effective means to open a lock. They are computer-controlled devices that are programmed to dial every possible combination while exploiting the tolerance errors of a specific lock. See **Chapter 36** regarding current technology.

35_3.1.8 Radiographic Imaging

X-ray and gamma ray imaging may also be employed to provide a representation of the position of wheels and gates.

35_3.1.9 Touch-Sensitive Materials

Fingerprint powder, ultraviolet indicators, and other materials may be utilized to show which buttons have been touched on a push button lock. Dust covers on dials and keypads can eliminate the practice.

35_3.2 Summary of Destructive-Entry Techniques

Destructive entry occurs whenever a container or its lock is physically penetrated using tools, temperature, or concussion. The principal methods of forced-entry can be divided into four major categories: **cutting**, **blunt force penetration**, **concussion**, and **drilling**. Each of these techniques is explored in detail in subsequent sections of this chapter, with special emphasis on drilling.

35_3.2.1 Cutting

Cutting is a less precise form of attack, often used by burglars and unskilled technicians. The technique encompasses sawing and grinding, employing common power tools to physically remove or penetrate barrier materials. Cutting may also be accomplished through the use of more sophisticated techniques including lasers, high-pressure water cutters, a thermic lance, torch,

creation of high-temperatures through the use of chemicals, or application of acids.

These tools are employed to melt, vaporize, alter, or remove protective metal barriers. Hinges, handles, or locks can be destroyed or large holes can be made to create openings through which access to contents can be obtained.

35_3.2.2 Blunt Force Penetration

Techniques of blunt force penetration are most often employed by burglars; they generally denote a low skill level. The techniques will include **punching, peeling, ripping, and chopping**.

35_3.2.3 Concussion

Concussion requires the application of pressure, generally created by an explosive such as nitroglycerine, gelignite, dynamite, plastic, or primer cord.

35_3.2.4 Drilling

Drilling is the generic process of making a hole at a precise location (drill point) somewhere in the safe or lock body. The ultimate purpose or use of the penetration will vary, depending upon many factors. Generally, a hole is created in order to allow a view or manipulation of vital components using a borescope or similar optical device.

35_4.0 Destructive Entry: Primary Tools and Techniques

LSS204: Owe Bengtsson on opening safes

LSS204: Owe Bengtsson introduction to opening safes

LSS204: Owe Bengtsson on the forced entry opening of safes

LSS204: Owe Bengtsson on the opening of high security safes

In this section, a historical overview of the tools and methods of forced penetration is summarized. Then, an inventory of basic and specialized tools is provided. The various types of drill bits, their proper use, and related drilling equipment, including drill rigs, are also described in detail. Finally, the penetration of hard plate is analyzed.

35_4.1 Historical Overview of Tools and Techniques

Enhancements in security containers during the past two centuries have most often been a response to the development and use of tools and techniques by criminals for defeating safes and vaults. In virtually every instance, once a manufacturer has introduced an improvement, the burglar has initiated a successful counter offensive.

Two centuries ago, the common safe-breaking tools were a crowbar, axe, steel wedge, pick, or bolt cutter. Protection generally meant heavier metals, with sophisticated linings. Later, manufacturers adopted techniques of poured metals that created seamless corners, joints, and bonds that offered additional protection against these forms of attack. When drills became an accepted means of penetration, then anti-drilling barriers were incorporated into doors. These took many forms, as described later in this Section, and spawned an incredible array of hard plate metals.

35_4.2 Common Methods of Attack

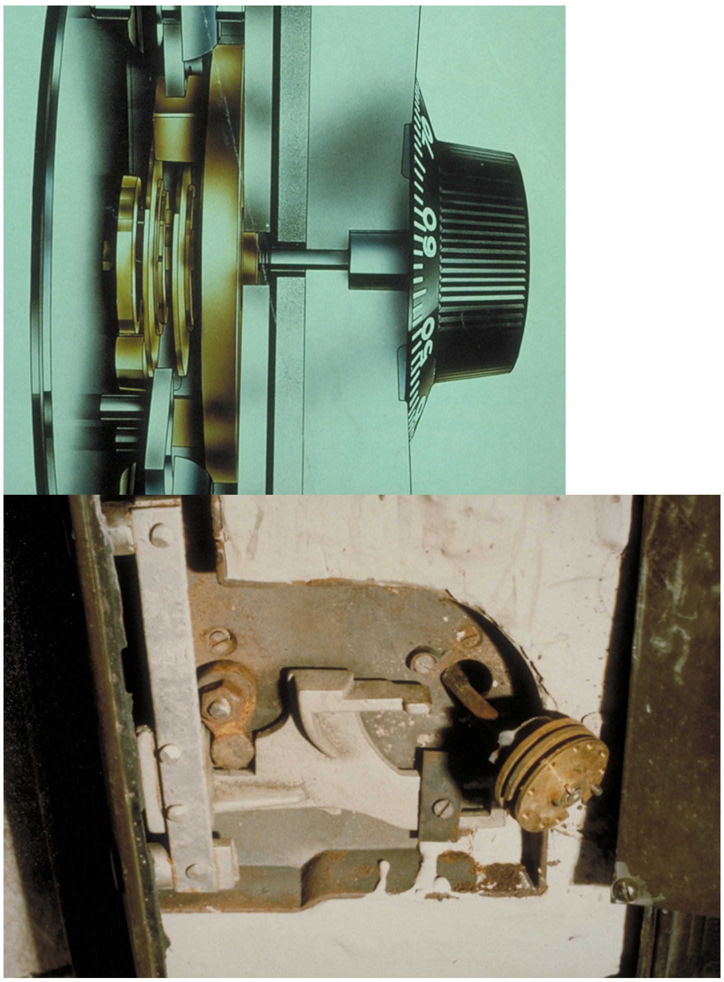
LSS201: A primer on the burglary of safes, Courtesy of Bill Sherlock.

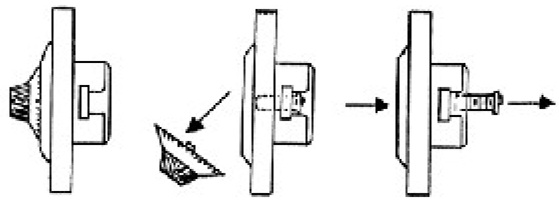
LSS201: Forensics and locks, Courtesy of Bill Sherlock.

There are many tools, devices, and options available to the thief. Some are rather crude and merely require brute force. Others are more exotic and sophisticated and utilize temperature, concussion, or other methods to alter the molecular structure of metals. The following discussion summarizes the most common methods of entry, beginning in the early eighteenth century. They are based upon the construction of the container and will usually be successful if enough time and effort are expended.

35_4.2.1 Punching

Punching is a technique that is as old as the wheel pack itself. The dial is first removed, then the spindle or dial shaft is driven into the lock case. This will cause the tumblers to fall out of the way of the bolt. Bolts can also be punched, either from the front or side in order to move them out of the way of obstructions.





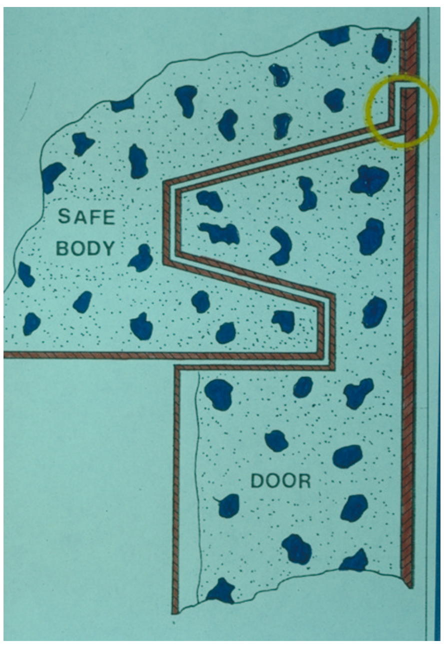


**Figure LSS+3508. Punching involves the wheel pack being forced inward (left,
ISP 35-3563), as shown in the photograph (ISP 34-3563). Courtesy of Illinois State Police, Bill Sherlock.**

In older safes, there were no internal relock devices to prevent

this practice. Due to the vulnerability of early lock designs, various countermeasures were applied. These included the use of relockers and placing a bevel on the spindle into the wall of the door. Safes that utilize locks with a UL classification of 1, 1R, and 2 are generally not subject to the practice.

35_4.2.2 Peeling

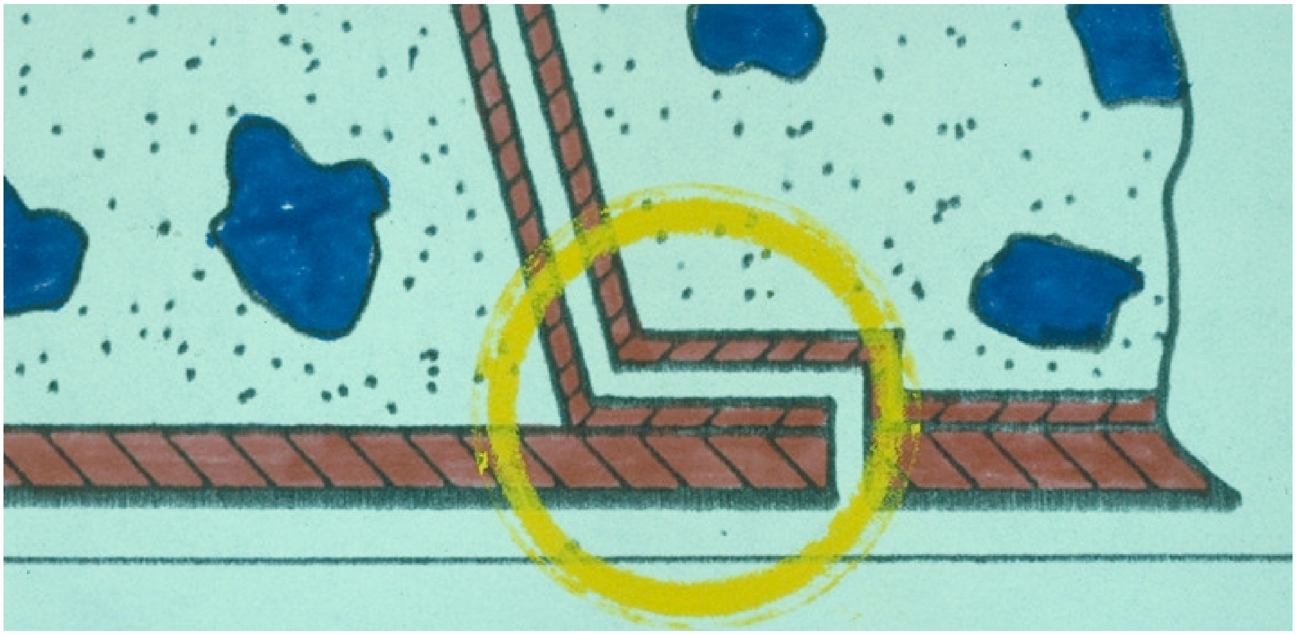

Figure LSS+3509, diagram showing how a safe is peeled by gaining an access point to remove layers of metal (left, ISP 23-3563, right, ISP 24-3563). Courtesy of Illinois State Police, Bill Sherlock.

Peeling or stripping is a brute force method of entry that usually indicates little expertise. The technique is employed with older and less expensive safes and is usually effective on containers manufactured prior to the 1960s. This form of entry requires the stripping of laminates of metal apart until the body of the container is penetrated. Generally, the edge of a square corner of the safe near the door is attacked. An axe is utilized to break the laminate bond. Then, with a lever or pry bar, the layers of metal are separated. Each exposed sheet is removed in succession, much like peeling an onion. This can be a very time-consuming and labor-intensive method of entry.

Figure LSS+3510. In this figure, peeling was accomplished from the corner using a cold chisel.

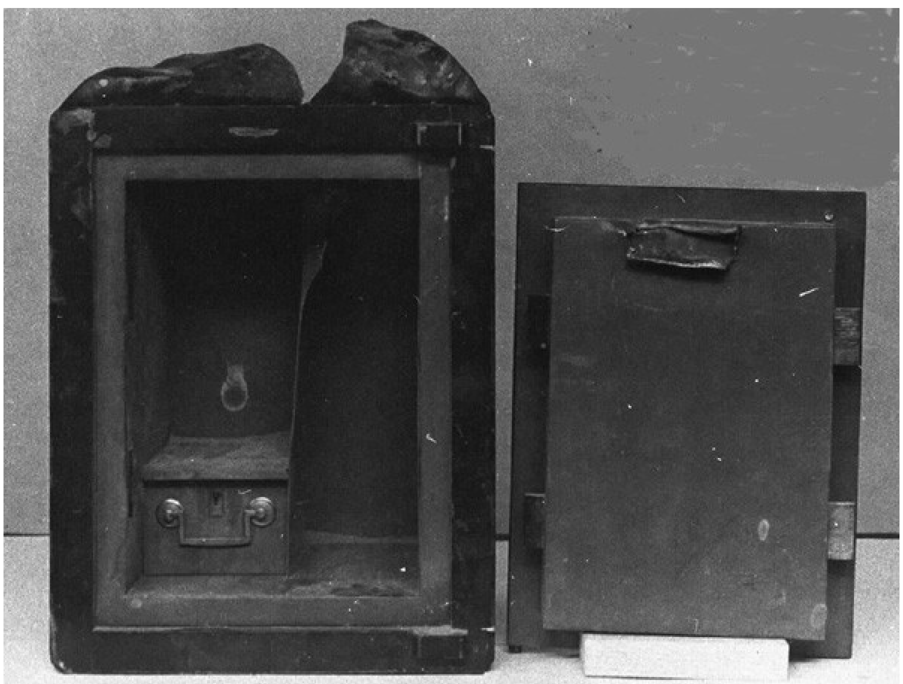

Figure LSS+3511 This was a peel and punch attack to access the bolts (left). A classic peel attack is shown (right)

Figure LSS+3512, examples of peeling of the outer skin on the top of the container (left), and the rivets popped through peeling (right).

35_4.2.2A Prying and Wedging

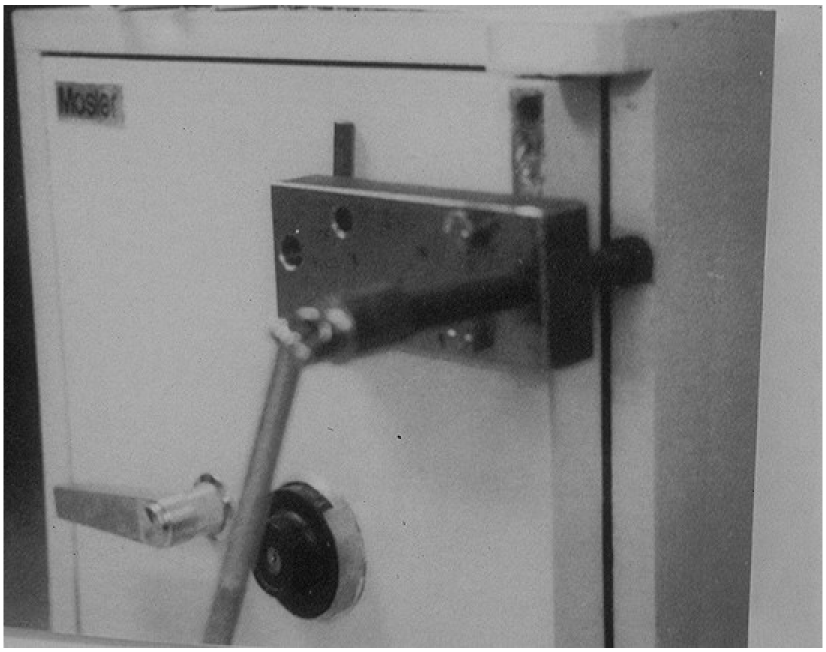

Figure LSS+3513 Prying and wedging. (center, ISP 29-3563, and right, ISP

30-3563). Courtesy of Illinois State Police, Bill Sherlock.

In this mode of attack, wedges and pry bars are utilized to attack the door, or sides of the container. The procedure differs from peeling, in that layers of skin are not removed, but rather plate is separated from the structural support.

35_4.2.2B Pulling

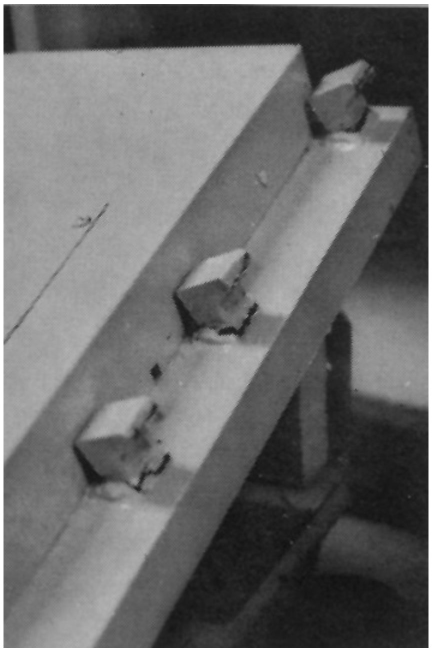

Figure LSS+3514 (ISP 31-2963 left, 32-2963 right). A safe that has had the door pulled loose by the application of extreme pressure.

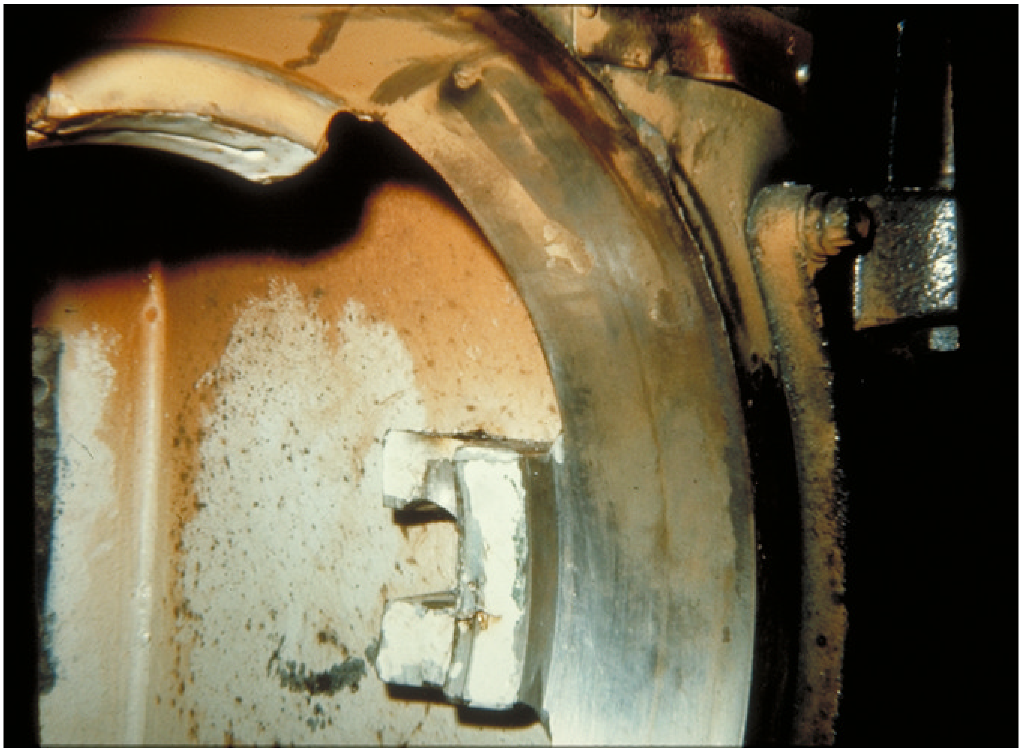
35_4.2.2C Pounding

Punching involves another form of brute force attack, designed to deform the metal in order to destroy the structural integrity of the container.



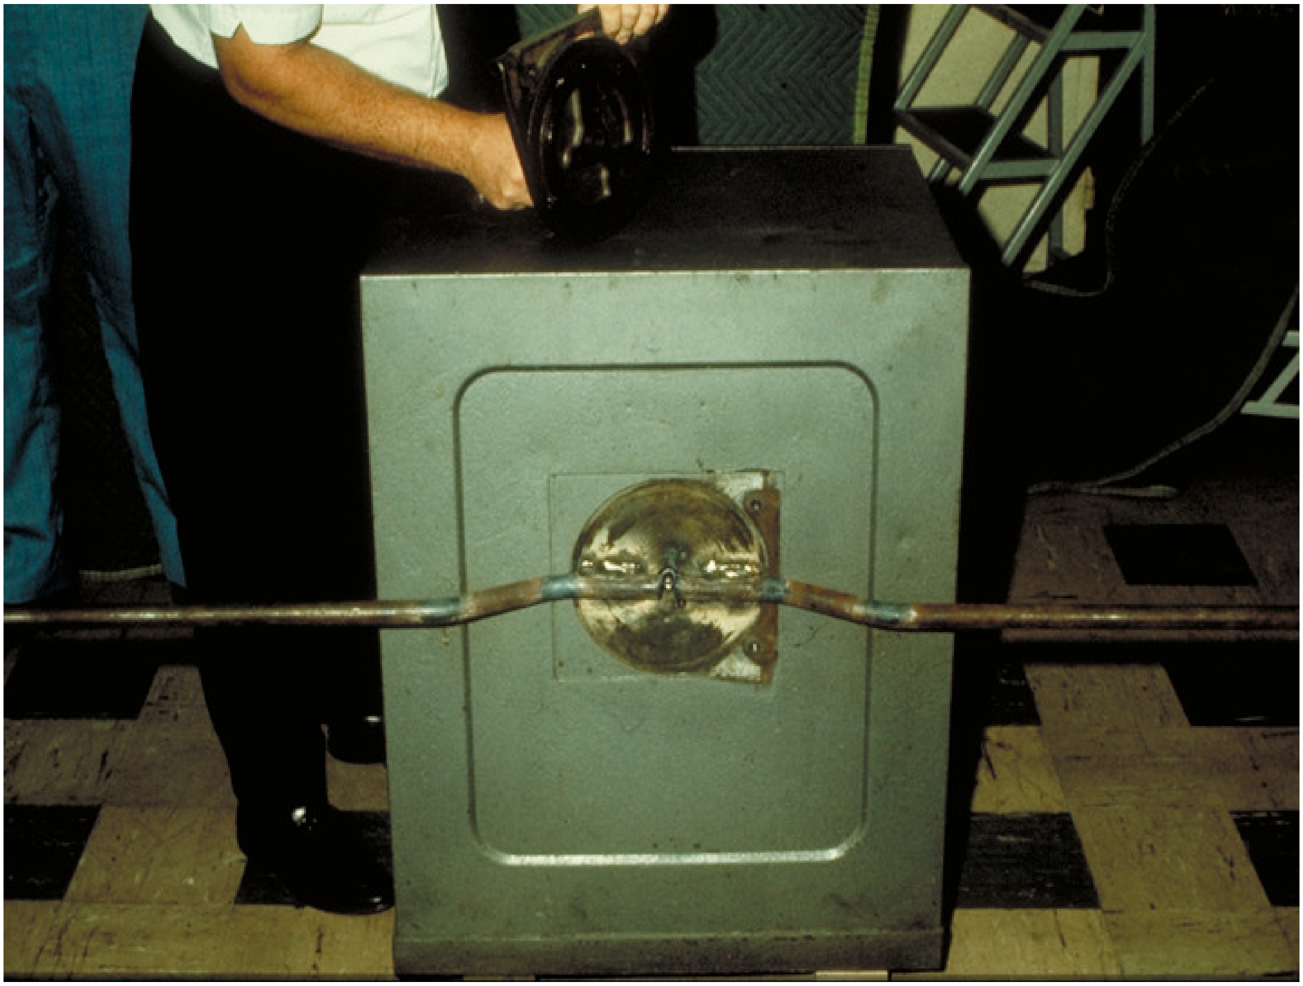


Figure LSS+3515, (ISP 38-3563 left, and 39-3563 right). The results of a pounding of components.

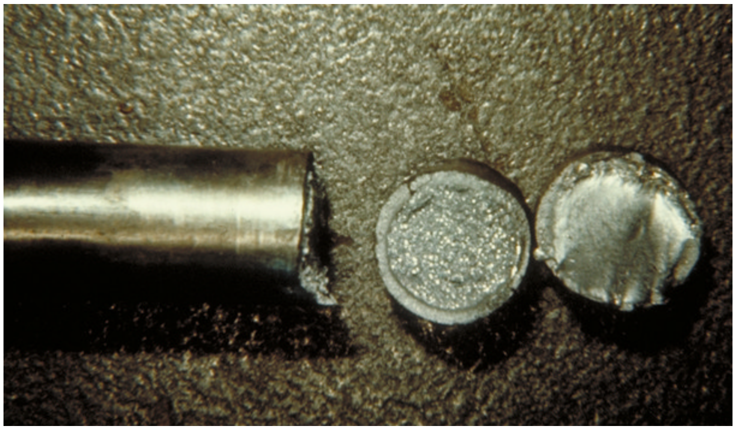

Figure LSS+3516, (top, ISP 40-3563, left, ISP 41-3563, middle, ISP 42-3563, and right, 43-3563). In this attack, the bolts were sheared by causing severe shock waves through the use of the welded bar to the front of the door. This attack changed the design of the round door from hardened to soft bolts . Courtesy of Illinois State Police, Bill Sherlock.

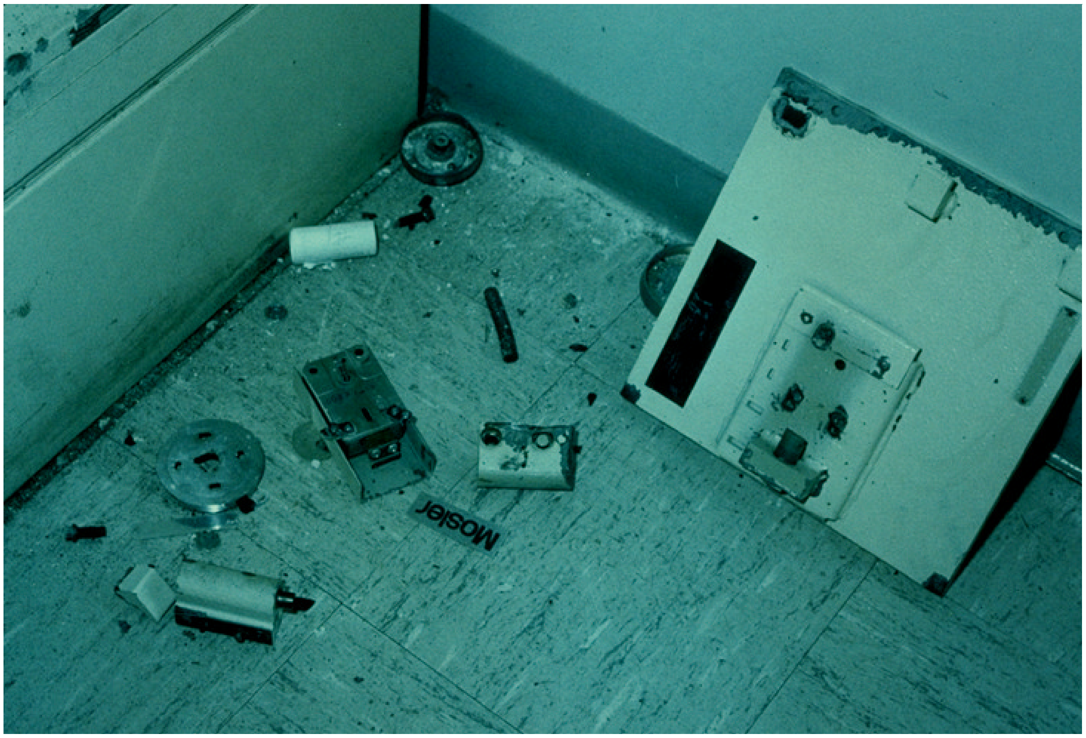

Figure LSS+3517. Another example of punching (left, ISP 47-3563, right 48-3563). Pressure was applied to the hinge side (47), all the welds were broken (48).

Mosler

35_4.2.3 Chopping

Chopping is an extremely primitive technique, applicable to older containers that are thin-walled or made of softer materials. An axe, sledgehammer, pick, or other sharp pointed heavy tool is used to deform metal plates and make holes in the top, sides, and bottom of the container. Often, metal sheets would pull away from rivets once struck.

Another popular technique, called the “can opener” features the

use of a sledgehammer and axe to break open a container. This procedure requires a great deal of force, noise, and time to accomplish. In response, manufacturers employed thicker metals and framing.

35_4.2.4 Hinges

In older containers, the destruction, removal, or shearing of hinges was a favorite method of attack. In many of the early doors, only one bolt was utilized. This practice was a natural way to compromise the enclosure. Manufacturers responded with multiple bolts linked to the primary locking system to prevent the technique from working.

35_4.2.5 Cutting, Sawing, and Grinding

Disc cutters, grinders, and hole saws can be utilized to penetrate containers, especially fire safes. Equally effective is the reciprocating saw, such as manufactured by Makita. High-speed grinders placed at the appropriate cutting angle and location will penetrate most containers. The exception is the Chubb Planet safe, constructed of an elastomer that is extremely resistant to grinding and drilling. As described elsewhere in this text, Chubb received a patent for their unique plastic fire and burglary-rated safe. Any attempt to burn through the material will result in the formation of a hard crust, creating an even wider barrier. Attempts to cut the barrier will wear a disc in about fifteen seconds once the aloxite layer is reached.

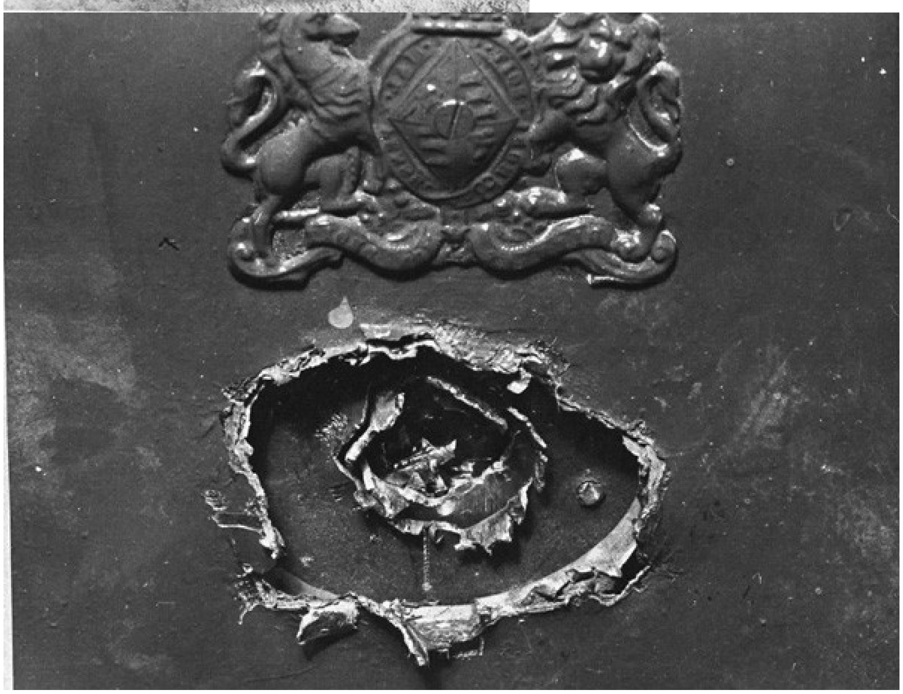

**Figure LSS+3520, examples of cutting. In the photograph (left), the top of the safe was cut
into to provide access to the bolt works. Shown (right) is a cold chisel attack.**

35_4.2.6 Use of High Temperature

The application of high temperatures to defeat barrier materials was described in **Chapter 32.** The process involves the molecular alteration or destruction of metals and plastics with an electric arc, torch, thermic lance, or chemicals. This particular technique has become popular because of the availability of equipment, low skill level, ease of opening, and absence of noise. The prime target is usually the lock for obvious reasons.

The first documented use of heat to alter metals probably involved a process of reverse hardening or annealing. This technique was developed to remove the temper from a metal in order to make it softer. As detailed in **Chapter 5**, the process required the temperature to be raised and then quickly lowered. Safe makers utilized metals that were more resistant to heat and incorporated layers of copper to act as a conduit for high temperatures. In fire safes, concrete is effective in the dissipation of heat. If the safe technician is utilizing high temperature penetration, care should be taken to insure that tear gas is not incorporated within the container and that the internal temperature does exceed 350^{o}.

35_4.2.6.1 Blowpipes

In the nineteenth century, criminals developed a device known as a blowpipe. It was used for concentrating a gas flame directed at the face of a safe or vault. The resulting high temperatures could be used to penetrate one-inch-thick steel plate by drawing the temper from the material. A bellows directed and propelled the flow of gas to create a large hole in the barrier.

35_4.2.6.2 Blowtorch

The commercial production and sale of oxygen in 1886 by Brinks Oxygen Company created a new and efficient means for penetrating safes: the **blowtorch.** The theory underlying this new technique was based upon the principle that iron and steel will burn in an atmosphere of pure oxygen.

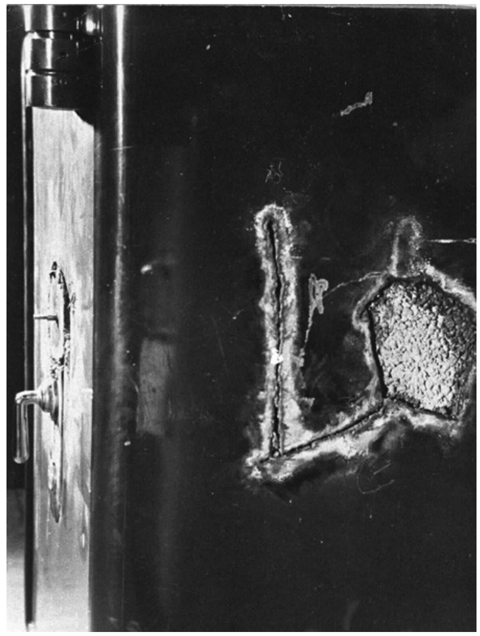

Figure LSS+3521 These photographs show attacks by torch. In the middle picture, an inept attempt to open the safe by cutting through the side. The burglar knew how to use a torch, but had no idea of where to cut. In the photograph (right), a torch attack on the lock box.

Figure LSS+3522. (Left), an attack using a torch where there was obviously no knowledge of where to cut. In the photo (right) the burglars burn and cut the bolt works. The parts are displayed.

RATNER
LONDON

Figure LSS+3523 Additional examples of the use of a torch. In the photographs, the lock box is burned out.

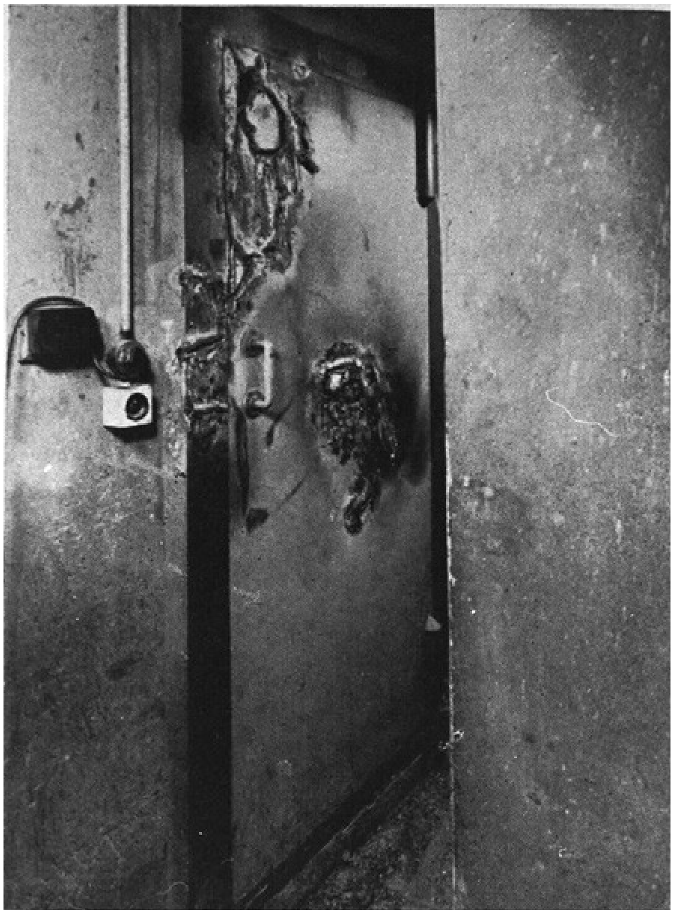

**Figure LSS+3524 (left) photograph showing lines scored by an oxyacetylene torch in
the outer shell of a Chubb safe. The burglars tried to cut the lock out of the middle
of the door. In the photograph (right), a close-up of an oxyacetylene attack of Chubb
safe which was not successful.**

In practice, the skin of the safe was preheated with a gas flame; a stream of oxygen was then forced through a steel tube or pipe onto the surface of the barrier material. The resulting combustion of the metal with oxygen would vaporize anything in its path. The use of oxygen to destroy the molecular structure of a metal would also form the basis for the development of the **thermic lance.**

By 1901, the **oxyacetylene torch** was available to cut metal and was being utilized for the penetration of vaults. It was employed in 1907 in Antwerp, during the burglary of a diamond merchant.

Figure LSS+3525, examples of torch attack. (left) incorrect tools were utilized on the side of the safe. This accomplished nothing. (right) a suspicious burn on the spindle, indicating perhaps an inside job.

CHUBB

Figure LSS+3526, attack by torch that did not result in an opening. Center photograph (ISP 59-3563) involved a torch attack where several million dollars of goods were stolen. A diagram of the theft is presented to show the detail that went into this crime (ISP 58-3563). In the right photograph (57) a typical oxyacetylene rig is shown.

Acetylene, however, was unstable under pressure. In order to make the gas safe to handle, it was dissolved in acetone and the mixture absorbed into kapok or charcoal within a pressurized cylinder.

Today, the oxyacetylene torch is relatively safe to use in the hands of a trained operator. The flame will burn at temperatures between 4,000° F and 5,000° F, and can be utilized to open most of the older safes.

**Figure LSS+3527, (left) a torch attack where burglars cut a portion from the door
for access, and (right) where part of the skin was removed to access the bolt mechanism.**

Photos 61-66 show that the burglars had a competent knowledge of their tools, but no knowledge as to what to do with them. In 67 and 68, the burglars did not understand how to use their tools and had no knowledge of the container that they were attacking. Courtesy of Illinois State Police, Bill Sherlock.

35_4.2.6.3 Thermite

Thermite is a solid fuel developed in Germany for use in welding. It is a mixture of aluminum and iron oxide, toluene, and sulfur, and is ignited from the high temperatures generated from a burning strip of magnesium. As thermite burns, it feeds itself by producing oxygen. This maintains a very high temperature flame that is capable of melting steel.

The chemical is highly desirable for safe and vault penetration because it is portable, burns rapidly, and is silent. Once a reaction begins, it cannot be stopped until all of the fuel is spent. Thermite has been utilized for covert operations where its special characteristics can be of value.

35_4.2.6.4 Thermic Lance

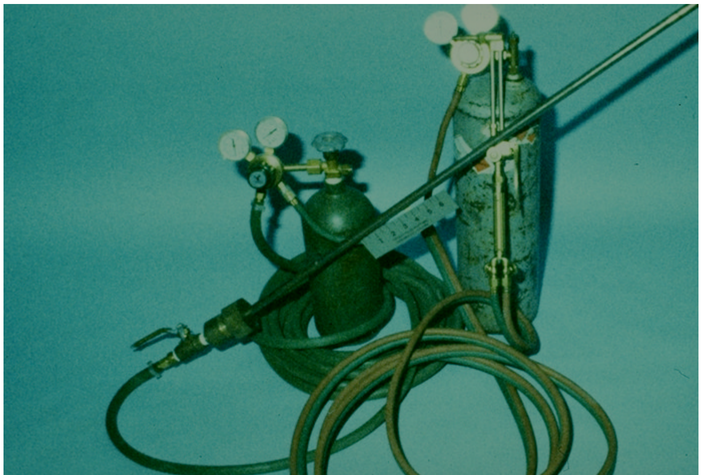

Figure LSS+3529. The thermic lance develops high temperature and can be utilized virtually anywhere. In the above photographs, the destructive power of this technology is shown. Photo ID: top left ISP 72-3563, right 73, bottom left 74, bottom right 75. In photograph 72, an older version of the lance is shown. Today, Broco produces this product in a small configuration that can be carried in a briefcase. Courtesy of Illinois State Police, Bill Sherlock.

The thermic lance or burning bar is discussed in detail in **Chapters 5** and **32.** Today, it does not have much application in safe work, although in difficult situations it can be invaluable and is often the only viable means for penetration. The use of the lance should be considered when it is not possible to drill through the top or sides of a high-security container, or there is not sufficient data available to formulate drill points.

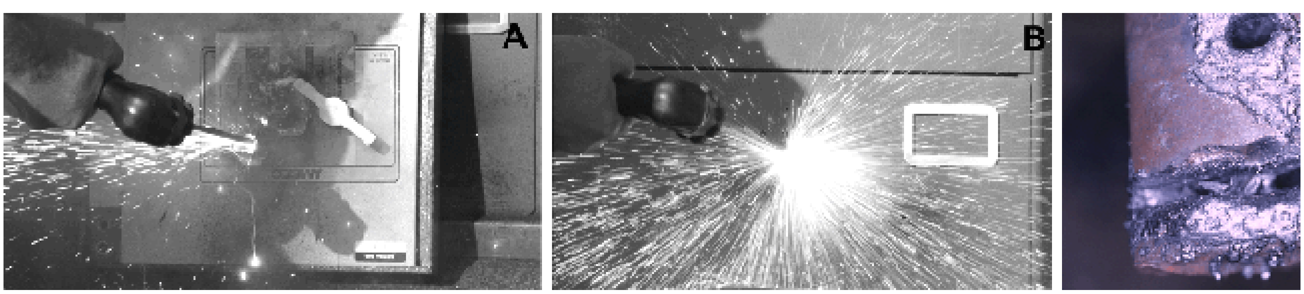

Figure LSS+3530 (ISP-76-3563) An example of a safe attacked with a thermic lance.

The cost of expensive drill bits must always be evaluated especially when doors are particularly thick. If time is a critical factor, these devices can expedite an opening.

The lance was developed in England around 1880, although it did not find widespread use by burglars until the next century. The original burning bar was a cumbersome device, measuring up to ten feet in length. It was awkward and dangerous to handle and required a fair amount of room in order to be manipulated. It would burn for a maximum of about six minutes. Today, the thermic lance can be carried in a briefcase, is relatively safe, and easy to use. The original devices consisted of long metal tubes filled with steel, aluminum, and magnesium wire. The modern version utilizes 18″ rods that are ¼″ in diameter.

The principal operating theory of the lance is the same as the blowpipe. The target metal is brought to its burning temperature in an atmosphere of pure oxygen, which is fed under pressure. As the metal melts, it will act as a flux to accelerate the burning process. The lance is effective with virtually any material including iron, steel, concrete, and granite.

The equipment to construct a lance is simple and consists of oxygen and tubing made of iron, mild steel, wrought iron, or plastic. The tube is filled with metal filings or a thin bundle of rods, having a hollow oxygen channel in the center. In operation, the working tip is heated, using a torch or spark to ignite the oxygen flow. The rod is then forced into the target material until penetration is completed.

The principal value of the thermic lance is its ability to penetrate thick barrier materials within seconds or hours, rather than days. It can be an extremely effective tool against a strong vault door, although a great deal of heat, smoke, and sparks are generated. The lance burns rapidly, requiring long fuel rods for lengthy burns. Generally, an 18" rod will provide a forty-five second burn, or enough to cut 1" of steel for each inch of rod. Temperatures as high as 10,000° F can be produced almost instantly, vaporizing any material. This means that a ¼" thick hard plate can be penetrated in less than five seconds; 3" cast manganese in forty-five seconds, and almost a foot of concrete in less than three minutes.

The lance has seen spectacular success in high-profile crimes, especially in the 1960s and 1970s. In 1965, there was a successful burglary in Knightsbridge, West London. After two minutes, almost two million dollars (one million pounds) was stolen from a safe in Lloyds bank. Then, in 1976, a bank safe-deposit vault was hit in Nice, France, after the burglars had tunneled for seven weeks. The holiday weekend burglary netted millions of dollars worth of valuables.

If a thermic lance is to be used, certain precautions and operating procedures must be observed. Thus:

- **Avoid excessive oxygen pressure that can cause blow-back of molten material, fire hazard, and injury;**
- **There should be no combustible materials in the area of use;**
- **Verify that the materials being consumed during**

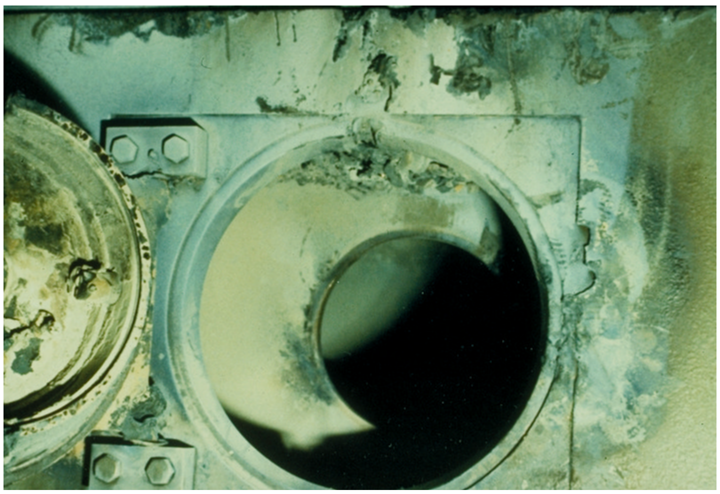
burning are not toxic;
- **Insure that there is adequate ventilation;**
- **Do not make more than a five-second burn, and inspect after every burn;**
- **Concentration of heat is intense and focused; thus, there is little danger to surrounding areas;**
- **Relockers will rarely be fired by the use of a lance;**
- **Conventional drilling should be accomplished to the hard plate prior to the use of the lance;**
- **Experience and practice are required for effective penetration;**
- **Protective clothing, gloves, face and eye covering is required;**
- **A gas mask should be utilized;**
- **Smoke detectors should be covered or disabled during use;**
- **Have a fire extinguisher available;**
- **Use a flame and heat-retardant drop cloth;**
- **Never use a lance in the presence of explosives;**
- **No spectators should be present;**
- **Know the contents of any container before penetrating it;**
- **Never penetrate the lock case with a lance.**

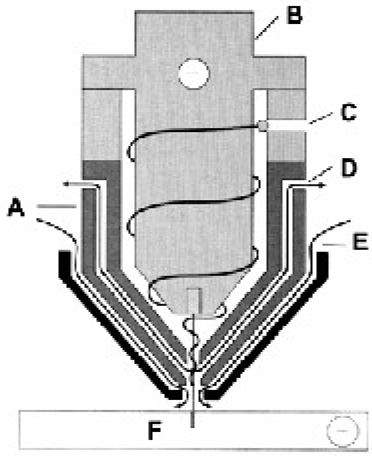
The Broco thermic lance that was developed by Brower has received several U.S. Patents (**4182947(401), 4069407(402)**). It is probably the best known in the industry. It is more thoroughly described in **Chapter 32.** The "**Prime Cut**" will cut virtually any material at twice the temperatures of oxyacetylene. Although the technique does not produce a fine cut, it can vaporize anything in its path.

The only required equipment is oxygen and a regulator, the torch valve and rod-holding device, power connector, and cutting rod. A 12-volt battery is used for ignition of the oxygen. A ¼" rod will require from 20-65 P.S.I. of gas, and a regulator with a 1200 CFH rating. An average small oxygen cylinder will hold 55 cubic feet. At 40 P.S.I., 4 Cubic feet is burned for each 18" rod. See the detailed instruction manual for the **Broco Prime Cut.**

35_4.2.6.5 Electrical Burning and Cutting

During the early twentieth century, burning techniques utilizing electric arcs became prevalent. Today, wire welders and cutters can penetrate virtually any material through the application of an arc created by a high electric potential. There are several different cutting technologies, including tungsten inert gas (TIG), magnesium inert gas (MIG), plasma arc, and oxygen plasma. Because of the precise cutting capabilities of plasma technology, it is described in detail here.





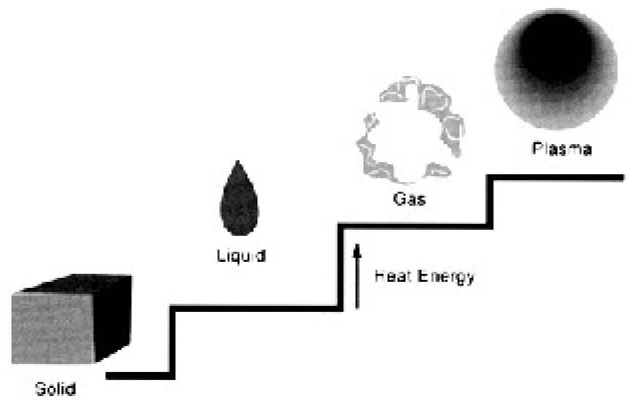


Figure LSS+3531 An example of arc welding with cutting rods. Photo ID: ISP 70-3563.

35_4.2.6.5.1 Plasma Torch

Plasma cutting utilizes high temperature ionized gas. It is created with an electric potential and is used for melting and cutting electrically conductive metals. A controlled nozzle opening is required to constrict and direct the flow of oxygen, nitrogen, or other gas. The device generally has an electrode of tungsten and uses an inert ionized gas such as argon to create plasma around the cutting tip. The torch can allow precision cutting but requires that the material be electrically grounded. Two leading companies that produce plasma torches are Hypertherm (Hanover, NH) and Thermal Dynamics (W. Lebanon, NH).

Exploded view 1, 2.

35_4.2.6.5.1.1 A History of Plasma Cutting

In 1941, World War II created a requirement for a process to bond light metals for the production of airplanes; electric arc welding was thus developed. The new process relied upon an electric arc to melt metals, an inert gas to form a shield around the arc, and the pool of molten metal to displace air. This was known as TIG, argonarc, or heliarc, because argon or helium was employed as the inert gas. At the time, the process was a perfect solution for precision welding and is today referred to as **GTAW**, or gas tungsten arc welding.

Plasma cutting technology began to mature about 1950 with the introduction of TIG welding. Shortly thereafter, scientists at Union Carbide made a significant discovery. They realized that if they reduced the nozzle opening that formed part of the TIG electrode (cathode) for the inert gas and it was electrically active with the work surface (anode), then the properties of the arc could be altered. In essence, the gas flow and arc were constricted. This increased its speed and heat dramatically. Rather than bonding, the plasma jet was now cutting the material.

Then, in 1957, conventional plasma arc cutting using “dry” arc constriction techniques was developed. This allowed the rapid cutting of virtually any metal. In 1965, water was substituted as the shield gas, and three years later water was used to increase arc constriction. Subsequently, advancements allowed underwater cutting as well as oxygen plasma cutting. In 1985, oxygen-injected cutting, using nitrogen as the plasma gas was introduced. Then, deep-water cutting and high-density cutting

that rivaled laser cuts became available.

35_4.2.6.5.1.2 The Physics and Chemistry of Plasma Cutting

There are three traditional states of matter: **solid**, **liquid**, and **gas**; **plasma** is described as the fourth state. Water, for example, is ice, liquid, or steam. The differences in states relate to energy level. The addition of energy as heat will cause a change in state. Thus, ice becomes water that changes to steam, which is actually hydrogen and oxygen gas. If additional energy is added to a gas, then its electrical and temperature characteristics are altered through **ionization**. This is actually the product of free electrons and ions within the gas atoms. The gas, now in the form of plasma, can conduct electrons or electricity.

Plasma and metals share certain common transmission characteristics based upon Ohm's law, and the relationship between voltage (E), current (I), and resistance (R) (I=E/R). Thus, if the conduction area of a metal is reduced, the resistance increases. When this occurs, a higher voltage (EMF) is required to force the same number of electrons across the transmission path. This will create heat through resistance.

Plasma gas follows the same laws. For example, if the plasma is moderately constricted by the nozzle being reduced in diameter, it can operate at twice the voltage. This will produce a much hotter plasma arc than in the equivalent TIG arc. The energy density that a plasma torch produces can be calculated in amps per square inch. This formula is based upon the ratio of current flowing through the nozzle, to the effective area of the orifice through which it passes. Conventional systems that utilize nitrogen, for example, have an energy range of 12,000 - 20,000 amps per square inch.

35_4.2.6.5.1.2.1 Flow of Electrons and Jet Characteristics

Plasma operates in both **transferred** and **non-transferred** modes. In the transferred mode, current flows between the torch electrode (cathode) and workpiece (anode). In the non-transferred mode, the current flows between the electrode and torch nozzle. Transferred mode is generally used in cutting because the heat transfer to the workpiece is greater. The gas type affects the plasma jet, flow rate, arc current, voltage, and nozzle size. These characteristics will determine whether the gas is used for

welding or cutting.

35_4.2.6.5.1.3 High-Density Plasma Cutting

This technology was developed in 1990 to compete with laser devices. The systems have the capability to produce cuts of high quality and accuracy, rivaling that of the laser but at a much lower price. Oxygen and nitrogen systems can cut carbon steels, aluminum, and stainless steels from 3/8" to 1 1/4", with high precision and a cut edge angle of 1-4° off square. For additional information, see **hypertherm.com**.

35_4.2.6.5.2 Laser Cutting

Commercial laser devices are now available that offer precision cutting and penetration to .005". These instruments, however, are not yet suitable for safe and vault work because of lack of portability. They are primarily designed for a factory environment where there exists sufficient operating space, control facilities, and power. Lasers are being utilized by a number of high-security safe manufacturers to produce extremely close tolerance joints between doors and safe bodies.

35_4.2.6.6 Temperature Extremes

The application of extremes in temperature has been effectively employed for opening certain types of containers. The prime example was the cannonball, which had particular appeal for burglars wishing to bypass these extremely secure safes. In this case, the procedure required that the circumference of the door be superheated. Cold water was poured on the metal, which would cause it to harden. Then, a hatchet was driven into the groove that existed around the door. When struck with a heavy hammer, the door would break open.

35_4.2.7 Using Explosives to Open Safes

LSS202: Steve Mattoon on the use of explosives to gain entry.

The application of explosives by criminals to open safes and vaults was natural and obvious and occurred fairly soon after their introduction and availability. Explosives can exist in many forms; they are based upon simple to complex chemistry. These special chemicals would be employed to penetrate locks and the security containers to which they were affixed. Their use can be

particularly attractive, because they can provide the capability to penetrate barrier materials that are 4” thick.

During the nineteenth century, many techniques were developed to open safes. As expected, explosives would become the preferred method of the safecracker, especially in England and somewhat later in America. The primary explosives were gunpowder, dynamite, nitro, and gelignite. Today, although nitroglycerine is still used, C4 plastic is preferred.

There was a constant and furious technological battle between the safe manufacturers and safecrackers, from which design innovations and improvements occurred. The use of explosives by burglars led to implementation of the following features:

- **Development, refinement, and implementation of the chemistry and metallurgy of hardened steel and special barrier materials;**
- **Changes in bolt and lock design;**
- **Introduction of time locks and combination locks;**
- **Design of secure joints;**
- **Welding and banding techniques;**
- **Use of laminates;**
- **Stronger boxes which could withstand explosive forces.**

Manufacturers soon realized that safes made of steel less than ¼” thick were ineffective against explosives; they could not resist the pressures and ripping forces created in a blast. Early safe attacks utilizing gunpowder were crude. They generally involved placing bags of the material next to the doors to cause sufficient distortion upon detonation to allow opening by a long lever. When Nobel made dynamite safe to handle through the addition of nitroglycerine, safe burglars shortly thereafter discovered how to extract that same chemical from dynamite.

Nitro was very useful to safecrackers, because its explosive force was concentrated in a very small quantity of chemical. They also learned how to create their own mixtures with nitric and sulfuric acid and glycerine. Preferred over nitro, dynamite became a favorite and powerful tool of the safecracker. This was because dynamite was solid, fairly stable, and safe to handle.

Figure LSS+3532, a free-standing Chubb safe was attacked with explosives. The violence of the blast blew the mounting plate away from the lock.

Explosives are not as popular today among the modern safecracker as in times past. This is in part because of the noise created, time involved, potential danger inherent in their use, as well as increased criminal penalties. Notwithstanding their limited acceptance, many safes are opened in this fashion. Interestingly, a recent series of safe burglaries in the United States involved a technique developed over a century ago. Holes were first drilled in the top of the safe and then the container is filled completely with water. Blasting caps were dropped through the holes. When the explosive is detonated, the safe will be opened without damage to the contents, because the water has no place to go.

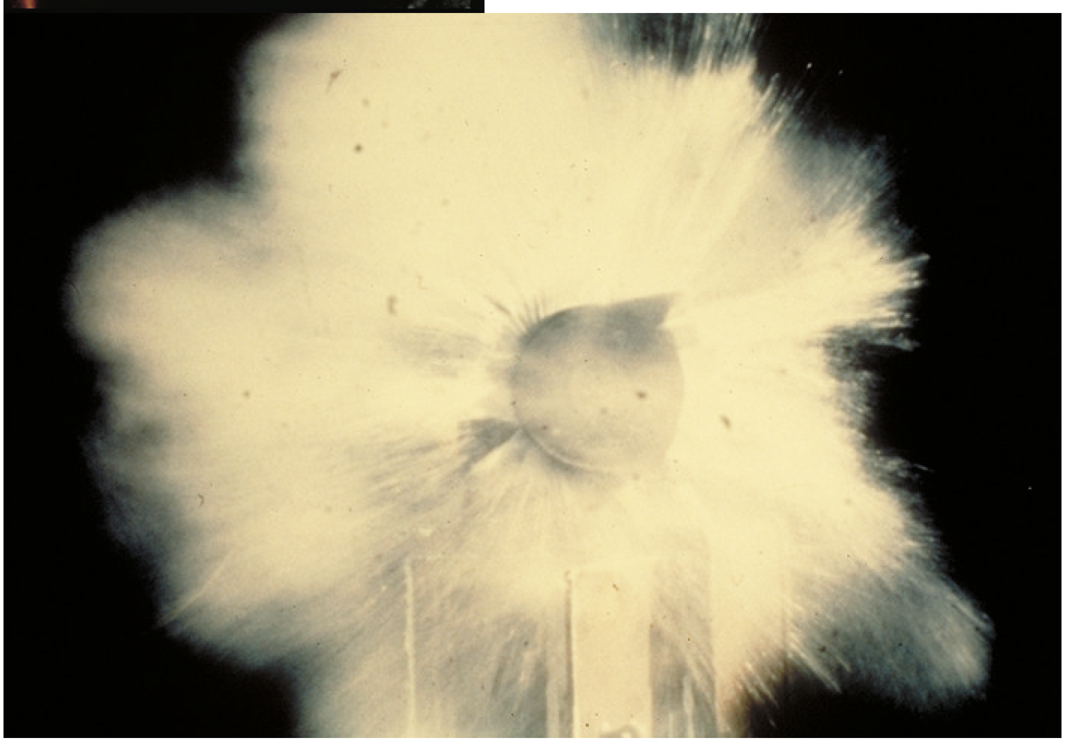

Figure LSS+3533 (Top left, ISP 29-2963, right 28-2963; bottom 26-2963). A safe was open with explosives, after being filled with water.

Many different kinds of explosives are available today, identified by their ability to create pressures and expansion of gasses. These are summarized below. Gunpowder, guncotton, nitroglycerine, gelignite, and the modern, sophisticated castable high- explosive materials, such as C4 putty, Flexible intershape, PETN, RDX, QUADREX, TRIEX, Detasheet (by Dupont, a flexible explosive) and TNT, have different potential for causing destruction. These materials will easily blast through 3/4" or thicker steel plate when properly applied.

Explosives are rated in terms of their measure of violence,

computed by the volume and speed of gas produced and displaced by a specific quantity of material. A high explosive will produce gas more quickly than a low explosive.

NAME	ALTERNATE NAME	COLOR	MAJOR USES	REMARKS
LOW EXPLOSIVES				
Black Powder	Schwarzpulver	gray to black; cocoa brown to black	safety (time) fuse; reloading (time) fuse	Very sensitive to friction, heat, a
Smokeless Powder	nitrocellulose	light brown to black	small arms, mortars, rockets, reloading of small arms	Very sensitive to friction, head, a shock. Normally deflagrates and a low explosive; wh initiated by a bl cap, may detonate as a high explosi
PRIMARY EXPLOSIVES				
DDNP	di-azodinitrophenol; dinol; diazol	greenish yellow to brown	detonators, priming compositions	Very sensitive to friction, heat, a shock. Has largel replaced mercury fulminate in blas caps
lead azide	lead hydronitride	white to buff to gray	detonators, priming compositions	Very sensitive to shock, and fricti
lead styphnate	lead tri-nitroresorcinate; trizinate	light orange to reddish brown	priming compositions	Very sensitive to shock, and fricti Relatively poor i in comparison wit primary explosive
mercury fulminate	fulminate of mercury; mercuric fulminate	white to gray or light brown	detonators, priming compositions	Very sensitive to shock, and fricti Largely replaced azide. Should be moist until used.
tetracene	-	pale yellow	detonators, priming compositions	Sensitive to shoc heat. Not efficie initiating high explosives; used sensitizer with c high explosives. used alone.

SECONDARY EXPLOSIVES				
amatol	-	buff to yellow to dark brown	main charge for bombs, projectiles	Developed during to conserve limi supplies of TNT.
ammonal	-	gray	projectile filler	Similar in compos Minol.
ammonium nitrate	-	white; my be dyed other colors	ingredient of explosive mixtures, dynamites; also used in fertilizer	Very insensitive shock. Must be ke Must not be worke tools of brass o
ammonium picrate	ammonium trinitrophenolat e, dunnite, Explosive D	yellow to orange to red	armor piercing projectiles and bombs; organic fule in composite propellants	Relatively insens shock and frictic Moisture reduces sensitivity to initiation.
Astrolite	(a) Astro-Pak (b) Saf-T-Pak	-	demolition	Two components a until mixed. Do r with tetryl boost to possibility o spontaneous igni
Composition A-3	-	white to buff	projectile and shaped charge filler	-
Composition B	see cyclotol	-	-	-
Composition C-3	plasitite	yellow to brown	plastic demolition explosive	Putty-like materi stains the hands used underwater. explode if burned large quantities
Composition C-4	Harrisite	white to light brown	plastic demolition explosive	Putty-like materi sensitive to impa slightly more bri than Composition be used underwate
cyclotol	tritolite, Composition B	buff to yellow to brown	fragmentation bombs; projectiles; grenades; bursting charges	Excellent for bla effects.
Explosive D	see ammonium picrate	-	see ammonium picrate	-

Flex-X	Detasheet, sheet explosive	olive-drab ; red, may be dyed any color commercial ly	cutting charges for irregular or curved surfaces	Flexible, easily very insensitive shock.
Go-4	-	tan	fracturing oil and gas well formations	-
HBX-1, HBX-2, HBX-3	HBX (= high blast explosive); Torpex-3	gray	main charge filler for underwater bombs and torpedos	Excellent for bla effects. When desensitizer is a Torpex, the U.S. the product HBX, British retain th Torpex.
HMX	cyclotetra- methylene- tetranitramine, homocyclonite	white	(a) used alone or (b) mixed with TNT or octol to form explosive filler for high blast warheads	By-product of RDX manufacture.
Kinepak	-	powder is white, liquid is pink	demolition	Two components ar until mixed.
Minol-1, Minol-2, Minol-3	-	gray	filler for bombs and depth charges	An ammonal contai less TNT and more ammonium nitrate aluminum; compara TNT in sensitivit initiation.
nitrocellulos e	cellulose nitrate, NC, guncontton, nitrocotton	white	blasting explosives, smokeless powder, propellants	Mixed with nitrog to form flashless
nitroglycerin e	glyceryl trinitrate, NG, blasting oil	thick pale yellow liquid	propellant ingredient, demolition ingredient, dynamite ingredient	Patente by A. Nob 1864. Liquid is r absorbed through inhaled vapors ca severe headache.

nitroguanidine	picrite	white to yellow	propellant composition ingredient, bursting charge ingredient	One of the least sensitive militai explosives.
nitrostarch	starch nitrate, grenite	white	bursting explosive, mortar shells, grenades	Another form of nitrocellulose.
octol	-	buff	projectile and bomb filler	Excellent for bla effects.
pentolite	pentritol (when 8 percent wax is added)	white to yellow to gray	shaped charges, demolition blocks, boosters	Presence of rust increases impact sensitivity.
PETN	pentaerythritol tetranitrate, penta, pentrit	white, sometimes dyed green	detonating cord, blasting caps, priming compositions, boosters	Presence of rust increases impact sensitivity.
picratol	-	yellow to brownish yellow	armor piercing projectiles and bombs	As insensitive to initiation as Exp D.
picric acid	melinite, lyddite, pertite	light yellow to lemon yellow, yellow red	used in manufacture of Explosive D	Stains skin.
RDX	cyclotromethylene trinitramine, cyclonite	white, may be died pink	detonating cord, blasting cap base charge, projectile and bomb filler ingredient, ingredient in Composition A and Composition B	Used on large sca explosive ammunit WWII.
tetryl	tetralite, pyronite, CE	yellow	boosters, blasting caps, ingredient of explosive mixtures	Causes dermatitis skin reddish brow Colorless when fr prepared and pure acquires to yello when exposed to l Addition of graph during loading ca to turn gray.

tetryl	tetratol	buff to light yellow	bursters, demolition blocks	Ranks between tet TNT in sensitivit heat and initiati
TNT	trinitrotoluene, trotyl, tolite, triol, triton, trilite	light yellow to brown or light gray	bombs, projectiles, demolition charges, grenades, propellant composition	Standard military explosive against others are measu
Torpex	TPX	gray	depth charges bombs, warheads, mines	Excellent for bla effect.
Tritonal	-	silver gray	bombs	More powerful anc sensitive to shoc TNT.

Figure LSS+3503 Table of explosives

35_4.2.7.1 Gunpowder

Gunpowder was a mixture of charcoal, saltpeter, and sulfur, and was developed around the thirteenth century by the Chinese. It would remain the primary propellant and explosive for the next six hundred years. It appears that it was first used for the penetration of containers in the seventeenth century in Hungary.

The early use of gunpowder was crude and imprecise. Bellman (users of explosives), boxmen, or petermen (safecrackers) developed a popular method of attack that involved **blowing powder** into the keyhole of the lock so that drilling would not be required. English safe makers combated this procedure by covering the cavity created by the keyhole with wood. Later, the use of the keyless combination lock frustrated this method of attack.

Another technique was known as the "puff and rod." It required drilling into the casing of the cast iron or mild steel box, then applying a bellows to blow a charge of gunpowder into the safe. The introduction of hardened steel ended this practice.

35_4.2.7.2 Guncotton

This substance was very popular for blowing safes. It was a combination of nitric acid, sulfuric acid, and glycerine impregnated into cotton cloth. A German chemist named Schonbein

invented the mixture when he spilled nitric and sulfuric acid in his kitchen. After using a cotton apron as a mop to clean up the chemicals, he set the wet cloth on the stove to dry. It blew up! As early as 1846, guncotton was used in simple blasting.

35_4.2.7.3 Nitroglycerine

In 1846, Sobrero, an Italian, created liquid glyceryl trinitrate. This mixture, known as **nitro**, was the first high explosive. **Grease** (as it was called) could be produced by placing dynamite in a sack and compressing it, so that an oily yellow liquid would ooze through the fabric. It was used by safecrackers in a concentrated form to blow safes.

Nitroglycerine was a versatile tool of penetration and provided many options for forced-entry of safes and vaults. For example, it could be used to blow a lock (known as **gunshot** or **spindle shot**) by dripping the substance into the lock after the dial had been removed and the safe was laid on its back. A similar technique (the **rag shot**) required that a small hole be bored directly above the dial. A rag was saturated with nitro, pushed into the hole, and sealed with laundry soap.

The material could also be contained within moldable material such as fels naphtha and fashioned like a funnel. This particular substance is very malleable, yet it will not permit the nitro to leak through it. A soap cup dam would be located on the center of the door after the safe had been placed on its back. Known as the "**space shot**," this technique would "dish the door," or cause a deformation of the barrier metal. Finally, the chemical could be seeped into the crack around the edge of the door (**jamb shot**). If done correctly, this would cause the door to blow open, still remaining on its hinges.

35_4.2.7.4 Dynamite

In 1867, Nobel turned nitro into dynamite. **Guhr** dynamite was a mixture of nitro and kieselguhr (diatomaceous earth) that was produced as a solid. It was completely safe to handle. Dependable control of the explosive reaction was achieved when Nobel utilized gunpowder and mercury fulminate to apply a shock rather than a flame to the charge. Because of the work of the Nobel family, dynamite would be the primary explosive until the middle of the twentieth century. Ironically, explosives directly or indirectly killed two of the Nobel family members.

35_4.2.7.5 Gelignite

This material was developed at the end of the nineteenth century and would be popular for about thirty years. It was a mixture of guncotton and nitro, and formed a blasting gelatin resembling Jell-O. Gelignite could be configured in putty-like blocks, cut into pieces, and formed in any required shape. The chemical was stable and powerful.

This material was popular for use in blowing locks and bolt works. When gelignite was utilized, it would be forced into the lock and held in place by plasticine, soap, or modeling clay. It could also be contained in a balloon or condom. The detonator was placed around the substance.

In some cases, two holes were drilled next to the locking bars. A balloon filled with gelignite would be inserted into the body of the safe so that it would hang over the boltwork. Opening then became a simple task.

35_4.2.7.6 Castable High Explosives

Today, sophisticated explosives are available that can be shaped and precisely controlled with respect to the energy they produce. These are known as **castable** high explosives, as noted in **4.2.7** above. They are mainly used for emergency entry operations rather than safe and vault penetration. Resources for explosives include Explosive Technology (Fairfield, California), Jet Research (Arlington, Texas), and Dupont. Barret (Australia) makes a bomb bag to contain explosives that are found at a crime scene, for detonation.

35_4.2.7.7 Definition of Conventional Explosives

The following definitions apply to conventional explosives, and were obtained from the United States Defense Threat Reduction Agency. They were cited in the ***Weapons of Mass Destruction Terms Handbook.*** *There are several federal statutes dealing with explosives:* ***18 USC 2332a Weapons of mas destruction; 18 USC 921 Destructive Devices;(403) 18 USC 831 Explosives and Other Dangerous Articles.(404)***

Ammonia Dynamite

A portion of the nitroglycerine content is replaced by ammonium nitrate in ammonia dynamite. It is lower in cost and less sensitive to shock and friction than straight dynamite. It is probably the most widely used explosive of the dynamite family.

Ammonia-gelatin dynamite

This dynamite retains most of the characteristics and qualities of gelatin dynamite, but derive a portion of their strength from the use of less costly ammonium nitrate.

Ammonium nitrate

Ammonium nitrate is one of the least sensitive and most readily available main charge high explosives. It is usually found in the form of small compressed pellets called prills. It is used extensively as a blasting agent, by the military as a cratering charge, an ingredient in certain dynamites, and widely employed as a fertilizer. Its use as a commercial fertilizer makes ammonium nitrate readily accessible to anyone.

ANFO

While the grade of ammonium nitrate used as fertilizer is naturally inferior as an explosive charge, it can be sensitized by the addition of fuel oil. This mixture is referred to as "prills and oil" or ANFO, and its use is fairly widespread because of its low cost. Car or truck bombs using ANFO are large in size and lethal to structures at a considerable distance.

Black Powder

The typical composition of black powder is saltpeter (potassium nitrate) or sodium nitrate 75 parts by weight; sulfur 10 parts by weight; and charcoal, 15 parts by weight. The form may range from a very fine powder to granules over ½ inch in diameter. The burning speed of black powder is controlled by the size of the granulation. Large grains of powder burn more slowly than fine grains.

Blast effects

When a high explosive detonates, the solid or liquid explosive material is converted into mostly gaseous product. These extremely hot gases expand immediately and compress the air

around the charge to form a blast wave. The strength of the shock at a given distance from the explosion is a function of the type explosive, the weight of explosive, and the distance from the point of detonation.

Blasting agents

A blasting agent is an insensitive chemical composition or mixture, consisting largely of ammonium nitrate, which will detonate when initiated by high explosive primers or boosters. Since they contain no nitroglycerine, blasting agents are relatively insensitive to shock, friction, and impact and are, therefore safer to handle and transport.

Blasting cap

A device used to initiate an explosive train. Commonly referred to as detonators, they contain primary explosives. May be either electrically or nonelectrically fired. Blasting caps are extremely sensitive and will explode unless handled carefully.

Blasting cap crimpers

Used to squeeze the shell of non-electric blasting caps around safety fuse or detonating cord to prevent separation.

Blasting machines

A device designed to deliver electric current directly into an explosive firing circuit. There are two types available: condenser discharge (DC) and generator. booster High-explosive boosters, also called Primer explosives, or simply primers, are explosives that provide the detonation link in the explosive train between the very sensitive primary explosives (blasting caps) an the comparatively insensitive main charge high explosives. It amplifies the detonation wave of the primary explosive.

Booster

High-explosive boosters, also called primer explosives, or simply primers, are explosives that provide the detonation link in the explosive train between the very sensitive primary explosives (blasting caps) and the comparatively insensitive main charge high explosives. It amplifies the detonation wave of the primary explosive.

Chemical bombs

Devices in which a chemical reaction takes place within a confined space, such as a bottle, the pressure is greatly increased. When the maximum pressure per square inch (p.s.i.) is exceeded, the container ruptures with enough force to shatter glass, destroy mailboxes, and split metal cans. The dangers come from fragmentation and burns to skin from the chemicals. The following are the most common types of chemical reaction bombs.

a. Acid Bomb. Common ingredients are hydrochloric acid and aluminum foil that chemically reacts to give off heat (exothermic), ultimately producing hydrogen gas and sufficient pressure to burst the container. Commercial sources for hydrochloric acid are toilet bowl cleaners (Sno Bowl or "The Works") and Etchant Solution (a commercially available solution for etching).

b. Caustic Bomb. Alkali based devices mixed with water and aluminum foil. The most common ingredient is sodium hydroxide (lye), a corrosive in both liquid and solid forms that can immediately cause serious burns to skin on contact. Commercial sources of sodium hydroxide are Drano toilet bowl cleaner and Red Devil Lye.

c. Dry Ice Bomb. When dry ice evaporates, carbon dioxide gas is released. It usually takes 30 to 45 minutes for enough pressure to build to rupture the container depending on the size. When detonation occurs before all the dry ice has evaporated, the remaining dry ice becomes fragments that can cause frost-bite when contacting skin tissue. It is inexpensive and easy to make powerful device.

Cluster bombs (CB)

The United States and Israel used U.S.-built cluster bombs in both Vietnam and Middle East respectively to suppress air defenses and destroy large-area targets. Since the 1960s, the U.S. has developed a wide variety of cluster bomb systems and warheads. To increase the rocket's accuracy when lofted or released from long range, the weapon can be fitted with a laser guidance seeker and a proximity fuse to initiate the release of the bomblets when the weapon nears the target. The U.S. Air Force has developed a series of laser-guided cluster bomb weapons. In addition to instantaneous-destruct antipersonnel or anti-armor

warheads, the cluster bomb's dispenser can release time-delay bomblets or special mines that can destroy trucks, armor, or personnel over a period of hours. The munitions dispenser can be fitted with either a laser guidance kit or television guidance seeker and fins for accurate long-range attacks.

Composition B

Designation for explosive material, also known as Hexolite or Hexotol, composed of a 60:40 mixture of RDX and TNT.

Composition C

Original British designation for plastic explosive; standardized by the U.S. with designations C-2, C-3, and C-4.

Deflagration

Rapid and powerful self-sustained burning of a propellant or explosive less than the speed of sound.

Det cord

Short for for detonating cord.

Detonating cord

A round, flexible cord generally containing a center core of an explosive such as RDX or PETN that is protected by a sheath of various textiles, waterproofing materials in the same manner as blasting caps. , or plastics. Detonating cord is used to detonate charges of high explosive in the same manner as blasting caps.

Detonation

A reaction within a solid or liquid explosive that uses the fuel and oxidizer in the compound to propagate a constant velocity reaction through the explosive charge, converting most of the explosive compound to hot gases.

Detonator

Sometimes used interchangeably with blasting cap. Fuze detonators or blasting caps, containing a primary explosive, are used to detonate main charges or secondary explosives in an explosive train. A detonator may be initiated either electrically or

nonelectrically. Another type of detonator is the exploding (or electronic) bridge wire.

Dynamite

Most commercial dynamites are made of liquid nitroglycerine, oxidizers, and binder material. All dynamites may be detonated using either electric or nonelectric blasting caps or detonating cord widely used for blasting operations throughout the world and frequently used by criminal . It is most bombers ammonia-gelatin dynamites. Also see straight, ammonia, gelatin and ammonia-gelatin dynamites.

Electric match

See squib.

Electroexplosive Device (EED)

An electrically initiated explosive device. It is susceptible to initiation from electromagnetic radiation.

EOD

See explosive ordnance disposal.

Explosion

A detonation resulting from a sudden release of energy. Explosives can be classified into three categories:

a. A mechanical explosion is illustrated by the failure of steam boiler or pressure cooker. As heat is applied to the water inside the pressure vessel, steam is generated and confined. If the container is not equipped with some type of safety valve, the mounting pressure will eventually reach a point at which it overcomes the structural or material resistance of the container, and an explosion will occur.

b. A chemical explosion is characterized by the rapid conversion of a solid or liquid explosive compound into hot gaseous compound having a much greater volume than the substances from which it is generated. The entire conversion process takes only a fraction of a second produces extremely high temperatures (several thousand degrees), and is accompanied by a shock wave and loud noise.

c. Nuclear explosion

Exploding (or electronic) bridge wire (EBW)

A detonator that contains no explosives. EBWs function by the rapid discharge of a high amperage charge causing the bridge wire to explode initiating the explosive train. EBWs are very safe to handle because they contain no explosives.

Explosive ordnance

All munitions containing explosives, nuclear fission, or fusion materials and biological and chemical agents. This ordnance includes bombs and warheads, guided and ballistic missiles; artillery, mortar rocket, and small arms ammunition. Also, ordnance includes all mines, torpedoes, and depth charges; pyrotechnics; clusters and dispensers; cartridges and propellant actuated devices; electroexplosive devices; clandestine and improvised explosive devices; and all similar or related items or components explosive in nature.

Explosive ordnance disposal (EOD)

The activity of neutralizing the hazards associated with ordnance and improvised explosive devices that present a threat to operations, installations, personnel, or material. EOD is carried by the U.S. military or other special units or personnel specially trained and equipped.

Explosive ordnance disposal procedures

Those particular courses or modes of action for access to, recovery, rendering safe, and final disposal of explosive ordnance or any hazardous material associated with explosive ordnance disposal:

a. Access Procedures. Those actions to locate exactly and to gain access to unexploded ordnance.

b. Recovery Procedures. Those actions to recover unexploded ordnance.

c. Render Safe Procedures. The portion of the explosive ordnance disposal procedures involving the application of special explosive ordnance disposal methods and tools to provide the interruption of functions or separation of essential components

of unexploded ordnance to prevent function as designed.

d. Final Disposal Procedures. The final disposal of explosive ordnance by explosive ord-nance disposal personnel, which may include demolition or burning in place, removal to a disposal area, or other appropriate means.

Explosive ordnance disposal unit

Military EOD personnel with special training and equipment who render explosive ordnance (such as bombs, mines, projectiles, and booby traps) safe, make intelligence reports on such ordnance, and supervise the safe removal thereof. EOD assistance outside DoD installations are normally the responsibility of civil authorities.

Explosive ordnance reconnaissance

Reconnaissance involving the investigation, detection, location, marking, initial identification, and reporting of suspected unexploded ordnance, by explosive ordnance reconnaissance agents, to determine further action.

Explosive train

A series of explosives arranged to produce a specific outcome, usually the most effective detonation or explosion of a particular explosive. For example, a three-stage explosive train consists of a detonator, booster and main charge.

Firing device

A device that causes the initiation of explosive charges either directly, or through its effect on a blasting cap, electric squib, or detonating cord. It may be electrical, mechanical, or electromechanical.

Flash bulbs

Although not explosive by nature, carefully prepared flash bulbs or light bulbs can be used as initiation devices when placed in contact with explosive materials that are sensitive to heat and flame. They can be initiated electrically to provide the necessary heat required to ignite black powder, smokeless powder, and other heat-sensitive explosive or incendiary mixtures.

F.P.S.

Short form for feet per second.

Fragmentation effects

If an explosive charge has a case, both fragmentation and blast effects will occur. Fragmentation can be the most destructive characteristic of a bomb. The concentrated power of a fragment can force penetration deeply into a target, tearing and shredding as it goes.

Fuel air explosives (FAE)

Fuel air explosives, a recent concept, dispense a cloud of fuel to form an explosive vapor. When the vapor density is distributed over the target area, time delay detonators are fired, creating a highly destructive shock wave. Fuel air explosives are three to five times more destructive than a similar weight of TNT. Late in the Vietnam War, the U.S. Navy and the Marine Corps employed CBU-55B fuel air explosive weapons in Vietnam for preparing helicopter landing zones and clearing mines.

Fuse

A continuous train of combustible substances enclosed in a standardized core for setting off explosives.

Fuse igniters

Used to apply sparks or flame to manufactured or improvised safety fuse.

Fuze

(Not be be confused with "fuse") A mechanical, electrical, or electro-mechanical device used to function an explosive device such as a bomb or projectile. In demolition work, a firing device may be termed a fuze.

Fuze train

One or more devices used to detonate the main charge. It consists of all parts of the explosive train up to but not including the main charge, plus any activating element such as a switch, timer, sensor, device etc. to initiate the explosive train.

Galvanometers

An electrical assembly for testing the electrical continuity of a firing circuit.

Gelatin dynamite

Gelatin dynamite contains a base of water resistant "gel" made by dissolving or colloiding nitrocotton with nitroglycerine. The gel varies from a thick viscous liquid to a tough rubbery substance. It is used extensively for blasting very hard tough rock or ore.

High explosive (HE)

An energetic material that detonates (instead of deflagrating or burning); the rate of advance of the reaction zone into the unreacted material exceeds the velocity of sound in the unreacted material.

HMX

Designation for a byproduct of RDX production, homocyclonite. This powerful high explosive is also known as octogen.

IED

Acronym for improvised explosive device See below.

IHE

Acronym for insensitive high explosive. See below.

Improvised explosive device (IED)

Any device that is fabricated in an improvised manner, incorporating explosives or destructive, lethal, noxious, pyrotechnic, or incendiary chemicals, designed to destroy, disfigure, distract, or harass.

Incendiary effect

The incendiary effect is usually seen as the bright flash or fireball at the instant of detonation. In general, a low explosive will produce a longer thermal effect than will a high explosive. High explosives produce much higher temperatures.

Insensitive high explosive (IHE) - Link to video

A high explosive that is specifically formulated to be less sensitive to shock and other stimuli that might be encountered in an accident; usually based on the compound TATB (triaminotrinitrobenzene); insensitive high explosives have lower energy densities than conventional high explosives, and thus more material is required to produce the same explosive energy.

Low explosive

Classification of explosives that deflagrate rather than detonate. Primarily used as propellants, low explosives may be initiated by a simple flame or acid/flame reaction, and do not require the shock of a blasting cap. Common examples include black powder and smokeless powder.

Match heads

A main charge consisting of ordinary match heads confined inside a steel pipe will produce an effective explosion. Bombs filled with match heads are extremely sensitive to heat, shock, and friction and should always be handled with care.

Misfire

The failure of a charge to explode in response to a proper initiation attempt. When the charge fires at some time later than intended, it may be referred to as a "hang fire."

Main charge

The ultimate object of detonation in an explosive train. Also referred to as bursting explosives, includes explosives such as Explosive D, amatol, TNT, tetryl, pentolite, picratol, tritonal, RDX compositions, Torpex, HBX, etc., (see table 4-3).

m/s

Short form for meters per second.

Nitroglycerine

The main explosive component of straight dynamite and is found in less concentrations in a number of other explosives. It is an

oily liquid about 1.6 times heavier than water and that will not mix with water. It may very in color from clear (pure) to amber (impure). In a pure state, it is very sensitive to heat, shock, and friction. Sensitivity is increased markedly by the application of heat.

PETN

Short form for pentaerythritol tetra-nitrate, a major component in U.S. C-4 plastic explosives.

Pipe bomb

A fragmentation device. Sections of pipe or pipe nipples are filled with explosive, or propellant (gun powder) and closed with end caps through which a fuze has been introduced. When the filler is ignited, the resultant explosion causes the pipe to fail and form fragments.

Plastic explosive

Plastic explosives are known by different names, including "plastique," "plastex," "plastico," and "composition." Plastic explosives consist of an explosive material, such as RDX or PETN (see table 4-3 for physical characteristics and uses), and a plasticizer component. The explosives are well suited to military applications as they are insensitive to rifle bullet impact and can be molded by hand for various applications. The are sensitive to initiation by a blasting cap and have great brisance, or shattering power. This is the explosive of choice for various international terrorist groups. Small quantities may be optimally placed to do maximum damage.

Percussion primer (impact)

Uses the shock of a firing pin or striker impacting to initiate the explosives contained in the primer.

Potassium/sodium chlorate

Potassium chlorate or sodium chlorate and sugar mixtures are widely used as incendiary and explosive materials. Though essentially incendiary compounds, these mixtures will explode when initiated in confinement.

Power

In relation to explosives, the term refers to relative end results. It takes into account such factors as brisance, detonation rate, cratering potential steel penetration capability, etc.

Primer

An explosive charge used in the intermediate (boost) process of an explosive train.

Primary explosive

Classification of explosives that are used as the first step (detonation) in an explosive chain. Primary explosives are initiated by shock, impact, heat, or heat-producing friction. Common examples include lead azide, lead styphnate, and mercury fulminate used in blasting caps.

RDT&E

Acronym for Research, Development, Test and Evaluation.

RDX

Original designation for "rapidly detonating explosive" or "research development explosive." Also used for the high explosive cyclonite.

Render safe procedure (RSP)

To remove the explosive threat through any of a number of procedures and techniques. RSP is to be accomplished only by qualified technician.

Safety fuse

Used for detonating explosives nonelectrically. Since its burning rate can easily be regulated in manufacture, black powder is widely used as the core burning powder in the safety fuse used commercially and by the military to provide a delay time prior to an explosion.

Secondary explosive

Classification of explosives that are used as a booster and/or

main charge after the first step in an explosive chain. Secondary explosives are relatively insensitive to shock, friction, flame, or heat compared to primary explosives. They may be initiated or detonated by a strong explosive wave. Common examples include:

(1) boosters: pentolite, TNT, RDX. PETN, tetryl, and tetryl;

(2) main charges: dynamites and ammonium nitrate; and

(3) blasting agents: nitrocarbonitrate. (see table 4-3)

Shaped charge

Shape charges are explosive devices that focus the explosive force in a specific direction, usually by forming a cavity in the charge, to create a directed pressure or projectile. Conical shape charges are used to penetrate armor or punch holes. Linear shape charges are used to cut a straight line.

Sheet explosive

Also known as Flex-X or Deta-sheet is a flexible rubber-like explosive that be easily cut with a knife, remains flexible through a wide temperature range, and is waterproof. Military sheet explosive has pressure-sensitive adhesive backing, making it possible to quickly apply the sheet to irregular or curved surfaces.

Shock tube

"Shock tube" and "signal tube" are generic names for a small diameter plastic laminate tube that has the inside of the tubing coated with a very thin reactive material that transmits in initiation signal or "shock" to an attached blasting cap.

Shrapnel

Any metallic case shards or included objects that are thrown from a charge upon detonation to enhance the fragmentation effects. Among the favorite objects used as shrapnel in terrorist bombs are nails and large fence staples. Pipe bombs are a common fragmentation device.

Smokeless powder

The world standard propelling powder for small arms, cannons and

in a slightly different form, some rockets. All low explosives currently used as propellants have a nitrocellulose base and are commonly referred to as smokeless powder.

Squib

An electric match. Used primarily for initiating low explosives where a burning action is desired.

Straight dynamite

Liquid nitroglycerine absorbed in a mixture of various carbon rich materials, such as wood pulp or ground meal. Sodium nitrate is added primarily to supply oxygen for complete combustion of the carbon1-rich materials, thereby increasing the strength of the explosive. This is the most hazardous of the dynamites to handle and store.

TATP

Short form for triacetone triperoxide, also known as tricycloacetone peroxide.

Tetrytol

Effective as a cutting or breaching charge, tetrytol may be used as an alternate to TNT in general demolition work.

TNT

Short form for trinitrotoluene, a powerful explosive. It is the most common military explosive and, alone or as part of a composite explosive, is widely used as a booster charge bursting charge, and demolition charge. It is used as a standard explosive against which other military high explosives are rated.

Two-part explosives

Consist of two inert components that are nonexplosive until mixed. After mixing, the solution becomes cap sensitive and is considered a high explosive. Unmixed components may be shipped by common carrier or by airfreight with no special handling required. Astro-Pak and Kinepak are the most common examples.

X-ray

Typically, a stream of relatively high-energy photons, used for their penetrating power in radiography, radiology, radiotherapy, and research. When used x-ray photography, provide a means for detecting structures that are shielded from normal view.

35_5.0 Tools for Destructive Entry of Safes and Vaults

In **Chapter 32**, methods of forcible entry to open locks were examined. Some of those tools and procedures can be used for and are equally applicable to safes and safe locks. Both common and custom implements are employed to effect a forced-entry. Generic and specialized equipment is required to drill, pry, punch, blow, rip, cut, chop, grind, break, pull, burn, melt, freeze, vaporize, alter, or destroy barrier materials. The following discussion provides information regarding the equipment used by the safe technician.

35_5.1 Generic Tools

The following inventory offers a guide as to the equipment that is required to properly and effectively penetrate a security container while causing the least amount of damage.

- **Allen wrenches for removing hinge bolts;**
- **Ballpeen hammer;**
- **Center punches;**
- **Change-keys for common safe locks;**
- **Dead blow hammer;**
- **Drill motor, high speed, 3500 RPM or faster;**
- **Drill motor, low speed, 550 - 1200 RPM;**
- **Drivers, socket ends;**
- **Hammer drill, variable speed;**
- **Hammer;**
- **Hand tools;**
- **Ice picks;**
- **Illuminator, battery powered, flexible and straight;**
- **Laptop computer for access to Internet databases;**
- **Mall, two pound;**
- **Manipulation aids;**
- **Pickup tool, magnetic, long telescoping model;**

- **Pin punches and removable pins (Lockmasters Ram sets, 3″ length);**
- **Pointed vice grips for gripping broken spindles;**
- **Punch rods, 8, 16, 24, 30″, stainless steel round stock;**
- **Punches, flat and chisel pointed, ¼″, 5/16″, 3/8″, used to break up hard plate. Several are generally required. Tool steel tip and mild steel handle are recommended;**
- **Reamer;**
- **Reference data for safes and locks;**
- **Rods, long, water hardened, all diameters;**
- **Safety glasses;**
- **Screwdrivers;**
- **Sledgehammer;**
- **Tape measure;**
- **Tool caddy;**
- **UV light source;**
- **Vice grips;**
- **Wire cutters;**
- **Wire;**
- **Wrenches.**

35_5.2 Specialized Entry Tools

- **ATG driver;**
- **Audio amplifier;**
- **Borescope, long fiber optic;**
- **Bosch drill, heavy duty;**
- **Broco thermic lance;**
- **Change-key set;**
- **Compressed air can, or turkey baste syringe;**
- **Dead-blow hammer;**
- **Dial puller;**
- **Drill bits, cobalt;**
- **Drill bits, core drilling;**
- **Drill bits, high-speed steel, 6″-24″ length, 1/8″, 3/16″-1/2**

diameter, for drilling mild steel (not stainless or hard plate);

- **Drill bits, masonry;**
- **Drill bits, metal-cutting carbide bits, ¼″, 4″-6″ in length;**
- **Drill motor: Bosch 1198 VSR ½″, Hilte, Milwaukee, or Makita. Drill chuck, 3/8″-1/2″, variable speed, 3000 RPM maximum required, allows application of torque with pressure, >4.5-7.0 amps;**
- **Drill point locators;**
- **Drill rig, Collins lever;**
- **Drill rig, magnetic, Lockmasters #457 or equivalent;**
- **Drill rig, snap-on type;**
- **Drill rig, Strong-Arm MiniRig;**
- **Drill rig, vacuum;**
- **Drill templates;**
- **Emergency dials, different diameters, or Prob-A-Scope;**
- **Emergency spindles;**
- **Flashlight, fiber optic;**
- **Flexible lights;**
- **Forceps kit;**
- **Grinder for sharpening punches;**
- **Grinding wheels;**
- **Hole saws, different diameters;**
- **Iron pick;**
- **ITL 1000 computerized solenoid;**
- **LaGard skip pick;**
- **Lock picks for pin tumbler and lever locks;**
- **Lubricant, Group 1 lock;**
- **Lubricants and grease;**
- **Nose puller;**
- **Ophthalmoscope;**
- **Optivisor;**
- **Otoscope;**
- **Read-Eze manipulation aid;**

- **Safe-deposit penetration kit;**
- **Safe-saver pins for hole repair;**
- **Safety goggles;**
- **Saws, reciprocating, Makita or equivalent;**
- **Saws-all cutter;**
- **Screwdriver, mini;**
- **Silica gel;**
- **Stethoscope;**
- **Torque measurement kit;**
- **Video camera, adapter, monitor;**
- **Welder, metal inert gas;**

Note: Suggestions from readers or manufacturers for the inclusion of new tools in subsequent editions would be welcome.

35_5.2.1 Optical Viewing Devices

There are two essential categories of tools used for professional safe penetration: **optical viewing devices** and **drills** (and related components). Our discussion of tools begins with brief comments regarding the borescope, because it is the primary instrument utilized to view locking components after penetration. See **Chapter 31** for a detailed discussion relating to optical viewing devices and their use for decoding locks. A borescope, otoscope, or ophthalmoscope is an optical device that is employed to view inaccessible areas within a combination lock or security container. They were developed for use in the medical field to inspect internal organs; they are ideally suited for safe and vault work. To "scope a lock," means that an internal component is viewed externally through an optical probe.

Each of these three devices can be used to perform specific types of observations, based upon the thickness of barrier material, diameter of the hole, and location of critical locking components. All of these implements are essential to allow the qualified safe technician to perform his task. There are many different designs for the borescope in terms of length, diameter, viewing angle, optical relay system, and image capture. Price will provide an index as to the clarity of the image and the degree of sophistication of image transmission and light-gathering efficiency.

Although there are many manufacturers, Olympus is probably the most well known and respected vendor of precision borescopes in

the world. They manufacture rigid, flexible, and fiber-optic-based devices. See **Chapter 31** for a detailed description of optical viewing devices.

A borescope may be handheld and self-contained, or it may rely upon an external light source with its own power supply. The handheld models will contain batteries and high- intensity illumination, generally within the handle. Usually, fiber strands carry light to the scope tip. A special internal lens may also be provided for different fields of view. A mirror tube may fit onto the shaft of the scope to allow for different viewing angles of up to 90°, for full 360° rotation. A second mirror can allow a "back angle view" to observe the entry point into the container.

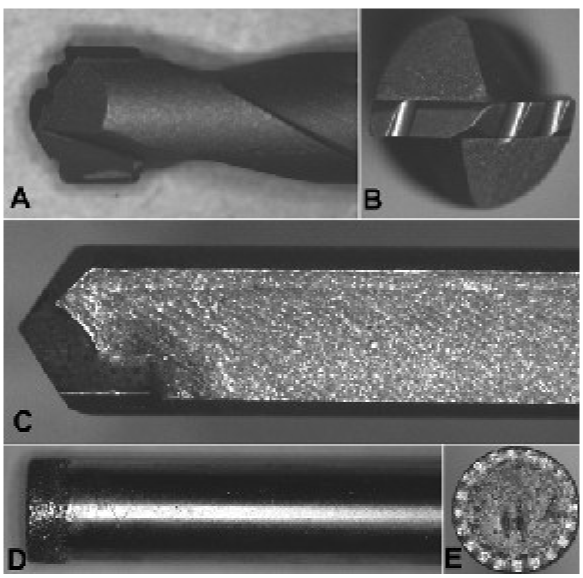
35_5.2.1.1 Special Precautions

Before a borescope is inserted through a hole, insure that the area to be probed is free of debris. Dust on the surface of a mirror or lens will decrease light transmission and the quality of the image. Take great care with the surface of the lenses; they can be scratched or easily damaged. The author utilizes lens tissue and alcohol, or cleaner and pressurized dry air.

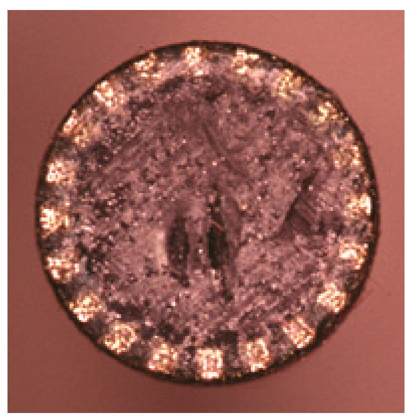
35_5.2.2 Drills, Bits, and Related Tools

35_5.2.2.1 Introduction

The subject of drilling, from the perspective of the chemistry and physics of metallurgy, was described in **Chapter 5**. Safes are opened with drills in the vast majority of forced penetrations. In most cases, the **lock** rather than the safe mechanism is actually drilled. Even more important, **accurate drilling** constitutes 90% of an effective opening technique.



Virtually every safe that carries a **TL** rating can be opened in this manner. When a safe is drilled, locks are usually bypassed through a drill point under the dial ring. This allows for straight-in penetration unless there is glass. The reader is cautioned that drill point information published prior to the 1970s should not be relied upon as accurate.



A drill bit constitutes more than just a hard and sharp cutting edge; it is a very complex cutting tool, as has been discussed in earlier chapters. Its components must be understood in order to

master the process of removing metal and the proper maintenance of the cutting edge. Many complex components must work in unison in order for the drill to efficiently remove material from a work surface.

35_5.2.2.2 Drill Bits: Classification and Materials

Many types of drill bits are available to the safe technician. They are required because of the various grades of barrier materials that must be penetrated. There are three primary categories of drill bits: **carbon, high-speed steel (HSS),** and **special alloy.** They are produced in six different materials: carbon steel, high-speed steel, cobalt, carbide, diamond core, and tungsten.

35_5.2.2.2.1 Carbon Steels

Carbon steel drills are used for penetrating mild steel and softer materials that have not been hardened. If a tougher bit is required, then more carbon and other alloys are added.

35_5.2.2.2.2 High-Speed Steels

High-speed steel drills (HSS) are produced in many grades of hardness; perhaps the most common is M2. These may also be referred to as 18-4-1 and 18-4-2 alloys, with the designation indicating the percentage of other metals within the steel.

Thus, the above example would refer to a metal with 18 percent tungsten, 4 percent chromium, and 1 or 2 percent vanadium. The alloy contained within these tools is altered for optimum hardness, shock resistance, heat conductance, resistance to annealing, and abrasion resistance, allowing them to tolerate higher speeds with more applied pressure. They are also more efficient at cutting metal as compared to standard carbon steel bits. An HSS bit can penetrate 1” of steel in about two minutes.

Masonry bits are used for penetrating concrete but can also be used for hard plate and composite materials. They have a large carbide chip insert that is soldered into place. Generally, the chip is not sharpened. **Cobalt drills** (M45 steel) are required for barrier material that creates high temperatures during cutting. The alloy, when added to HSS, maintains hardness and cutting surface during red-point drilling. These bits are tempered to an **austentite** condition for optimum hardness and toughness. They are quite hard and brittle and will often snap during drilling.

The cobalt drills will outperform HSS bits; they can cut more material at higher speeds. However, they are less resistant to destructive shock and stress, often caused by a constant change of drilling angle. The tip can be easily shattered if hard nugget or spots are encountered. These bits are used to penetrate stainless steel, armor plate, and manganese.

35_5.2.2.2.3 Special Alloys

Carbide Drills are even harder than HSS or cobalt and will withstand higher temperatures than the hard plate they are drilling. Hardness ratings for carbides range from 89.5-93.0 on the Rockwell “A” scale. Carbides produce chips during penetration that are very hot and blue-black in color. A great deal of squealing usually accompanies the drilling process.

Although there are hundreds of grades of carbide, only four are relevant in the context of drilling alloy hard plate. These can be classified as **tungsten carbide, crater resisting carbides, titanium carbides, and coated carbides**. A standard carbide bit is simply a drill with two chisel-edged planes to form an angle for cutting. The chisel edge is the least efficient because it does not cut but actually squeezes or extrudes the work material. This type of bit actually does more scraping than cutting.

Tungsten Carbide

Tungsten carbide drills are utilized when penetrating most barriers except diamond and ceramics. They are one of the hardest man-made materials, approaching that of a diamond. There are hundreds of degrees of hardness of T/C, achieved by the addition of different metals. They are usually composed of between 94 - 97% tungsten carbide, with cobalt the remaining material. The first carbide drills were made of a steel shaft, slotted on the tip, with a spade-shaped piece of carbide soldered to it. The cutting edge was sharp, and brought to a point.

They were originally developed at the beginning of the twentieth century (1896) by a French chemist. An incredibly tough drill was created when a mixture of iron, charcoal, and sugar were added to pure tungsten. This mixture was then crushed into a powder, together with cobalt. Actually, tungsten carbide was developed as a hardening agent. It was an outgrowth of the addition of carbon, chromium, and tungsten. Then, carbide chips were added to the drill point with cobalt for extreme hardness. Space-age metals, such as titanium, tantalum, and colombian have also been incorporated for enhanced characteristics.

Physically, carbide chips are brazed or soldered to a steel drill shank to create a very hard and brittle bit. Their design calls for a minimum relief angle and rake angle to maintain a cutting edge. The red-point drilling characteristics of tungsten carbide and tantalum carbide are excellent. When the proper pressure and speed are used, the bit turns into a homogenous structure that can create enough heat to melt the target material.

The life of a carbide drill bit cannot be accurately projected; many complex factors will determine how long the bit will perform. In one instance, several bits may be required to drill through one door. In another case, only one may be used. As noted in **Chapter 5**, the addition of certain elements enhances performance. The tungsten provides increased hardness and heat resistance, chromium offers shock resistance, and vanadium allows greater fatigue resistance and overall toughness. T/C is the most abrasion resistant of the cemented carbides.

Crater-Resisting Carbides

“Cratering” of hard metals is a characteristic that results from the interaction of the cutting edge of a drill bit with hard plate. A crater actually forms a short distance from the cutting edge and will continue to enlarge until the bit breaks through a portion of the surface. These drills contain titanium and

tantalum carbides added to tungsten. Their primary use is for machining alloy cast irons and other cratering-prone metals.

Titanium Carbides

Titanium carbide drills have small percentages of nickel and molybdenum. They perform well at higher speeds and temperatures but are brittle and will easily fracture from thermal and mechanical shocks. These bits have good cratering resistance.

Coated Carbides

Drills are coated to enhance resistance to thermal shock, although this characteristic is dependent upon the type of coating. Carbides can be treated with titanium oxide, titanium nitride, and aluminum oxide.

Cubic Boron Nitride

Diamond is the only material harder than cubic boron nitride. Drills with this composition, trade-named Borazon, are used to cut extremely hard and tough metals. A **Diamond core drill** resembles other core bits; they simply have diamond chips embedded around the circumference. Traditional core drills are a tool of heavy construction and are used to make holes up to 18” in concrete, brick, and other materials. These drills actually grind the material during the cutting process, rather than shearing as with other types of bits.

The diamond core drills are constructed as hollow tubes, coated and bonded with industrial diamonds. Their characteristics require that they be utilized with a fixed drill rig for stability and maintenance of constant pressure. Often used with hole saws, they can easily make a hole in most barrier materials. First, the HSS hole saw is employed to cut through the mild steel skin; the diamond core will then pierce the hard plate. They are not designed to work with softer materials, and only function efficiently with hard plate.

The diamond inserts have a very limited cutting life, generally from 1.5 - 2 inches of material. A blue wax material within the center of the drill provides lubrication, and melts as the barrier material is penetrated. It also will carry away chips from the work surface. Although they offer a very hard surface, carbide tipped drills can be sharpened using a green silicon carbide wheel with K120 grit. Professional safe and vault

technicians are familiar with the Diamatip core bit, manufactured by Magnum.

35_5.2.2.3 Tip Failure

There are two primary causes of tip failure. In the first instance, the drill body acts as a heat sink to carry high-temperatures away from the bonding agent. Failure occurs when the silver solder breaks down. If the drill is utilized for hot drilling, then pressure must be intermittently reduced to allow the tip to cool.

Many manufacturers include carbide chips and abrasive materials within their hard plate. These are bonded with bronze or nickel alloys and contained in rods or nuggets. Materials that contain such hard chips or nuggets, such as aloxite manufactured by Chubb, will shatter a tip during drilling. This is precisely what the manufacturer intended. As noted elsewhere in this text, a negative rake angle can improve performance when these materials are encountered, but the problem is not solved.

35_5.2.2.4 Drill Design

An understanding of the geometry of the cutting edge will allow an insight into how metal is removed during the drilling process. This in turn will provide guidance as to the best bit to use for a specific type of barrier material. Knowledge as to bit design will also permit them to be easily sharpened for optimum use. A more technical discussion is presented in **Chapter 5**.

35_5.2.2.4.1 Flutes

It appears that the Egyptians, around 4000 B.C., utilized the original straight-fluted drill for making holes. The first patent was issued to Stephen A. Morse in 1863 for a fluted bit. Flutes carry the cuttings from the work surface. Their design is quite complex and must encompass the correct web thickness to reduce cutting pressures. Additionally, chip splitters are incorporated into the cutting edge to increase the flow of cuttings through the flutes.

Generally, two flutes are designed to transport chips from the base of the hole (tip of the drill) and be ejected. The lands and the way they are spiraled determine the rotation of the drill (right or left). This will control how the chips are carried.

35_5.2.2.4.2 Rakes: Positive and Negative

The cutting edge of a drill is defined and referenced as to whether it is positive or negative. The "standard" bit has a positive rake, indicating that the cutting edge leads when making contact with the work surface. Its function is to slice material during rotation.

Positive-rake drills cannot be used with included hard plate, as the cutting edge will be destroyed almost instantly. Instead, a negative rake is recommended. These bits have their leading edge modified so that there is minimized contact with the irregular surface. Negative-rake angles make it possible for the cutting edge to ride above an irregular included surface. This reduces shock, minimizing fracture and shatter. Unfortunately, shocks encountered in drilling certain hard plate will eventually destroy the drill.

The rake angle is directly related to required pressure to effect cutting. An increase in angle of approximately 1° will increase pressure by one percent. The converse is true for positive rake drills.

35_5.2.2.5 Primary Components of the Drill Bit

The traditional fluted drill can be subdivided into two primary components: the body and shank. The body does the actual cutting and contains the flutes and relief areas. It is the complex portion of the drill. The shank allows the drill to be fastened to a drill motor, and is shaped in a straight or tapered design. Its diameter can be reduced for acceptance into a smaller drill chuck.

The **margin diameter** or **body diameter** creates a clearance for the drill; it is measured from edge to edge. The diameter of the drill is actually reduced behind the tip to create clearance so that the drill can cut. The design of the **helix angle** is based upon the material to be penetrated, the depth of the hole to be made, and the type of chips being produced. A low twist or low helix design is preferred for soft material such as brass, copper and plastic.

Steels that can be machined produce small, curly chips that may encounter difficulty in riding the flute. A "standard" helix angle is used for most drilling operations. As the helix angle

increases, more chips will be produced with softer materials. The helix in the carbide drill will have a greater angle in order to eject the fine metal chips produced by drilling hard plate. Drilling cast iron and hardened steel can produce flake or powder that can cause a packing problem at the tip of the bit.

35_5.2.2.5.1 Point Angles

The point angle is generally described as the included angle of the tip. The two standard point angles are 118° and 135°. A 118° point is for general-purpose cutting. An angle of 135° (that forms a flatter point) is used for alloy steel hard plate. A drill for manganese steel, for example, would have a point angle of 140° with a 6°-9° relief angle. This drill would require slow speed and high pressure.

The point angle and the length of the cutting-edge lip are inversely proportional. That is, as the point angle increases, the length of the lips decrease with a corresponding decrease in pressure required to cut the material. A 135° point angle makes it more difficult to begin penetration, and it generally requires a pilot hole.

The lands meet to form a **chisel edge** in the center of the drill point. Its function is to move material away from the center of the bit in order to allow transport by the flutes. The **web** (material at the center of the drill bit) provides structure and strength. Generally, the web increases in thickness toward the shank.

35_5.2.2.6 Sharpening of Drill Bits

Drill bits must be sharpened to increase their performance and prolong their useful life. Sharpening can also modify and control the operation of the bit, based upon the type of material being penetrated. The complex angles of the drill point all must work in unison for optimum cutting and removal of material. These angles are maintained by proper sharpening. Sharpening can be dangerous because microscopic fractures may exist throughout the bit and shank caused by previous stress. The result: the drill can separate or disintegrate at high speeds.

Accurate sharpening requires either a commercial machine or a bench grinder and drill gauge in order to properly accomplish the process. The gauge provides a scale to measure the lip length

and its angle (but not the relief angle). This is a simple tool, but it requires practice to be used properly. If a grinding wheel is employed, it must be dressed to maintain a flat surface. All sharpening is done on its face and not on the side. Caution should be exercised because improper grinding practice can cause the wheel to explode or shatter.

35_5.2.2.6.1 The Sharpening Process: Definitions and Rules

The process requires the alteration of three critical components: **point angle**, **relief angle**, and **lip length**. Using the two-flute drill as a model, the following rules apply for sharpening drill bits:

Chip breaker is a groove cut into the lip of a drill bit to prevent chips from clogging the flutes. They are used when drilling soft materials and steel. Grooves are generally offset between lips and are usually closer to one than the other. These tips are shaped likes spades and cause the removed material to be ejected sideways with more efficiency than a rounded HSS bit. It is, however, more difficult for the chips to move from the cutting area. In reality, a chip breaker is a divider, thus creating a multifaceted web that forms several chips. These are easier to disperse, requiring less pressure to cut the work surface. Although chip breakers can be effective, they weaken the tip and are often used in high-speed drilling with a coolant. They may reduce the ability to cut and can shorten drill life.

Lands, often called the "surface of the point" behind the lip, provide support while the lips are cutting and transport heat from the tip. However, too much relief will cause the tip to melt.

Lip Angles to the center of the bit must be identical. If not equal, the bit will cut chips with different material thickness. This will result in distortion of the tip and an oversize hole that is not linear. The hole will appear as a helix and will not allow the insertion of a straight shaft.

Lip Length must also be identical in order to create a round, true hole. If one of the lips is longer, then only it will cut. In such case, the drill will wobble in the hole.

Negative Relief Angle will increase the durability of the tip because the cutting edge is reduced. The technique is used with

a hammer drill to transmit impact to the material being penetrated. This tip design will not penetrate hard plate.

Point Angle is measured from the centerline of the drill body and will encompass the included angle of the tip.

Rake Angle of the cutting edge is controlled by the helix angle. Generally, the rake angle should not be changed. A **reduction** in the angle will prevent "grabbing" as the material is broken through, and will cut more efficiently. High pressures are withstood better while heat is transported away from the tip. Bits with a reduced rake angle are best for cutting soft materials such as copper, brass, plastics, laminates, and thin metals. However, less efficient chip transport will also occur. Instead, chips become tightly wound around the bit rather than being produced in ribbons.

Relief Angle must be sufficient behind the lip to allow the cutting portion of the drill to work properly. The land behind the lip must be angled to prevent contact with the bottom of the hole. The relief angle is usually between 8-12°. If 0° or less, the bit will not cut any metal. The relief angle controls the thickness of the chip that is produced during cutting. If too shallow, the drill will cut less metal while generating excessive heat at the tip. If the angle is too great, too much material will be attacked. Placing too much stress on the bit can cause it to shatter. As material is removed behind the lip to relieve the cutting edge, the corners of the bit can break.

Split-Point and Reduced-Point Bits will bore into materials easier and will be less likely to "walk." Modifying a drill in this fashion will relieve the heels of the drill point. A sharp-cornered grinding wheel is used to create a second set of cutting edges across the web of the body. The alternate sides of the chisel-point are ground away, thus creating a drill point within a larger drill point. This design is popular on long drills and is known as a "crankshaft" or "split-point grinding" drill point. The technique will almost eliminate the chisel-point and greatly reduce required pressure during drilling.

Web Thickness or P**oint Reduction** reduces the width of the chisel point. It is accomplished on the heel of the drill tip, not into the lips. Reduction of the width will minimize the feed pressure.

Web Thinning or thinning of the drill point can add cutting efficiency to a drill. This occurs because a more efficient

cutting area is placed into contact with the work surface. Cutting pressure is thereby reduced.

35_5.2.2.7 Maintenance of Drill Bits

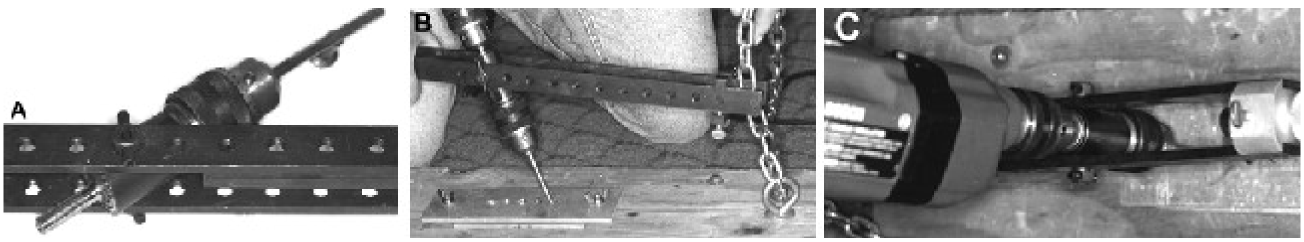
The life of a drill bit depends upon its physical composition, the material being cut, the skill of the operator, and its maintenance. Efficiency and profitability can be enhanced by proper care. The drill bit that is correctly maintained and sharpened can cut materials faster with less operator fatigue and will produce a cleaner hole. A sharp drill will generate less heat.

What happens to a bit as it is used? Generally, most wear will occur at the corners of the lips. They will tend to break down and extend across the surface of the bit. Heat will increase as the drill fails, resulting in the inability of the cutting edge to remove any material. Proper maintenance of drills, including sharpening, can restore cutting edges. An equally important benefit is the minimization of the effects of the heat generated by the drill point upon the barrier material. If the drill is not operating properly, a “work-hardening” will result or the tip can melt or become annealed (soft).

35_5.2.3 Drill Rigs

Handheld drill motors are not acceptable where high tolerance in the location and angle of a hole is required. Precision drilling can only be accomplished with a drill rig. There is no best drill rig. The choice depends upon a number of factors, including time, weight, type of safe, and the work place. This section will examine professional hardware that is available for placing exact holes in a safe or vault.

Certain rigs will not work on particular safes. Thus, magnetic drill rigs may not adhere to stainless steel or non-magnetic surfaces, or to materials that are too rough, or not thick enough to hold the rig. Rigs are categorized based upon their method of attachment to the surface of the safe or vault. Drill rigs can thus be described as:

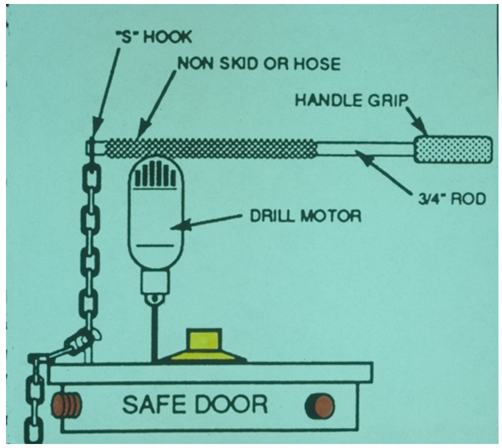


- **Pressure bar lever rig (not fixed);**
- **Simple fixed rig;**
- **Magnetic;**
- **Vacuum.**

35_5.2.3.1 Non-Fixed Drill Rigs

In situations where precise drilling is not required, a handheld drill rig can be utilized. The simplest form that is in use by many technicians is the Pressure bar lever rig described below.

35_5.2.3.1.1 Pressure Bar Lever Rig



The pressure bar lever rig is probably the cheapest and most widely used tool. Although rudimentary in design, it will allow freehand angle drilling at the back, sides, and top of a container. These rigs are used for non-critical drill points.

Many practitioners will construct their own tools made of wood, metal, pipe, and chain. The design simply requires that the drill is fastened to a length of chain and a fulcrum point (handle) is established. This will provide the ability to tighten and lock the drill motor into a fixed position and apply pressure to it.

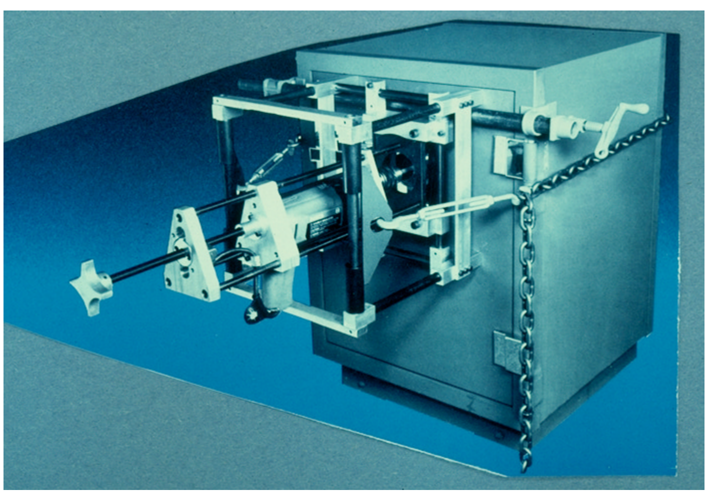
Some rigs are attached to the safe with pipe clamps, strap, and ratchet mechanism. Various drill motor holding designs are available for precise feeding. The rig allows the leveraging of applied pressure to the drill through the fulcrum point, up to a 20:1 ratio. The length of the handle and chain hookup bar can be adjusted, for maximum control.

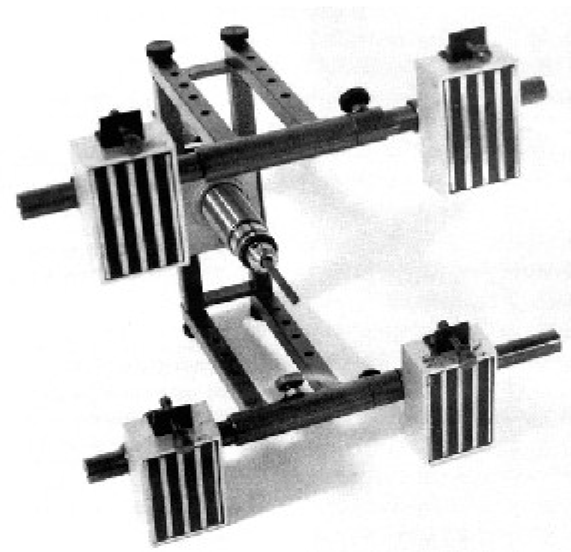
35_5.2.3.2 Fixed Drill Rigs

Precision tolerance with respect to hole placement means depth and angle control, requiring that a fixed rig be employed. These devices are actually a portable drill press that can be mounted in any orientation to the surface of a door. There are a number of designs available that vary in complexity, capability, and price.

35_5.2.3.2.1 Simple Fixed Drill Rig

A simple fixed drill rig has as its primary component a platform for the drill motor that can be positioned on the face of the safe. Straps, clamps, or chains attach the drill to the rig; a ratchet, turnbuckle, or other device accomplishes tightening. The drill motor is moved with an arbor mechanism or lead screw that also allows control of over-drilling.





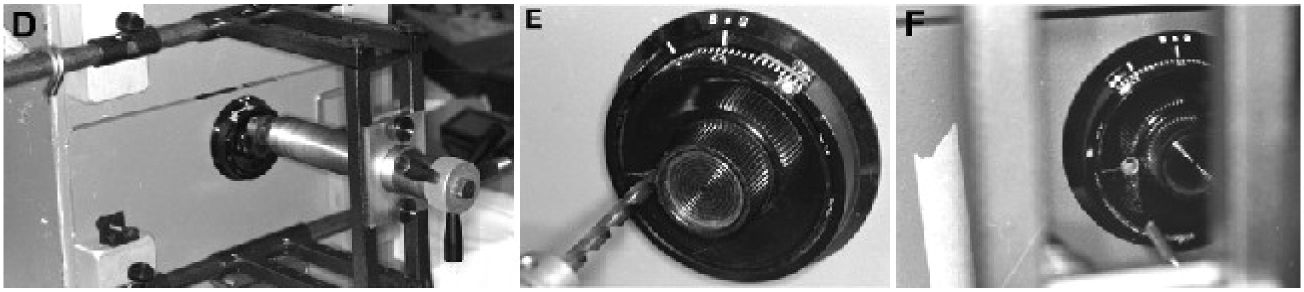


Figure LSS+3534 A fixed drill rig (ISP-87-3563).

35_5.2.3.2.2 Magnetic Drill Press

There are several such devices available to the professional safe technician. They all utilize a configuration of magnets to attach themselves to the surface material. Depending upon design, they will vary as to holding strength. Some of these tools have been produced in a very compact configuration because of the availability of rare earth magnets that measure a few inches in diameter and can deliver several thousand pounds of holding power.

35_5.2.3.2.3 Vacuum Drill Rig

The vacuum rig is a variation of the magnetic attachment. Suction, rather than magnetism, is utilized to hold the device to the surface of the container.

35_5.2.3.3 Drill Motor

Speed, pressure, and feed can be directly correlated to the drill motor design and related parameters. Many manufacturers, notably Bosch, Hilte, Milwaukee, and Makita produce motors suitable for safe and vault work. The greatest threat to a motor is heat. This can be caused by the use of an underrated armature or winding. An inadequate specification can be identified by low current consumption. Ventilation is critical, especially when extreme pressure is applied during the drilling process. If the motor becomes hot, it will sound differently while running. In such event, the drill should be run without any applied pressure until cooldown occurs.

Drill motors should have the following characteristics:

- **3/8″-½″ chuck;**
- **Variable speed;**
- **5000 RPM Maximum, although 3000 is generally sufficient;**
- **4.5-7 ampere current rating that controls the ability to apply torque;**
- **Should feel good when handheld;**
- **Assess how the motor is held;**
- **Assess how the motor feels when pressure is applied;**
- **Ventilation: how many air ports;**
- **Running temperature of the motor.**

35_6.0 The Penetration of Safes and Vaults by Drilling

35_6.1 Introduction

Drilling is a very complicated problem with many variables. The process is performed in order to neutralize a specific component within a lock or bolt mechanism. Successful drilling demands precise measurement, the proper equipment, and correct technique. The type of hard plate, drill speed and pressure requirements, and the calculation of the drill point are factors that can make the process of drilling quite difficult.

Drilling is accomplished in many ways and is dependent upon the lock, the design of the container, and the barrier material that is utilized by the manufacturer to protect the safe and its internal components. Most problems encountered in forced penetration can be traced to one of five errors:

- **Lack of accurate information about the container;**
- **Formulation of wrong entry approach or technique;**
- **Improper equipment;**
- **Improper drill motor speed;**
- **Improper pressure: too little or too much.**

This section offers detailed information about the complex factors that make up the technology of penetrating safes and vaults by drilling. We begin with an overview of the process, followed by information about the development of anti-drill barrier materials and methods of bypass. The location and computation of drill points are also explained. Finally, a comprehensive analysis of drill points in relation to critical locking components is presented, together with the supporting information required to successfully open a locked safe.

35_6.2 Drilling Safes: An Overview

The theoretical procedure for penetrating a safe is quite elementary. The actual drilling procedure, however, can become very difficult and time consuming. For the professional safe technician as well as the educated burglar, the preferred method of entry into a safe is by drilling, if manipulation fails. The reasons to drill, however, are often misunderstood. The reader

should also understand that an amateur might attempt drilling in order to create an opening into the container, regardless of size or resulting damage.

Then, there is drilling by a craftsman in order to accomplish a purpose that denotes knowledge of the safe, its lock, and contents. The evidence technician and case investigator should always be mindful of the difference.

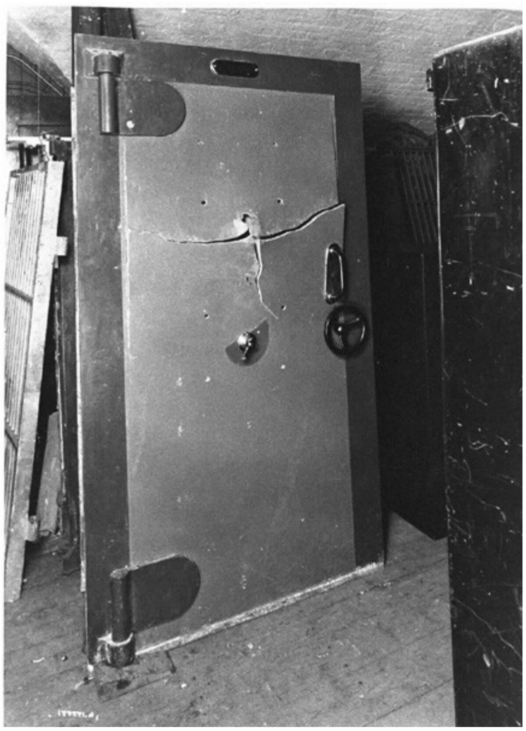

Figure LSS+3535 Shown (right) is a burglary where it is suspected that a drill rig caused the fracture of the outer skin of the door. In the photograph (right) a core drill was utilized.

In its simplest form, drilling is a straightforward procedure and will be summarized here. A detailed drilling sequence protocol is presented in Section **6.4**.

Generally, a high-speed steel bit (HSS) is used to drill **to the hard plate.** When no more cutting occurs, the technician changes to a tungsten carbide or similar bit specially designed for the purpose. If the carbide bit does not grab onto nuggets, steel balls, or other materials designed to block its path and cause fracture, then drilling continues through the hard plate. Another high-speed steel bit is used to finish the job, penetrating into the lock case.

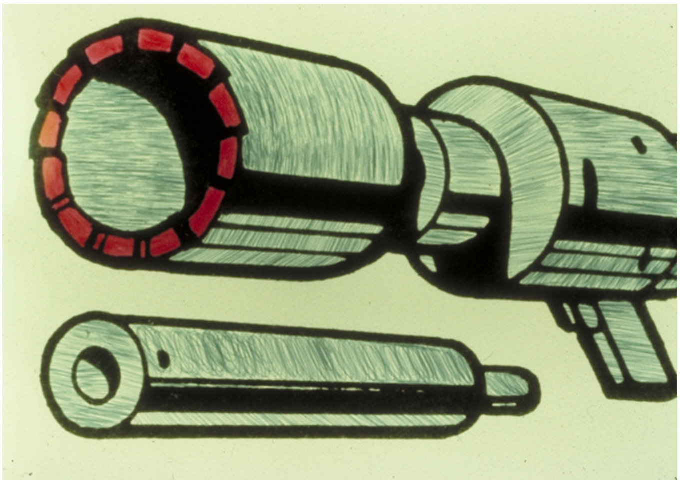

Figure LSS+3536 (ISP 77-3563 left, 78 right) Core drill can produce a large hole through which access can be gained to the bolt works or lock box. Courtesy of Illinois State Police, Bill Sherlock.

35_6.3 Drill points

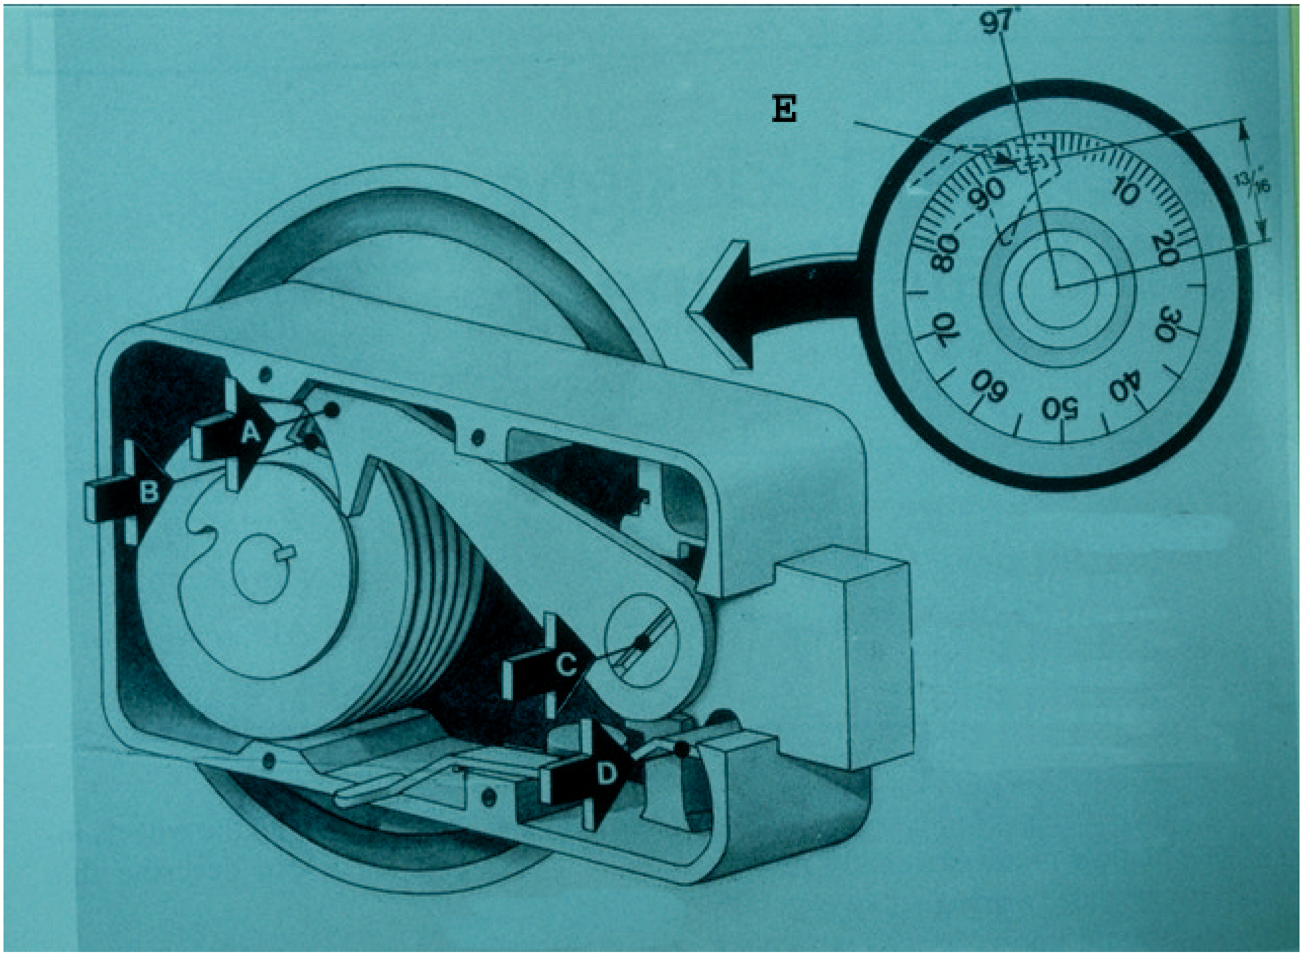

Figure LSS+3537 (ISP 102-3563) Critical drill points are shown. This is a rear view,
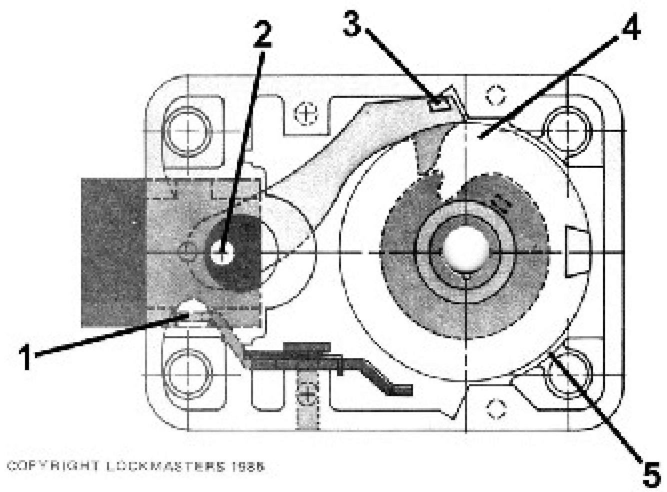
with the lock case removed, as if looking from inside the safe toward the dial.
(A) fence location; (B) gate location; (C) bolt screw location; (D) relocker location;
(E) fence drill point.

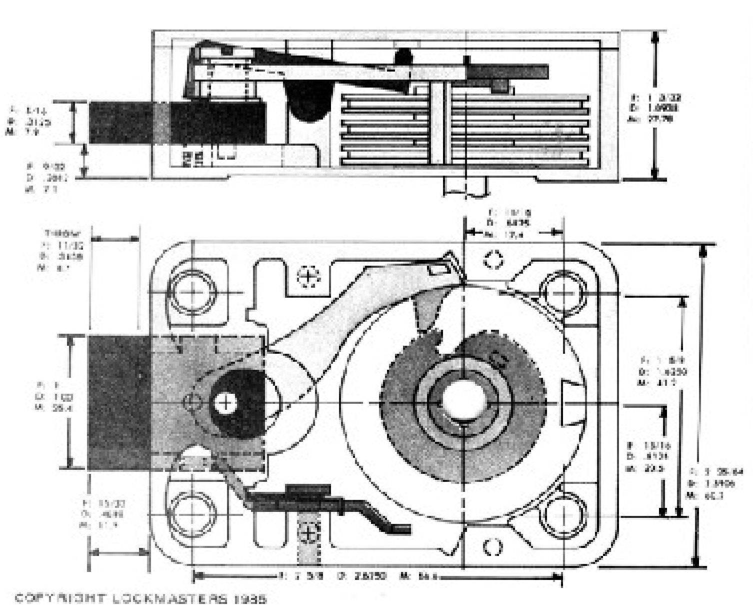
Although most professional safe and vault penetrations require that a hole first be made by drilling, the location and purpose will depend upon the method of bypass of the lock or boltwork. Because drilling is the preferred method of entry, the various techniques will be explored in detail. The precise location that is selected for penetration is called the **drill point.** It is calculated from measurements provided by references published by the lock manufacturer, Ed Willis, Mark Bates, Lockmasters, SAVTA, NSO, and other sources. Comprehensive information about most

safes and locks is also available at **security.org**.



Based upon the targeted component, there are up to twenty possible locations that may be selected as a drill point. Proper technique will allow any of these to provide the means to open the lock or bypass the boltwork. In every safe or safe lock, the following drill points can be identified to provide access to critical components:

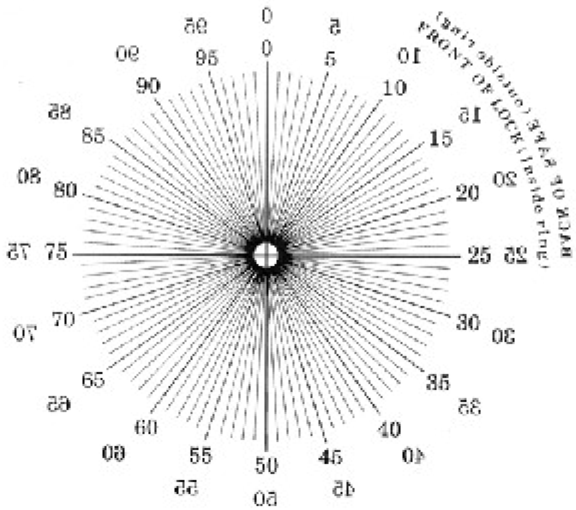
- **Bolt;**
- **Change-key hole;**
- **Creation of gates;**
- **Dial ring;**
- **Fence;**
- **Handle cam;**
- **Handle shaft;**
- **Lever screw;**
- **Locating relockers;**
- **Locking cam or lever;**
- **Manipulation of components;**
- **Mounting screws;**
- **Pilot hole through hard plate;**
- **Reading of gates;**
- **Relock devices that have become engaged;**
- **Relock trigger;**
- **Scope dial ring;**
- **Scope lock case;**
- **Spindle shaft;**
- **Square section of holes, creating;**
- **Viewing hole, front, top, sides, or back of safe, for introduction of borescope, to allow:**
    - **Reading of gates;**
    - **Locating relockers;**
  - **Manipulation of components;**
- **Wheel pack.**

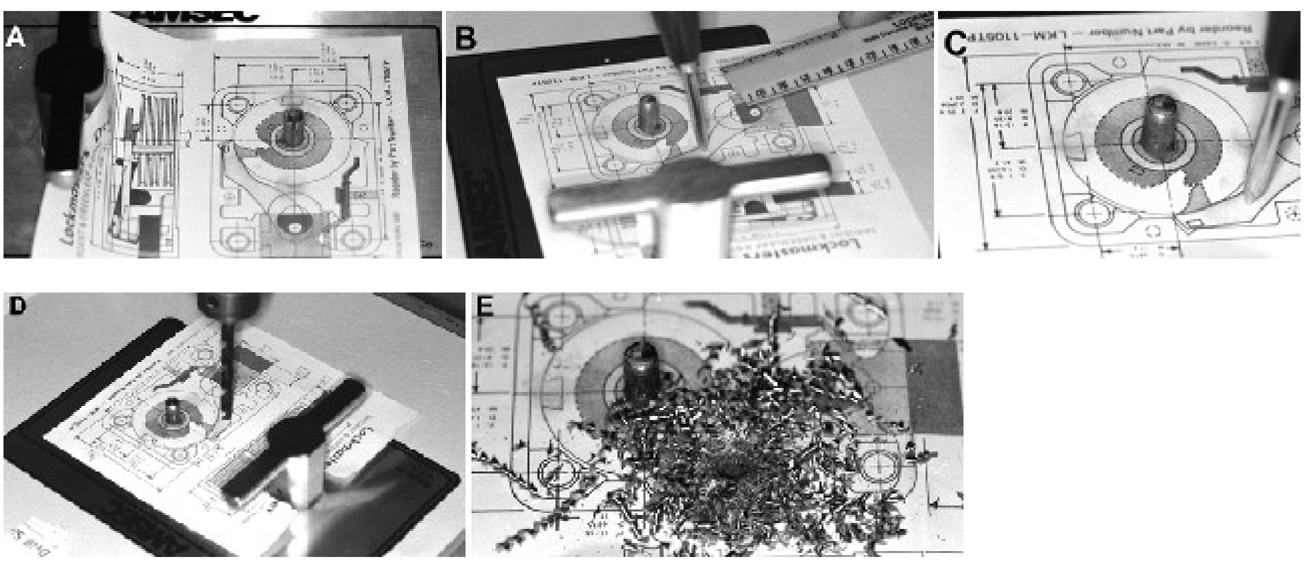


35_6.3.1 Drill Templates

There is no room for error when drilling open a safe. Most forced-entry difficulties can be traced to faulty technique on

the part of the technician in determining drill point location or in the actual use of the drill.

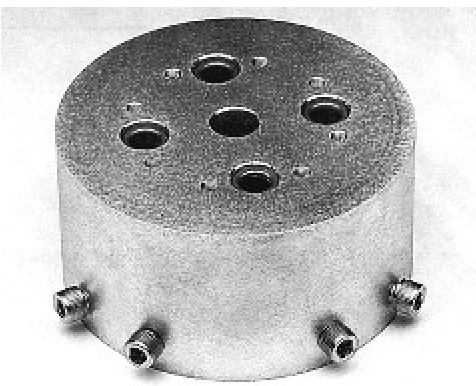




A hole drilled at the wrong angle, one placed in the wrong spot, or one that misses the intended target translates to wasted time, effort, potential damage to the lock, and frustration. Proper opening technique dictates that only one hole is made at the required position in order to offer a view or access to critical components.

Magnetic drill templates provide a precise method of determining drill points for all of the popular safe locks. Their use is

extremely popular and highly recommended. These templates provide the equivalent of an x-ray view of the critical locking components described earlier. Use of the correct template, once squared with the lock and oriented for proper handing, eliminates all measurement errors. The template is placed directly over the lock after the dial is removed or is utilized as a reference point for precise calculations. The exact drill point is located and center punched.



35_6.3.1.1   Predrilled Metal Templates

A guide plate is available that has predrilled holes for establishing exact drill points. If the proper handing and

manufacturer is known, it is virtually impossible to locate a hole in the wrong place. The angle, however, must still be precisely defined. If a drill rig is used with a guide plate, success is assured.

Once identified, the drill point location must be marked and punched to allow for precise penetration. Generally, this process occurs after the dial and dial ring have been removed. In practice, a template is located over the spindle, taking care that the handing orientation is correct. A center punch marks the location for the drill. If a template is not available, then measurements must be made from known coordinates. Their computation and location is discussed below, as well as in Chapter 34.

The drill point can be placed in many different spots, depending upon the ultimate goal. If, for example, the fence is to be scoped, then the drill must be positioned to allow the borescope to enter directly below the fence and at the edge of the wheel. This will allow observation of the end of the fence, as well as the gates.

35_6.3.2 Marking the Drill Point

Although precise measurements are essential for successful drilling, both vertical and horizontal movement of the spindle can cause problems. In such a case, the template should be moved up, down, left, and right to determine and mark the outer bounds of movement. An average between these dimensions should be selected as the optimum location to drill.

Sometimes the dial cannot be removed, but is reduced in size. In such case, a line should be extended from the dial center to the physical drop in point prior to the reduction in dial size. A

trammel may be utilized to allow measurement from a flat ruler or template to the irregular surface of the dial.

35_6.3.3 Computing Coordinates, Measurements and Dimensions

A method to precisely determine and communicate the location of drill points must be adopted for all drawings, diagrams, photographs, and reference materials if a safe or vault is to be properly penetrated. Of course, once the hole has been drilled, a **translation** must still be made between that point and the drop in, except in the case of the lever fence. Translation theory is discussed subsequently. There are two recognized formats for placing a drill point: **radial measurement** and **coordinates**.

35_6.3.3.1 Coordinates

The location of bolts and related mechanisms, relockers, and lock drill points can be determined using coordinates. The drill point reference is usually in relation to the vertical and horizontal axis center of the dial. It relates to whether left (LC), right (RC), above or below dial **center**. Sometimes, measurements are made from the edge of the door, based upon a specific safe or vault design. In an S&G 6730, the drill point for the fence would be expressed as 3/16” LC x 1 1/32” up. This translates to drilling a hole left of center of the dial, at 1 1/32” up from that point.

35_6.3.3.2 Radial Measurement

A radial measurement derives its reference from the center of the dial and relies upon the dial numbering to determine the location of the drill point. A line is extended from the dial center that shall be referred to as Point A, through the number on the dial Point B, referenced to the zero marker position. The location of the drill point is measured from A, **toward** B. For example, in an S&G lock, the precise drill point for the fence would be expressed as 97 x 1.” This means that the drill point is located 1” from dial center, along the angle created by running a line through 97.

The rules for radial measurement require that:

- **Measurement is always from dial center;**
- **The dial is referenced to the zero index marker;**

- **The marker will always be at the top of the lock;**
- **The handing of the lock is not considered.**

Measurements for drill points are generally based upon locks mounted RH, or right handed. A simple translation can account for locks that are positioned LH, VU, and VD. In order to determine the correct gate position, either 25 or 50 is added or subtracted from the radial location for LH, VU, and VD. From the RH orientation, add 25 for VU and LH, subtract the same for a VD.

Original Position Move	Translated Position	Lock	Compute
RH left	**VU**	**RH**	**+25**
RH right	**VD**	**RH**	**-25**
RH	**LH**	**LH**	**+50**

Note: The numbering on the dial is reversed for a LH type lock.

35_6.3.3.2.1 Computation of Radial Distance

Any variation in the angle at which the hole is drilled can cause distortion when viewing the gates. This can alter the accuracy by one or more numbers. The problem can be corrected by adding and subtracting one, two, or three numbers from the drill point number sequence.

35_6.3.4 Viewing and Translating the Combination Through the Drill Point

Once a hole is made in the correct position, a **translation** must occur between the location of the drill point and the actual drop in point (unless the drill point was for the fence). This translation must correlate the number of divisions of the wheels between the zero index marker and position of the borescope. Remember that the wheels must be rotated and their gates observed by the safe technician, based upon a view from a location other than the actual drop in point (the drilled hole).

All of the gates are first aligned to this "virtual" location to ascertain the **relative** position of each gate. Then, their position is computed so that the gates appear under the fence when the translation is factored into the equation. The ability to accurately translate the viewed gate data to actual drop in

point can be affected by the angle of the hole with reference to the wheel pack. Sometimes a "direct view" is possible; in other cases, the drill is fed at an angle. If not all of the wheels are visible, the hole must be enlarged, moved, or scoped.

If a direct view of all of the gates is possible, the procedure is straightforward. A line should be extended from the center of the drill point to the dial ring, in order to create an index marker. From this point, calculation of the gate position can be made, allowing a reading of dial numbers. Depending upon the design of the lock, the wheel closest to the hole will be the first or last to move. The farthest wheel from the drive cam will become the first number of the combination. In S&G locks that position the wheel post at the bottom of the lock case, the top wheel moves last.

35_6.3.4.1 Translation Theory

There are two fundamental principles that allow the translation of gate position from the drill point hole to the drop in point. Wheels are linked by flys and drive pins. They always retain their exact spatial relationship with respect to gate position. A combination that is run to a virtual index marker (positioned at the drill point hole) will result in all gates physically aligning to that point. The relationship between each gate and the virtual marker can be transferred to the real index marker. If the location of the physical drop is identified, then a correlation can be established between it and the drill point drop in point. The radial difference is added to each number of the drill point combination.

35_6.3.4.2 Translation Procedure

It is a relatively simple matter to translate the actual combination from the individual wheel position as each disc is observed with the borescope. An example, using an S&G 6730 three-wheel lock, will illustrate the procedure.

In order to extrapolate the number sequence of the combination, each of the wheels must be individually rotated as if the proper combination was being entered. A virtual index marker must be drawn vertically through the viewing hole. The center of each gate is aligned with this line. As each gate crosses the field of view, the number on the emergency dial is noted. When the "drill point combination" has been run so that all three wheels are aligned to an imaginary or virtual fence, the numbers are

translated to compensate for the difference between actual and virtual drop in point.

The hole must be in the proper location to provide a clear view of the edge of each wheel. Then the first, second, and third wheels are rotated, based upon the turning sequence of the lock. This is generally left-tight-left. Each of the gates is brought into view just as if there were an actual fence present. Once all of the gates are aligned to the virtual fence, **add** the proper number to equal the radial distance from the drill point to the drop in point. The product is the combination that will open the lock.

There may be a variance of up to five numbers. This will depend upon the precision of the computation of the radial distance from the actual drop in. Numbers are **added** to the combination to move the gates to the left; **subtracted** to the right. Test the combination on the drill point index marker first in order to be certain that each wheel aligns properly. It is always prudent to write down the translation numbers. If the lock won't open, oscillate the dial rapidly to shake or jar the fence into the gates.

35_6.3.4.3 Potential Problems in Translation

There are several factors than can affect the accuracy of translation. All can be determined through a process of trial and error.

35_6.3.4.3.1 Handing

The handing is significant when a lock is to be drilled. The position of the case must be known to determine the drop in point. If the door is open, the handing may be determined by examining the bolt and the direction it extends. A right-handed lock is one in which the bolt faces to the right, away from the hinged side. A LH lock will be the opposite. In VD and VU orientation, the bolts will face down or up. Generally, whichever direction the door opens or swings to will reflect the handing of the lock. Thus, if the door swings outward to the right, it has a right-handed lock.

35_6.3.4.3.1.1 Handing Error

A handing error can occur if the technician misinterpreted the lock or safe data. If a mistake is made in the determination of

handing, then the drill point will be incorrect for viewing wheels and their gates. If the gates can be observed, the problem can be corrected without drilling another hole.

35_6.3.4.3.2 Dial Removed Without a Reference Marker

If the dial has been removed without placing an index marker on the dial ring or safe body, then there is no direct way to correlate the position of the gates with respect to the drop in point. To remedy this problem, utilize a cutaway lock as a calibration model, or create a template and translate the information to another lock. A template is made by overlaying a piece of paper on the face of the door. Be certain that it is square, using the spindle as an anchor. Punch a hole through the paper at the drill point.

Remove the paper and draw a circle from the center of the spindle. If the drop in point is known and the handing of the lock is determined, then the radial difference between the two can be computed using another lock as a model. If the physical drop is not known, it can be extrapolated. This is accomplished by aligning the drive cam gate with the drill point hole, then rotating the emergency dial until the left and right contact points are determined.

The contact points can be felt as the lever rides on the drive cam. The left contact is most significant and provides the location where the fence can drop into the gates. Simply adjust the drill point combination by adding the difference. Obviously, there may be a tolerance error because the drop in area will not be precise with respect to the lever fence.

In all S&G, Federal, LaGard, and Diebold locks, the most common drop is 97. The Yale OC5 is 80 and Mosler 302 is 91. The physical drop for these locks will always appear between 80-97. In many of the Asian locks and some produced by Sentry, the bolt retracts directly into the gates. In such cases, the physical drop is 75. In the older Yale OB locks, the physical drop is 50-52.

If there is no indication as to where the physical drop might appear, it should be assumed that it will fall between 50-97. Start with 97, then 91, 80, 75, 60, and 50. Add a window of ±5 to allow for variances. Remember that the physical drop is the actual location where the fence drops into the gates, and not a

dial reading or dial number. The **drop in area** or **dial indicator** is the left and right contact points and provides the range wherein the drop in point can lie.

35_6.4 Detailed Drilling Sequence Overview

Drilling is the preferred method of forced-entry. As described elsewhere, a safe is penetrated by drilling, resulting from many factors. The technique will vary, depending upon whether the safe is rated for fire or burglary. This is because barrier materials are constructed and designed differently, based upon the security of the container.

Regardless of the design of the safe, however, the basic drilling procedure is uniform. It is premised upon creating an opening in a strategic location through which access to a critical locking component can be achieved. The goal is to disable, bypass, remove, view, or neutralize that part which is preventing bolt retraction. Usually only one hole is drilled and entry is effected; then the hole is repaired. Of course, if the placement of the hole is incorrect, then additional intrusions will be required. In 1987, Philips received a patent for a method to drill a safe under the dial ring that would permit precise measurement and viewing of the gate positions (**4662201(405)**).

35_6.4.1 Safe Construction and Drilling

The construction of the safe will define drilling procedure. Most safes contain three primary layers of protective metal: the outer mild steel skin, hard plate barrier material to protect the lock, and a final mild steel layer to which the lock is affixed. In most cases, three bits are utilized for penetration. The mild steel outer barrier is drilled with a high-speed steel bit to the **edge** of the hard plate. These HSS drills should never be used for stainless or hard plate. Titanium carbide tipped or diamond drills are usually employed for cutting through the armor plate. On the backside of the hard plate, an HSS bit is again used to enter the lock case.

35_6.4.2 Drilling Sequence

The drilling sequence for the lever fence in a **Group 2** lock with a regular dial (a Group 1 lock uses a similar technique) is illustrative of the required steps in the process. In order to penetrate a container to neutralize the fence, the technician

must:

- **Inspect the safe;**
- **Set the dial to zero;**
- **Mark the zero point on the dial, for reference. This is accomplished by drilling through the dial with a 1/8″ bit so that the tip will mark the door corresponding to the zero point;**
- **Drill a 3/16″ hole in the center of the dial knob until the spindle is reached;**
- **Tap the hole with a ¼ x 20 tap into the spindle;**
- **Thread a ¼ x 20 screw until the dial separates from the spindle. A puller can also be used if the dial is made of zamak;**
- **Remove the dial and dial ring or reduce the diameter of the dial;**
- **Overlay a drill template and square it or make precise measurements from coordinates;**
- **Center punch the drill point;**
- **Position the drill rig and determine the depth of penetration for each type of barrier material;**
- **Using a high-speed drill, penetrate the first mild steel barrier, generally 3/16″-1/4″, until reaching the hard plate;**
- **Verify that the drill bit is entering the container at precisely a perpendicular or proper angle (if not at 90º);**
- **Enlarge the hole for clearance of a tungsten carbide bit;**
- **View the barrier material to assess its makeup. For example, determine if the surface is rough or discolored, indicating an alloy hard plate;**
- **Using a tapered drift punch, break up or create small carbide chips, disturbing an otherwise smooth surface;**
- **When using carbide bits, alternately punch and drill at a speed of 1200 - 2200 RPM, with applied pressure;**
- **Periodically check the bit to insure that it is still cutting. This is accomplished by examining the material being ejected from the hole. It should**

be very fine metal powder;

- **Once the hard plate has been completely penetrated, use a high-speed drill to enter the lock case. Use extreme caution once zamak or similar soft material is encountered. Ejection of white metal chips is evidence of this. Once the case has been penetrated, stop drilling and replace the bit with a sharp one;**
- **Slowly penetrate the lock case, then blow out the hole to remove all chips;**
- **Use an emergency dial connected to the spindle to control the wheel pack;**
- **Scope or feel the wheel pack and drive cam and rotate until the lever drops;**
- **Open the lock.**

35_6.4.3 Drilled Hole Size

Once the decision has been made to open a safe by drilling, consideration must be given to the diameter of the hole. Although a larger hole can afford more room to manipulate a borescope and other tools, it is also more difficult and time consuming to complete. The size of the hole will in part be based upon the tool used to create the opening: drill, hole saw, torch, thermic lance, or other technique. This in turn will be dependent upon the type of container, the lockout problem, the amount of accurate data available regarding the container, and whether the hole is to be repaired.

The rule of practice has always been a ¼” opening. However, such a hole has several disadvantages:

- **A small hole requires precision in locating the drill point;**
- **There is no tolerance for error, especially through a thick door, if the drill point has been calculated in error. This is even truer where drilling is at an angle or the drill has drifted;**
- **The tunneling effect when using an ophthalmoscope or otoscope is severe; it is compounded with a small opening. Without a borescope inserted into the body of the container, the view resembles that of looking through a drinking straw;**
- **A small-diameter drill bit has a weak shaft and will**

break or bend easier when under the pressure required to penetrate hard plate;
- **Enlarging a hole can be time consuming, difficult, and costly.**

Although a greater hole size can take significantly longer to achieve, there are several advantages to a 3/8″ or larger opening, including:

- **Measurement errors can be overcome and the target area still observed or manipulated;**
- **Errors in angled drilling may be remedied;**
- **Bits will not be so likely to break under pressure;**
- **Room to manipulate internal components, especially relockers and bolts, can mean the difference between a successful opening and failure.**

A preliminary determination should be made as to the tools that will be required to pass through the hole in order to open the safe. If a hole is made solely for scoping the wheel pack or other components and the borescope allows for an angled view, then the size of the hole becomes far less critical. The diameter can be just slightly greater than that of the scope. If, on the other hand, relockers, bolts, levers, or other components must be physically manipulated, then a larger tool and leverage may be required.

35_6.5 Hard Plate Barrier Material

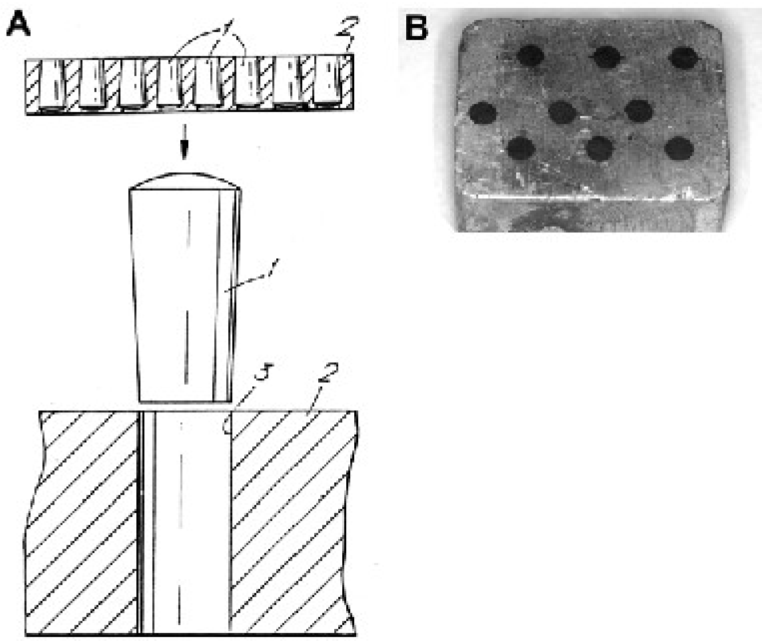
35_6.5.1 Introduction

Hard plate is a specially formulated metal that is used to protect the lock, boltwork, and relockers from drilling. The material can be extremely hard, often having a Rockwell C rating approaching 90 or above. Hard plate can also be a combination of hard and soft metals. This discussion will address anti-drilling features incorporated into most types of barrier material, as well as drilling technique that must be utilized with these metals. See **Chapter 5** for a detailed analysis of the metallurgy involved in the formulation of tempered hard plate.

Hard plate is known by many names, depending upon the manufacturer: Relsom (Mosler), Maxaloy, Kimloy, aloxite (Chubb). The composition can be case-hardened, laminates, or plastic

polymers, and incorporate other materials for secondary protection. There is a class of hard plate known as "superalloys," based upon their exotic mixture of additives. These are employed in very high-security containers. Interestingly, the metals are not as hard as hardened steel but have optimized high-strength with deformation characteristics. This will allow them to deform plastically when pressure is applied during cutting.

The characteristic of **plastic deformation** explains a condition that is encountered by safe technicians when drilling these materials. The condition is identified by the appearance of a small, bright conical indentation within the hole being drilled. The crater is caused by the application of pressure from a hard drill bit that actually rearranges the work surface. A small amount of metal is actually removed during drilling; its position is simply altered.



All hard plate is designed to accomplish one primary task: prevent penetration or cause significant delays in the process. Differences in each product, or even each within a batch from the same manufacturer, may present varying levels of difficulty in drilling. This can be based upon the ratios of chrome, tungsten, carbon, nickel, and other elements. Characteristics of hard metals are dependent upon complex and sophisticated metallurgy that may take years to develop. Regardless of origin, the material will provide significant resistance to drilling, abrasion, concussion, and heat. Special tools and procedures are required to penetrate it.

Hard plate is generally placed between the lock and the front of the door, mounted either vertically or at an angle of up to 15°. The barrier, usually ¼"-3/8" in thickness, will protect critical components from attack. Fire safes generally have a barrier of no more than 1/8" because the goal is to protect against fire and not burglary.

35_6.5.2 Overview: Metallurgy of Hard Plate

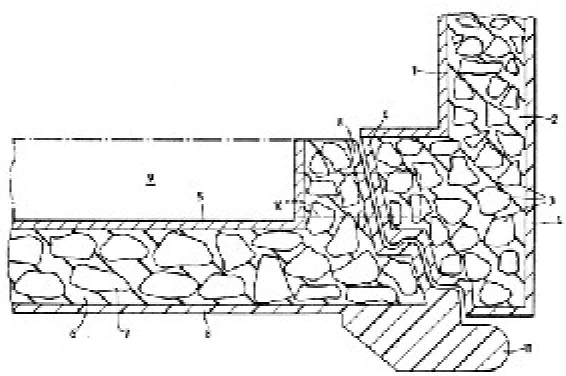
The principles of metallurgy that form the basis for the development of hard plate is discussed in detail in **Chapter 5** but will be summarized here. Metals are hardened in many different ways. Each technique utilizes different processes involving the absorption of carbon (case-hardening), as well as heat treating and quenching. The method of hardening will in part dictate the procedure for drilling. Case-hardening, for example, will only

affect the skin of the material, but not the center. See **Chapter 3** of Price for a historical reference regarding the use of case-hardening in safes.

Usually, cold rolled plate steel is placed within a furnace in an atmosphere of oxygen or nitrogen for a precisely controlled period. Carbon, ammonia, and other elements and compounds may be added. The material is cooled or quenched to complete the hardening process. The hardness of the steel is primarily dependent upon its chemical composition (iron and carbon). Alloy steel will contain other materials such as nickel, molybdenum, and chromium. These metals will add special characteristics, detailed in **Chapter 5**, and will be classified according to a numbering system developed by the Society of Automotive Engineers (SAE). This protocol, using a four-digit number, will define the type of metal and carbon content.

Hard Plate Alloy is a unique blend of metals used for high-security containers. It should not be confused with alloys that are mixed with hard plate to enhance the strength or hardness characteristics of the metal.

"**Included Hard Plate**" contains a layer of ceramic, bronze, epoxy, or other metals. Within this layer are included a matrix of small chips or pieces of cobalt, cemented tungsten, tantalum, titanium carbon grains, carbide, aloxite, nickel, or other materials.



Their consistency and density forms a coarse and jagged skin that presents an irregular surface to a drill bit.

Laminates may form a sandwich of hard plate with soft steel, copper, and other metals. Each layer will provide unique protection against a form of attack.

Spattered hard plate is steel coated with tungsten carbide or T/C, brazed or welded to the surface.

Ceramics comprise another group of barrier materials. Characteristics of ceramics provide drill resistance and heat deflection.

Composite materials will contain high tensile-strength concrete and steel. The more sophisticated of these will be mixed with hardened pins, ball bearings, ceramic balls, chips, deformed steel rod, and other materials.

35_6.5.3 Anti-Drilling Techniques and Materials

Many improvements in barrier materials have occurred during the past two centuries to frustrate drilling. Originally, the concept was to protect the door with laminations composed of iron, laced with studs. Then, steel was employed with hardened discs that were free to rotate. Case-hardened plate was also placed behind the keyhole for added protection. Chubb has continued to lead the industry in methods to make barrier materials more resistant to attack. See for example their process for producing an anti-drill barrier structure for safe or strong room doors or walls (GB **2153406A(406)**) granted in 1985. Other relevant patents include (GB **2197362A(407)**) issued to Chubb in 1988

Today, a variety of materials and techniques are available to make penetration by drilling and other forms of attack extremely difficult. Barriers utilize metals having high Rockwell C ratings. Layers of aluminum, mild steel, high-density concrete, and manganese provide additional resistance. Randomly embedded ceramic or metal nuggets, anti-drill closely spaced arrays of carbide pins, balls, rods, discs, or loose or pressed ball bearings also make drilling difficult. Bearings that are free floating will generally be suspended in oil.

Metal chips can also be welded to the surface of hard plate to make drilling extremely difficult. Mosler, which produces a barrier material, utilizes this technique. Sophisticated heat sinks using beryllium and copper plates, or metals with similar characterizes, are employed to draw high temperatures away from an area that has been attacked by a torch or red-hot drill point. Various mechanical obstructions can also impede drilling. For example, the **Deflector** is incorporated within high-security Chubb safes to deter drilling. This is actually a piece of angled steel that is placed in strategic locations to prevent a drill bit from penetrating critical locking components.

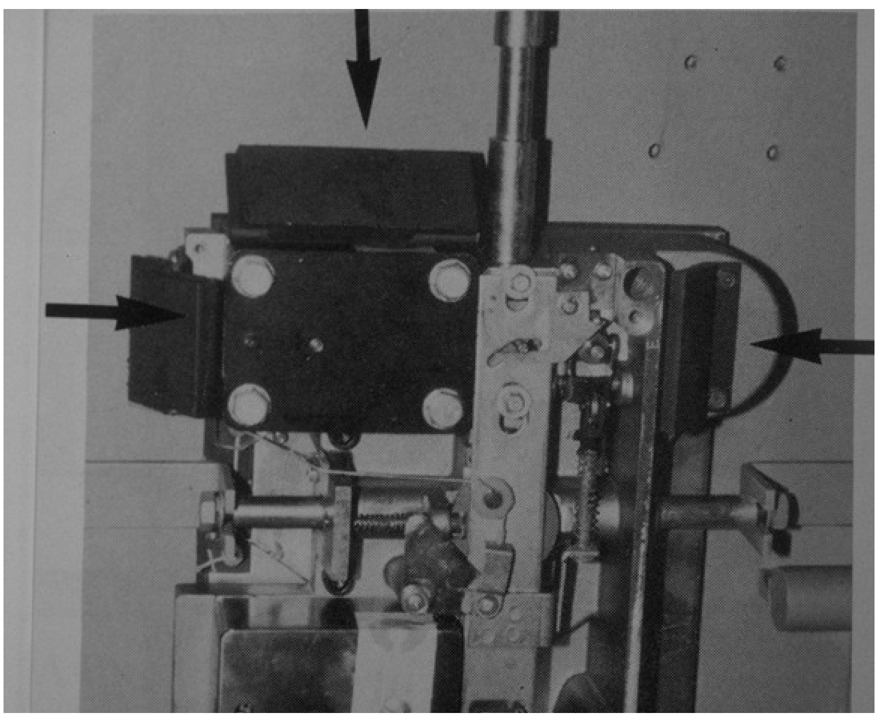


Figure LSS+3538 (ISP 23-2963) Deflector plates made of angle iron are added to deter drilling.

35_6.5.4 Penetrating Hard Plate by Drilling

Depending upon the material, there are several basic approaches to the penetration of hard plate. However, all principles of drilling are based upon **speed, pressure, and stability**. Their proper combination will cause the drill to become hot enough to melt or anneal the barrier, allowing removal of material from the hole. Drilling technique is also based upon the type of drill employed. Cutting techniques for each bit is discussed subsequently. A description of the different types of bits was covered earlier in this chapter.

35_6.5.4.1 Speed

Speed is dependent upon the material and is identified as low (0-600 RPM), moderate (600 - 1500), and high (2000 - 5000). Drilling speed is of prime importance in the penetration of hard plate. It controls the way in which the bit attacks the metal, how much metal is removed, and the life of the drill bit. The differences in hard plate and drill tips will determine speed.

There is a divergence of opinion as to the most effective way to penetrate hard plate. One theory holds that extreme speed and pressure is the optimum technique. The other theory requires that controlled pressure with low speed will yield the best results. Both methods work. Personal choice dictates the approach that is taken.

35_6.5.4.1.1 High RPM Drilling

High-speed drilling requires that the drill motor is operating at 4000 - 5000 RPM and that it is accompanied with high pressure placed on the bit. When the two functions are combined, friction and heat are the products. The heat, in turn, will anneal or soften the work surface so that the red-hot tip will be more efficient at cutting.

Once drilling has commenced, it should be continued until the hard plate has been completely penetrated. If drilling is interrupted, then the material can become heat treated and hardened. A balance must be reached because the carbide tip can become brittle and shatter or may soften and lose its ability to cut.

35_6.5.4.1.1.1 General Guidelines for

High-Speed Drilling with Carbide-Tipped Bits

The following general rules apply to high-speed drilling:

- **Only use a carbide bit to penetrate treated metals;**
- **Be certain that the bit is not dull in order to optimize cutting and reduce the generation of heat;**
- **Use a high-quality bit with brazed, rather than soldered tips. The plating finish will be gold in color;**
- **Insure that the bit has a positive rake for tempered steel and a negative rake for alloy hard plate;**
- **Create friction and heat through the application of the proper amount of pressure;**
- **Stop drilling when the hard plate has been drilled through;**
- **Do not use a carbide bit to penetrate the lock case;**
- **Be certain that there is a controlled pressure feed to avoid damage to critical components;**
- **Only penetrate alloy hard plate using high speeds.**

35_6.5.4.1.2 Low RPM Drilling

Low-speed drilling generally falls into the range of 500-2000 RPM. A drill motor with high torque is required to compensate for the decrease in speed due to the applied pressure. Usually a four-ampere or higher motor is necessary with fixed speed, or a gear drive change for speed ranges.

Speed is a function of pressure; to optimize both can be somewhat tricky. Perhaps the best indication is the continuous ejection of metal filings from the hole. Tempered steel drilling requires sufficient pressure to cause the bit to cut metal. Bits can utilize soldered rather than brazed tips, because the generated heat is diminished. Although the drill bit will have a greater tendency to catch and break, less expensive bits can be used successfully.

35_6.5.4.1.2.1 General Guidelines for Low-Speed Drilling with Carbide-Tipped Bits

- **Drill motors must be relatively stable to eliminate wobble and drill misalignment;**
- **Inexpensive drill bits can be used;**
- **Utilize high pressure on the bit;**
- **Utilize a drill rig if possible, rather than a handheld motor;**
- **Optimum speed and pressure will result in a continuous curl of metal being ejected from the hole;**
- **Do not penetrate soft metals with carbide bits;**
- **Do not penetrate alloy hard plate at low speeds;**
- **Most barrier materials can be drilled at 1000-1500 RPM, with a properly sharpened bit;**
- **If attempting to drill through the Chubb aloxite barrier material, low RPM and high pressure is recommended.**

35_6.5.4.1.2.2 General Guidelines for Drilling with HSS Bits

If a high-speed steel bit is to be used for penetrating alloy hard plate, the following guidelines apply:

- **Prevent excessive heat that can cause work-hardening of the material. This can be accomplished by controlling drill motor speed and the drill rate. Generally, an accepted rate is 40 - 50 surface feet/minute (SFM). The formula to compute speed is based upon the drill bit diameter. Thus: RPM = 3.8 (SFM/DRILL DIAMETER IN INCHES);**
- **Use caution to avoid fracture or breaking of the bit;**
- **Sharpen the drill bit with an included tip angle from 135º-140º and a clearance angle of 6º-8º;**
- **Do not allow the drill bit to run in the hole without the application of pressure;**
- **Cobalt drills can be run approximately twenty percent faster;**
- **Carbon steel drills should be operated at forty to fifty percent slower rate;**
- **Use cutting fluid, if possible.**

35_6.5.4.2 Pressure

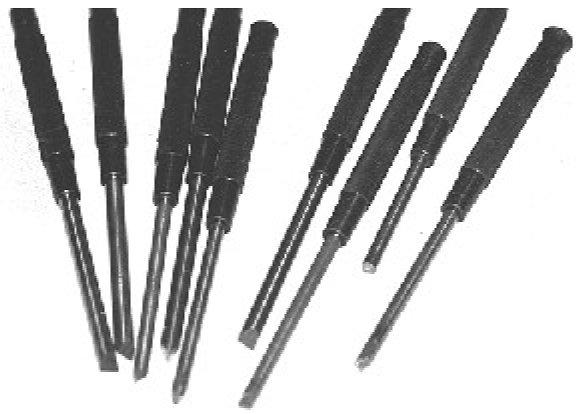
Pressure is a critical component of the drilling process. It controls how a drill bit cuts and the temperature that is created during penetration. Improper pressure will cause bits to fail and break, thereby sealing the hole. Fracture can also occur as the bit breaks through the hard plate.

Sufficient pressure is required to begin the cutting process on the outer surface of the hard plate. Usually, the more pressure, the better, although this is not always the case. However, the larger the bit, the more pressure that is required. The best rule in determining the proper amount of pressure: listen to the drill motor. Pressure is a function of speed. Tungsten, cobalt, and carbide-tipped bits require high pressure, together with speeds between 2000-5000 RPM. Drilling angles are usually set at about 15°, depending upon the thickness of the material.

35_6.5.4.3 Drill Motor Stability

The stability of the drill motor is extremely important for many reasons:

- **Prevent failure of drill shank and tips;**
- **Allow application of proper pressure while drilling;**
- **Allow for the proper generation of heat caused from the interaction of the drill tip to the work surface;**
- **Reduce the danger of injury to the operator.**



35_6.5.4.4 Drilling Technique for Hard Plate

Hard plate requires special drilling technique due to the toughness of the material. Two primary rules apply: **the drill bit must be harder than the hard plate, or the hard plate must be altered to allow cutting by the drill.** Pilot holes should not be made in hard plate, especially if using a handheld drill. The irregular surface and small bit diameter will cause the shaft to flex and break. Generally, red-point drilling (that anneals the material) is required. A punch is also employed prior to the use of the drill, in order to shatter the carbide and ceramic bits that are bonded to the surface of the hard plate.

Once drilling begins, there will come a time when progress is

slowed. At this point, a punch is again employed to shatter the hard chips. This may require several blows. Drilling is resumed. The process of alternating between drilling and punching takes advantage of the brittleness of the barrier material to fracture it, allowing the bit to penetrate.

Standard punches can be utilized if there is a means for sharpening them during the drilling process. Pieces of drill rod, flame-tempered until straw in color, can be immersed in oil to make a hard punch. A hammer drill, with an impact bit or star drill, will also work.

Steel ball bearings may be embedded in the hard plate. These can be loose, either suspended in oil or pressed. In such a case, they must be hit with the punch to stabilize them, then drilled.

35_6.5.4.4.1 Drilling Alloy Hard Plate

Drilling in wood, mild steel, and tool steel has little resemblance to penetrating hard plate. Drilling of alloy hard plate requires special procedures because of the usually rough surface of the material. The following guidelines apply:

- **Be certain that the drill bit is harder than the material to be penetrated;**
- **Prepare the surface prior to drilling. This requires that any rough texture is smooth or flat and any irregularities such as chips are removed. Failure to do so will destroy the cutting edge of the drill bit;**
- **Chips are brittle and can be hammered and punched until they are broken and can be removed. Use a**

flat-end drift punch and a two or three-pound hammer, followed by a center punch;
- **Both positive and negative rake bits can be used, although negative is recommended;**
- **Alternate between punching and drilling;**
- **Do not use a slow drilling speed. This will avoid catching the tip on the work surface;**
- **Do not use high speed unless quality bits are employed. Otherwise, a mid-range speed of about 2000 RPM is optimum;**
- **Controlled high-pressure is required. This can only be provided by a lever or fixed rig;**
- **Keep the drilling sequences of short duration, generally no longer than thirty seconds;**
- **Continually check the cutting tip and depth progress;**
- **If a very fine metal dust is produced, the pressure must be increased or a new bit installed;**
- **Few chips will be created during drilling; this is normal.**

35_6.5.4.4.2 Included Hard Plate

A "punch and drill" protocol is required for these types of materials, using motor speeds of between 1000-1500 RPM. Masonry or a die-marker type bit should be used initially to make an indent in the surface. Then, a punch is placed in the hole and struck with a sledgehammer in an attempt to fracture the surface. Drilling is resumed. The process is repeated until the hard plate is penetrated.

35_6.5.4.4.3 Splattered or Welded Hard Plate

A combination of techniques previously described may be used with this material at a drill speed of 1500-2000 RPM, and moderate pressure. Red-point drilling is not required.

35_6.5.4.4.4 Composite Materials

A fixed drill rig is required for penetrating these materials. Utilize HSS, masonry bits, cobalt, TIN coated bits, hammer drills, or a thermic lance. Composites can be exceedingly difficult to drill and usually have secondary layers of barrier

materials for added security.

35_6.5.4.5 Red-Point Drilling

Red-point drilling is a process that anneals the work surface to make it less resistant to penetration. The procedure generally requires high drill-motor speeds, coupled with moderate pressure using a carbide bit. The result is a rapid generation of heat, causing the tip and work surface to become red-hot.

35_7.0 Detailed Drill Point Information

35_7.1 Introduction

Holes allow observation or manipulation of critical components. The lock or safe body is penetrated to accomplish a specific goal, based upon the design of the container, barrier material, its condition, previous entry attempts, security rating, and type of lock. The following discussion describes all of the traditional drill points (whether inside or outside the dial ring), as well as special application notes where relevant.

35_7.2 Specific Drill Point Identification: Inside or Outside the Dial Ring

The following discussion provides detailed information regarding all drill points used for the penetration of safes. Drilling can be defined within two distinct categories: **inside**, or **outside** the dial ring. Drill points outside the dial ring can be further subdivided: drilling **within the door area**, and **all other places** within the container. The decision as to where to drill is based upon many factors, including:

- **The container;**
- **The lock;**
- **Reasons for penetration;**
- **Personal preference and experience;**
- **Cost and benefit of each method or technique;**
- **Opening strategy.**

Drilling within the dial ring is required in order to obtain a view of critical locking components or to neutralize them. Each

of the recognized techniques is described below. Drilling outside the dial ring is generally performed to manipulate, view, or bypass the bolt works or relockers.

Generally, a hole is made under the dial ring if the dial cannot be removed, the lock cannot be identified, or the physical drop cannot be determined. Once a hole is placed in the correct location, the gate positions are read and translated to the physical drop. If the drop in point is also unknown, a correlation is computed between the hole and cam gate. Our discussion will identify all drill points that are available for successfully penetrating a security container, without differentiating whether they are inside or outside of the dial ring.

35_7.2.1 Bolt

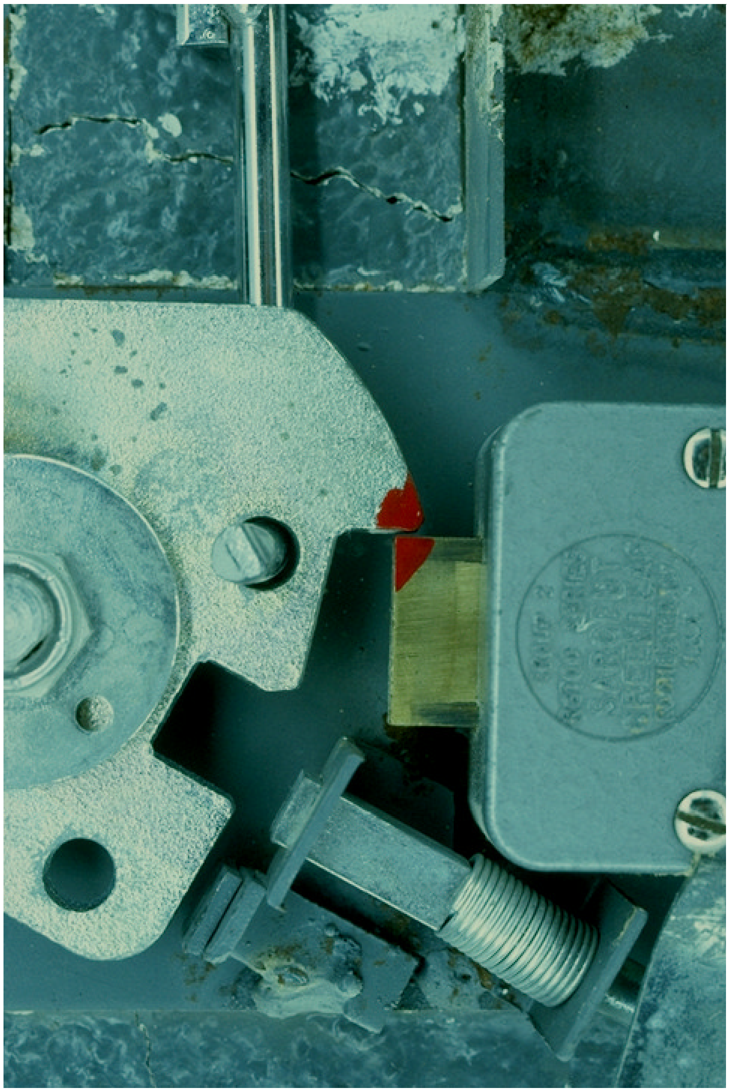


Figure LSS+3539 (ISP 104-3563) The bolt is punched out of the way (shown in red) in order for the handle cam to be rotated.

A hole may be made to the side of the bolt in order to accomplish three tasks:

- **Manipulate or punch the locking bolt out of the way;**
- **Permit the locking cam to be rotated or moved;**
- **Force the bolt, through the application of**

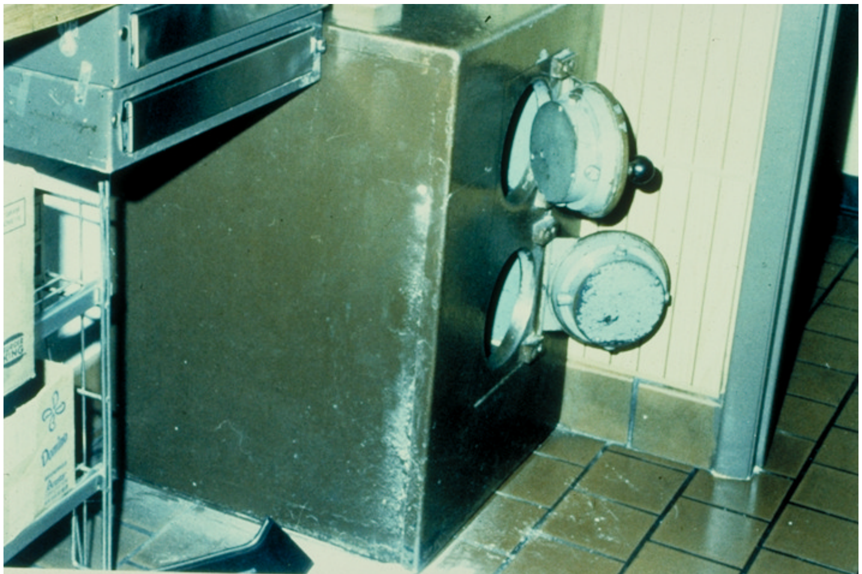
pressure.

35_7.2.1.1 Pressure Applied to Bolt works

Penetration through the side of the safe is standard procedure when there is a mechanical linking problem that prevents the handle or other mechanism from actuating the bolt. In some inexpensive safes with a direct-entry fence, the connecting piece fails, causing the handle to spin freely. The same opening procedure can also be applied to a fired relocker. The container is side-drilled on a line equal to the centerline of the dial and handle, and toward the rear, a couple of inches. A ¼″ hole is made, and a punch or long rod is used to push the bolt to the unlocked position.

If a punch fails to move the bolt bar into the door, a larger hole should be made and then tapped. Use a grade 5 bolt, forcing it forward as with a dent-puller. This method can also be employed to dislodge the lock and relockers. When this technique is employed, care should be exercised not to apply pressure to the bolts near the top or bottom of the bolt bar, as bending may result. Target the bolts closest to the lock.

If the location of the bolt cannot be determined, check the jamb for paint chips or markings. Bolt width for most standard combination locks, including S&G, Mosler, and LaGard, is precisely 1″; the door bolts are generally ¾″ to 1″ in diameter. Although most high-security containers include protection to neutralize side pressure applied to the bolt, the procedure can be used to bypass glass plate, relockers, and hard plate barrier materials. In some instances, a small safe can be moved or vibrated so that gravity can remedy the problem of a broken link. This is not, however, a reliable method in all cases.



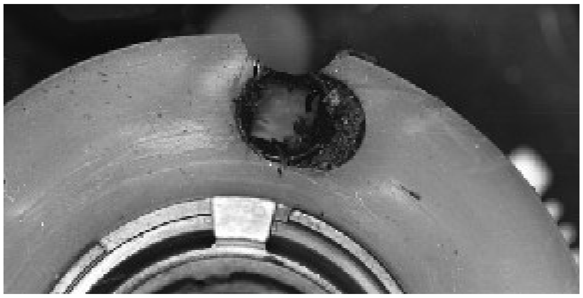


Figure LSS+3540 (top left, ISP 2-2963; right 3-2963; bottom left 5-2963; right 6-2963) In 2,3 above, burglars drilled into the side of the safe to punch and drive the bolt out of the way. The same procedure was utilized in 5,6. Courtesy of Illinois State Police, Bill Sherlock.

35_7.2.2 Creation of Gates

An infrequently used procedure allows for the creation of a completely new set of gates in the wheel pack. This is

accomplished by drilling a hole through the edge of all wheels to allow retraction of the fence.

35_7.2.3 Change-Key Hole

Use of the change-key hole for reading wheels, by Harry Sher

All modern programmable mechanical locks have an opening directly into the wheel pack through the back of the lock case. This aperture provides a view of the gates of each wheel, eliminating the need to make a hole through hard plate barrier material and obviating the hazard of triggering a glass relocker. This method of entry eliminates penetration of the door, and the attendant need to replace the lock. Some safe technicians will drill directly through the **front** of the lock, at the precise position opposite to the change hole.

The change-key opening can also be probed using a borescope in order to view and decode the wheel pack. A drill point must be located that will allow the borescope to view the back of the lock case through the keyhole. Depending upon the angle of entry, a 90° viewing angle for the borescope may be required. A hole can also be drilled through any side of the container in line with the change-key entry point in order to accomplish the same result. This procedure can eliminate the requirement of drilling through hard plate.

Prior to drilling for a view of the wheel pack from the side of the safe, the following information must be determined:

- **Door thickness to the back of the lock case. There is often a metal strip called a "door stop," to prevent the door from swinging inward too far. A thin ruler or sheet of plastic can be slid into the crevice between the door frame and door in order to**

determine its thickness.

A precise method for determining door thickness requires that the dial be pulled from the spindle. Be certain that the drive cam is against the lock case cover, by pushing the spindle inward. A thin wire is inserted next to the spindle until stopped by the drive cam post. Add ¾" to the length of the wire in order to compute the dimension between the door face to the back of the lock case for an S&G. It is often wise to add another 1/8" to account for the thickness of the case covers and spindles that may have been cut slightly longer than required.

- **Handing of the lock. The shape of the change-key hole appears like an arrow, and will point in the direction of the locking bolt. In this manner, the handing of the lock can be determined;**
- **Internal layout of the boltwork;**
- **Location and design of relockers;**
- **Interior design of the safe;**
- **Critical components or obstructions;**
- **Position and mounting of the safe;**
- **Location of the hinges.**

The procedure to determine the combination from the change-key hole requires:

- **Alignment of the square holes in the wheels so that they are in line with the change-key hole to provide the combination to the change index, then correlate the reading;**

- **Alignment of the gates at the change-key hole, beginning with the wheel closest to the probe.**

A video camera head attached to the borescope allows this procedure to be performed without difficulty. Otherwise, the scope must be placed within arm's reach of the dial, so that the wheels can be rotated while observing them.

35_7.2.3.1 Obstacles and Difficulties

Hard plate between .375"-.5" will often be placed at the back of the door to which the lock is affixed. There may also be a plate that covers the lock or there may be an air gap of up to ½". If

the drill point is not positioned correctly, the scope may be outside of this plate and adjacent to the lock. This will make viewing almost impossible. Poor lighting or the angle of view can cause translation errors, too. This can result in greater difficulty in alignment of the gates.

Locks with the drive cam next to the rear cover can pose added difficulty. In such cases, once the first wheel has been decoded, the discs behind it are obstructed from view. The cam must then be read at the change index line. This wheel will constitute the **third number** of the sequence. The second and third wheels are actually read through the gates and require special positioning of each disc during the decoding process.

The process requires an understanding of the relative position of the **gate**, **change hole**, **balance hole**, and **rivet** on the wheel. The gate and change-key hole are always fifty numbers apart. The rivet in the center of the wheel is equidistant between the two (twenty-five numbers from either). The balance hole is approximately ten numbers from the gate. Knowing the reference markers can make the process of decoding these locks straightforward.

Although necessitating replacement of the lock case, some safe technicians will drill the lock from the front at the opposite side of the change-key hole. This will provide a direct view, allowing wheel alignment in the normal sequence. A modified change-key is then inserted through the door and into the lock. The wheels are unlocked and set to a single number for opening. High-security Group 1 or 1R locks can contain non-metallic wheels made of synthetic materials. White plastic or other polymers can present a problem in viewing due to the lack of contrast.

35_7.2.3.2 Alignment of Gates v. Change Hole

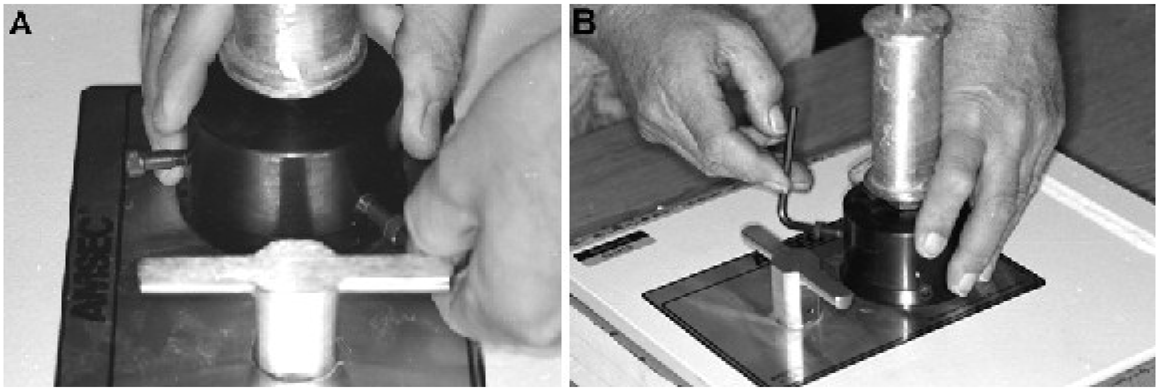
Both the square change hole and gates can be aligned to derive the combination at the index line. If the square hole is chosen, simply decode the combination. Then factor in the radial distance between the changing index and the zero-index marker to determine the correct number sequence. The wheel gates and the change hole are 180° apart (fifty numbers). If the change hole were positioned at 10 on the index line, for example, then the true combination would be 60 at the zero marker.

35_7.2.4 Drilling Within the Dial Ring

A full-sized dial ring will cover all of the drill points within a lock case that are traditionally utilized for scoping or neutralization of components. In older safes, an exploratory hole can be made through the ring to determine the position of the physical drop. It is necessary to drill through the dial ring when working on old locks with brass and steel dials, because they cannot be removed. In certain cases, the only facts that may be known about a safe are:

- **The absence or presence of a change-index marker on the dial ring;**
- **Whether there are numbers between 0 and 20;**
- **Whether the dial can be removed;**
- **Whether there are any welds on the container.**

A small hole for a probe will reveal the location of the gates, and the type of lock.



35_7.2.4.1 Overview of Drilling Procedure

Two critical drill points can provide information sufficient to open the lock. In the S&G, these are at 14 and 36. Generally, holes are angled to the left and downward toward the center of the dial. The optimum exit point will fall below the mounting screw, yet at the edge of the wheel pack.

Care should be taken to execute a proper angle of entry. This will avoid missing the lock entirely, or obtaining a view of the wheels that yield no information. If the angle is incorrect, redrill through the same hole. The actual angle will be dependent upon two factors: door thickness, and the position of the lock.

35_7.2.4.1.1 Dial Removal

The above-described procedure usually requires that the dial be removed or modified to allow clearance for the drill. There are four primary means for accomplishing the task. Certain dials cannot or should not be forcibly removed from their connecting shafts because they are threaded and pinned to the spindle. If pulling is attempted, the dial, drive cam, and internal components of the lock will be destroyed.

35_7.2.4.1.1.1 Excessive Force

Do not use excessive force. If the dial cannot be pulled easily, utilize other means of removal. Do not pull if the following conditions exist:

- **The dial is made of brass, bronze, steel, or resists pulling efforts;**
- **The dial is not made of zamak;**
- **Dial is on a TL rated container;**
- **A Manipulation-proof lock such as S&G 8400 or 8500 series, where the butterfly and inner spindle must be used for opening;**
- **Dial that is threaded or pinned to the spindle.**

Failure to adhere to these guidelines can result in:

- **Damage to the spindle;**
- **Damage to the lock;**
- **Damage to lock case;**
- **Spindle breakage below the surface of the door;**
- **Loss of contact between the drive cam and the last wheel.**

35_7.2.4.1.1.2 Pulling the Dial

Most dials can be removed with a pulling tool described in **Chapter 32.** Dial or dent pullers utilize a sliding weight to exert a counterforce that is sufficient to separate the dial from the spindle shaft. Generally, the process used by the

manufacturer for affixing the dial involves pressing of the straight knurled end of the shaft into the soft metal (usually zamak) dial.

35_7.2.4.1.1.3 Center Tapping

Dials can also be removed by tapping a hole in the center, just to the end of the spindle. A ¼ x 20 bolt is then utilized to forcefully withdraw the dial by screwing it in and tightening it against the spindle. This method reduces the possibility of warping the lock case.

35_7.2.4.1.1.4 Prying Loose or Breaking

Use one or two screwdrivers, sharp wedge, or a chisel placed under the dial to slowly pry the entire assembly upward. The dial should be rotated to insure that a constant and equal force is applied. A sharp chisel and hammer can also be employed to crack the dial and break it apart, or vice grips can be used to rock the dial loose.

35_7.2.4.1.1.5 Reducing the Dial Size

If the dial cannot be physically removed, then its diameter must be reduced using a 1½" hole saw. This method will provide drill point access behind the numbered portion, by separating it from the nose of the dial. The procedure also makes repair of the door easier, without the necessity of welding, grinding, or repainting. Prior to performing this procedure, the following steps must be accomplished:

- **Note the left and right contacts points;**
- **Mark the zero point of the dial on the center of the nose and on the face of the door;**
- **Rotate the dial four times right to pickup all drive pins, thus preventing them from slipping when the dial is removed;**
- **Prevent the dial from moving by wedging a small screwdriver underneath the lip;**
- **Certain drill rigs require a reduced nose diameter, to approximately 1 1/8", in order to accommodate the template. A die-grinder can be used for this purpose.**

A standard hole saw without the pilot bit is utilized with a

variable-speed drill. Care should be exercised that the drive cam is not suddenly rotated, thereby damaging drive pins and flys. Saw evenly around the dial.

Note that zamak is an alloy of relatively soft metal. Generated heat will have a tendency to cause the material to become spongy and clog the teeth of the saw. This results in binding and grabbing of the dial. Cutting should be accomplished in short bursts to minimize the potential for damage to the lock and insure the safety of the operator.

35_7.2.4.1.1.6 Emergency Dial

An emergency dial may be required for use with a burglarized safe where the spindle has been broken and the dial and dial ring have been removed. If the spindle can be turned and the lock has not been damaged, an emergency repair dial can be utilized to rotate the wheels. The safe technician should carry dials with different shaft diameters for this purpose.

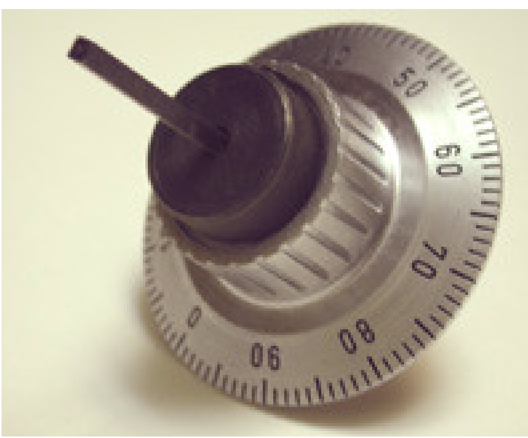


Figure LSS+3504 Emergency dials

The emergency dial has three components: the main body (knob and pointer ring), a moveable number ring, and a square rod with a pointed end. Generally, the number ring is secured on the pointer ring with a setscrew. The rod is removable from the knob and its length is adjusted with a setscrew. A round nut with a soft wire pointer, tapped to accept a specific spindle thread, can also be used as a dial. In such case, a number template must be utilized to simulate a normal dial.

In order to use the emergency dial properly, the contact points must be known. Once the dial is attached, it is turned to the right to feel the contact area. Once determined, the knob is

placed at the precise location of the right contact, and the number ring rotated and locked to that position. A note of caution: if the dial must be hammered onto the spindle, the spindle should be isolated with a wedge or vice grips prior to exerting force. This will prevent driving the spindle into the lock case, which can result in knocking off the back cover and triggering a relocker.

35_7.2.4.2 Scope the Wheels

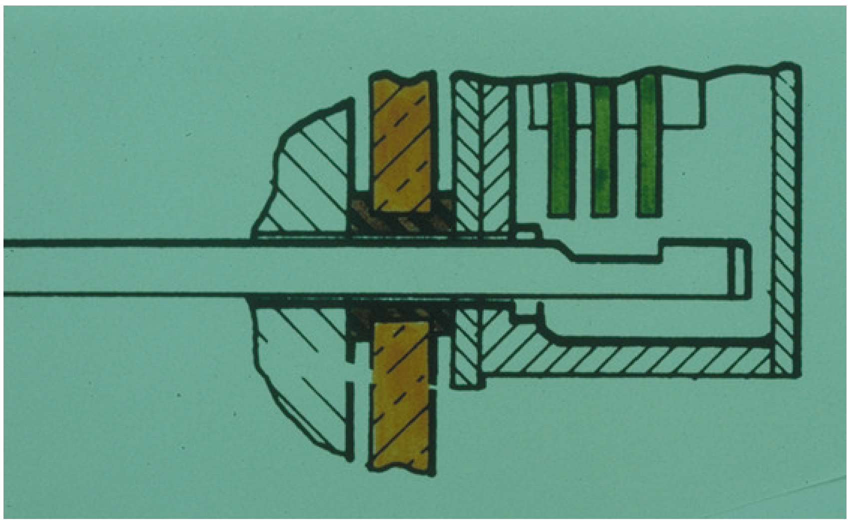

Figure LSS+3541 (ISP 17-2963) A scope is inserted to obtain a view of the wheel pack.

A hole can be made almost anywhere under the dial ring for scoping the wheels. The view will provide the location of the gates, so long as the hole is near the edge of the discs. The preferred location on an S&G lock is at 14 or 36, with a slight angle toward the center.

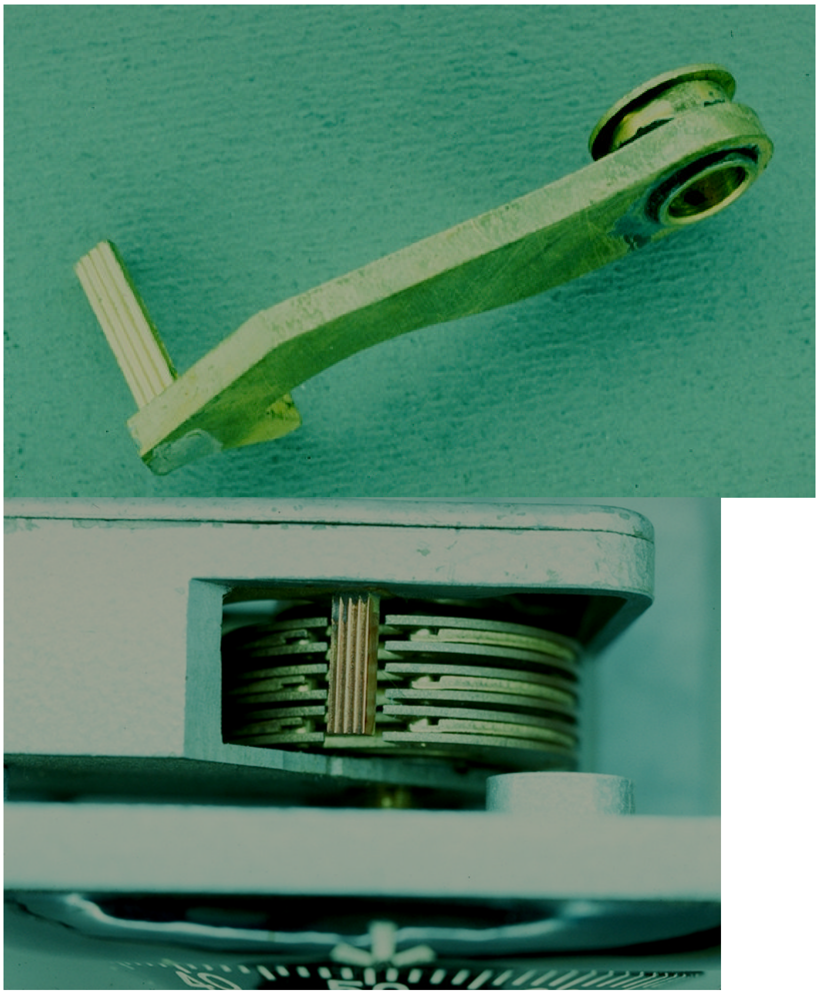
35_7.2.4.2.1 Feeling Wheels and Gates

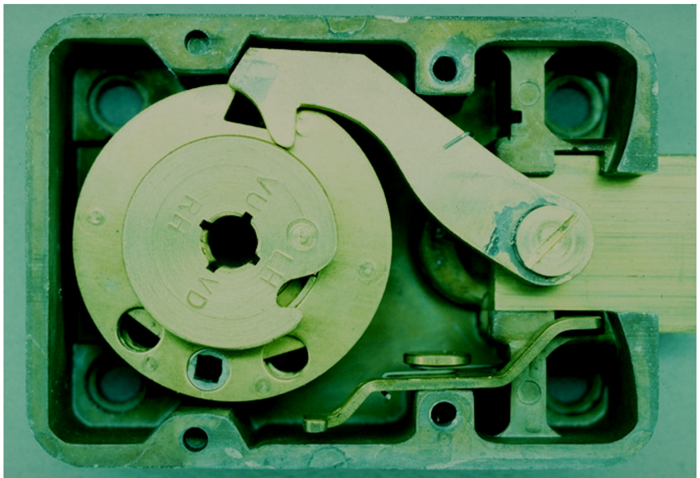
When a borescope or other optical device is not available, a feeler probe may be used to obtain a tactile response. This allows the technician to determine gate position and to physically move wheels. A probe is inserted into the hole and pressed against each wheel, in the same fashion as if an optical device were being used. To determine the position of each gate, the wheel farthest from the drive cam must be probed first. As each disc is rotated, the device is pushed forward to read the

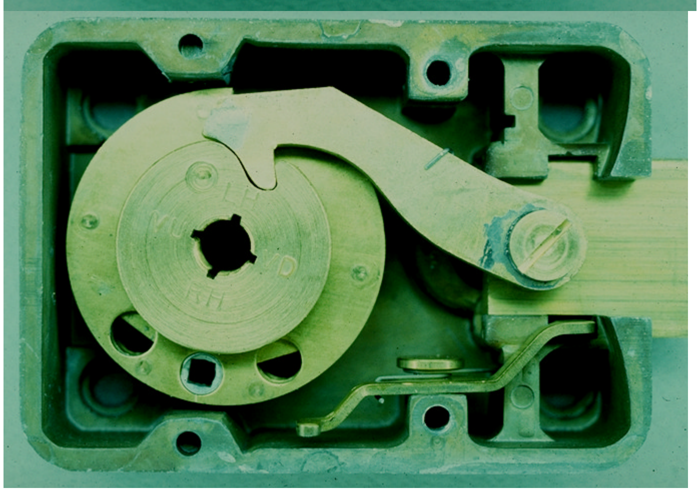
next gate, until the wheel pack has been completely decoded.

35_7.2.4.3 The Fence

There are two procedures pertaining to the fence: **scoping** and **drilling.** The first involves observing it and the position of the gates. The other procedure allows it to be removed by drilling, thereby freeing the lever to drop into the drive cam.







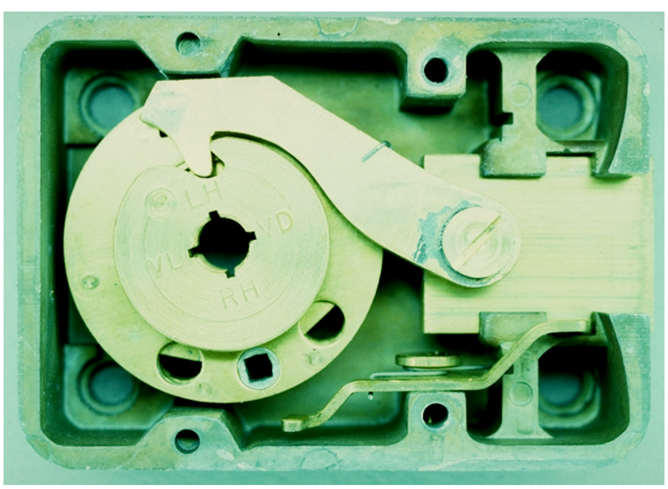


Figure LSS+3542 The fence is a prime target for drilling, either the soldered link or the actual
fence material. (Photo ID ISP 82-3563 left, and 83-3563 right).

35_7.2.4.3.1 Scoping the Fence

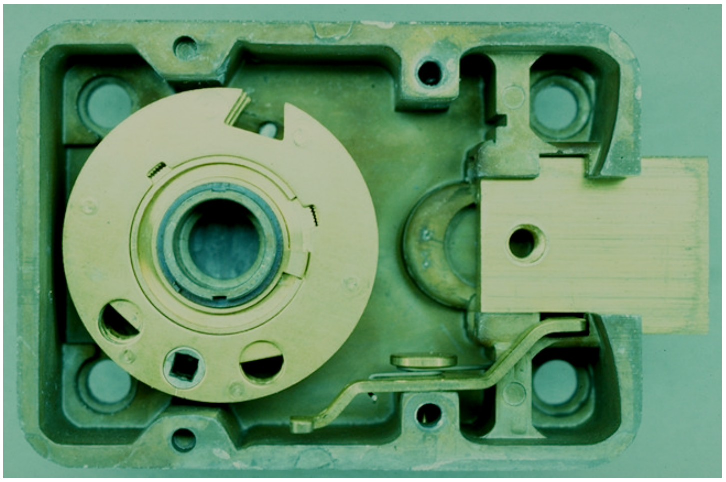

Figure LSS+3543 This series of photographs shows the progression of movement of the fence
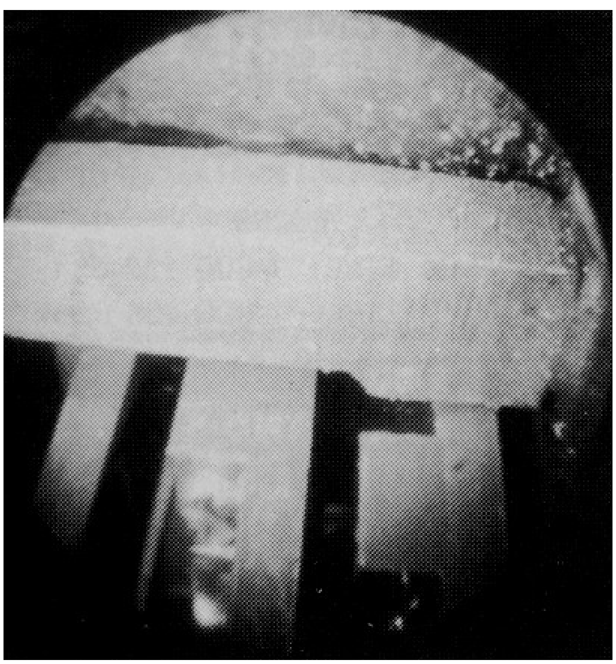
into the gate of the wheel pack, and a lock case with the lever fence removed. (Photo ID
top left ISP 84-3563, top right 85-3563, bottom left 86-3563, and bottom right, 81-3563).
Courtesy of Illinois State Police, Bill Sherlock.

The drilling procedure to view the fence and align the gates is probably the most common method to penetrate a safe.



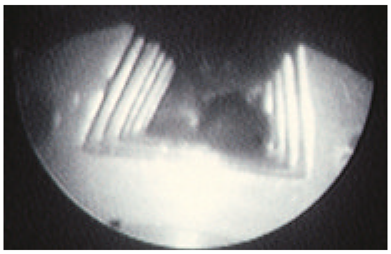


Figure LSS+3544 (ISP 22-2963) A 90 degree

angle view with a borescope using a mirror on a Mosler MR 302.

A hole is placed in such a position as to allow the technician to insert a borescope in order to view and align the gates under the lever fence. The penetration occurs directly underneath the fence. Certain manufacturers, such as Mosler and Federal, make this impossible because the fence is oriented toward the rear of the lock.

35_7.2.4.3.1.1 Procedure

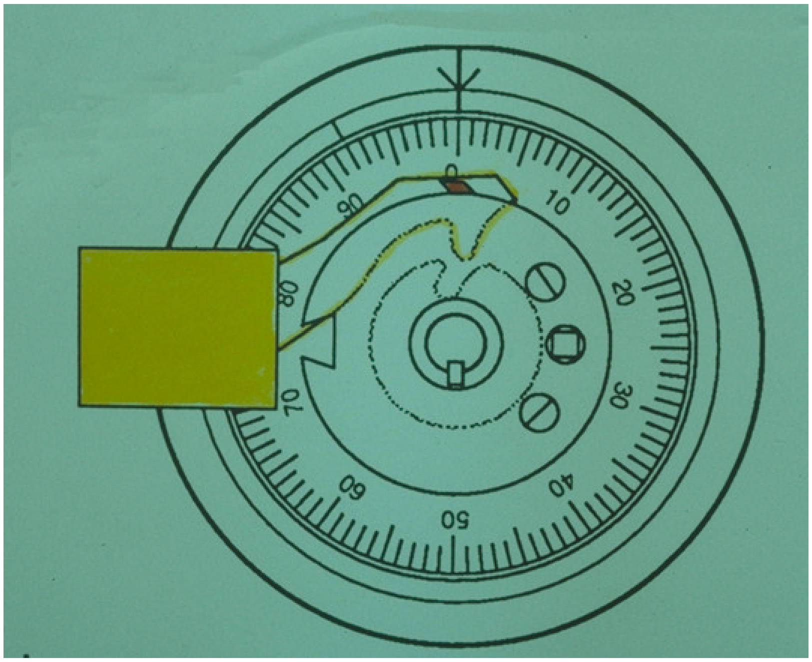
A 1/8” pilot hole is made to the hard plate after the drill point location is determined. Be certain that the drill is exactly perpendicular with the door, because the precision of this entry will control the accuracy of the final hole. A clearance hole is created that is somewhat larger in diameter in order to permit the carbide bit to penetrate the barrier plate. The tolerance of this hole should be at least 1/16” so as to prevent the bit from being caught by the softer metal of the door.

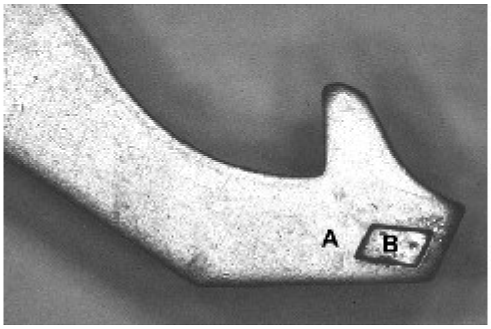
Upon reaching the hard plate, the carbide bit is inserted and the barrier material completely penetrated. An HSS bit is used to penetrate to the lock case. Drilling between the hard plate and the lock case should be done with great care. Frequent inspections are made for signs of zamak chips. Upon reaching the lock case, a very sharp drill should be used. This will prevent the formation of ridges or bubbles on the inside wall that can rub against the bottom wheel. As the lock case is penetrated, the bit will vibrate, indicating a different type of metal. Once a clean hole is created, brass should be visible.

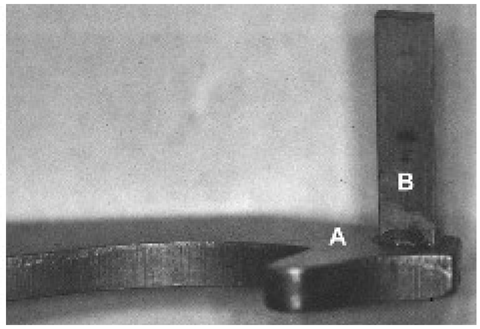
Great caution should be exercised when drilling into the lock case. If too much pressure is applied, the bit may thread itself through the zamak barrier and damage the wheels. Turning the drill bit by hand is often the practice in an effort to insure that the wheels are not disturbed.

Once drilling is completed, a view of the first wheel and lever fence is possible. If an S&G is the target, then the wheel that is first viewed will be the first digit of the combination. The wheels are rotated in the proper sequence as each is aligned below the fence. When the drive cam is under the fence, the lock can be opened after all wheels have been properly positioned.

35_7.2.4.3.2 Removing the Fence by Drilling







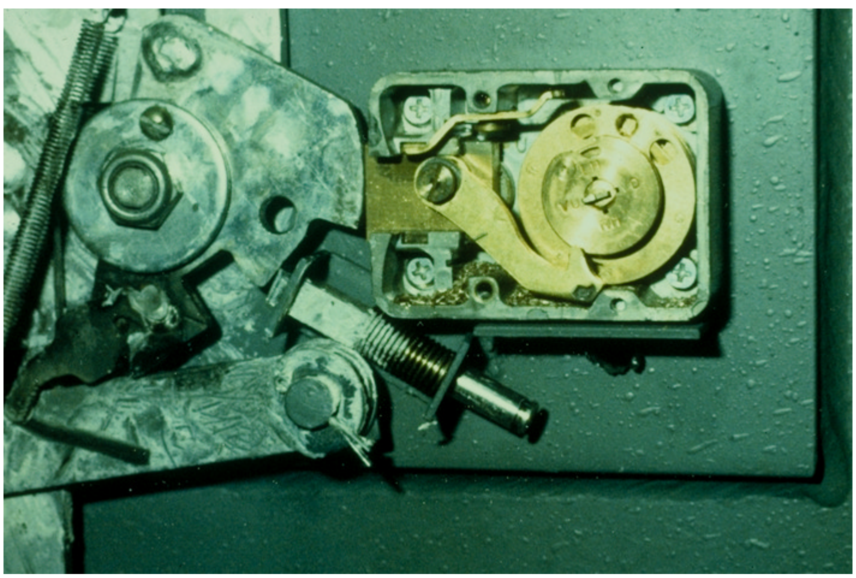


Figure LSS+3545 (ISP 103-3563) Locating the fence for drilling.

The fence is normally soldered to the lever assembly. It can be completely severed and removed by drilling. This is one of the most popular and reliable methods for neutralizing a mechanical combination lock, regardless of the manufacturer. The technique eliminates the obstruction that prevents the lever from being retracted into the drive cam. The dial must be removed or reduced in size to gain access to the drill point.

If done correctly, there will be no obstruction to block the lever from entering the drive cam gate, thereby allowing actuation of the bolt. Once drilled, the fence will usually become dislodged and fall away from the wheel pack. Some technicians drill **to the fence**, then attempt to dislodge it by punching. This practice is not recommended because connecting components can be damaged or broken, especially with a direct-entry fence.

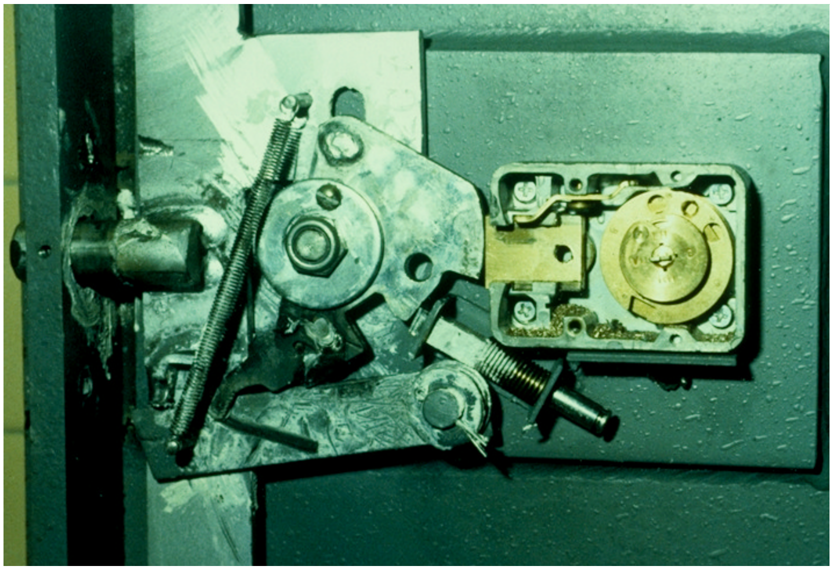

Figure LSS+3546 These photographs show a lever fence that has been drilled, and then removed. Photo ID ISP 97-3563 (left) and 98-3563 (right).

Removing the fence by drilling is utilized in a vast majority of forced openings and is particularly applicable:

- **When the combination is unknown or does not work;**
- **To bypass a mechanical failure;**
- **When the lever is bound;**
- **When drive pins or flys are broken or inoperative;**
- **When the wheels are seized or immovable and must be manipulated with a probe in order to align their gates.**

35_7.2.4.3.2.1 Drilling Procedure

The procedure requires precision accuracy in formulating the drill point ±.0625" from the center of the fence. The hole must be exactly perpendicular to the door and have no entry angle whatsoever. If done correctly, the penetration will allow removal of the fence, viewing of the wheel pack, and manipulation of each disc to alignment.

Using a fixed drill rig with a sharp HSS bit, very slowly drill the fence without causing distortion or twist. Remember that the fence is usually slightly more than ½" in length, so penetration

should be controlled to prevent drilling through the lever. If the end of the lever becomes severed, it may be impossible to retract the bolt. Once the fence has been removed, the drive cam can be rotated so that the nose enters it. A long screwdriver or ice pick may be required to accomplish this task.

35_7.2.4.3.2.1.1 Direct-Entry Fence

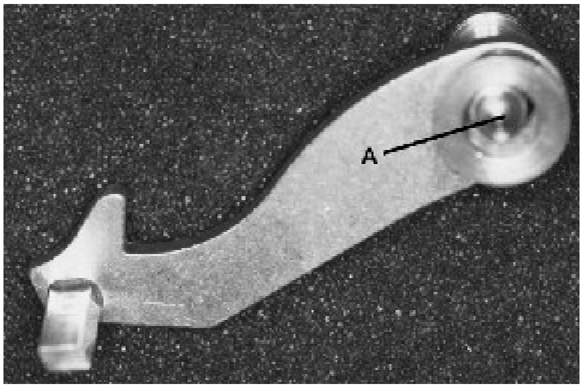
This type of mechanism is the easiest to neutralize because the fence is actually part of the bolt works. The method is the same for locks with different direct-entry fence designs.

35_7.2.4.4 Handle Cam

In most safes, the handle controls the boltwork, through a round cam. It is rotated once the correct combination is dialed, allowing the lock bolt to be retracted. The punching technique allows the cam to be bent or pushed inward far enough to clear the bolt of any obstruction.

The technique is often used with burglarized safes as a last resort. This is because it will require repairs to the door, can loosen the mounting plate under the lock, and can disconnect linkage. The procedure will usually have no effect on relockers. Caution must be exercised when working with older safes, because they may be outfitted with tear gas loads behind the bolt linkage and lock case. The chemical is stored in glass vials that are set to break upon impact.

35_7.2.4.5 Handle Shaft



In certain cases, the handle shaft (arbor) can be utilized to push back the cam. This technique is a variation of punching the handle cam. It requires that the bolt handle be severed. Then the shaft is forced into the door to bypass the bolt. In practice, the arbor is drilled completely through the spindle shaft in order to shear the mechanism and the threads of the nut. This will provide access to the cam, which can then be depressed to allow the bolt to pass.

35_7.2.4.6 Lever Screw

3563-99

One of the surest methods to open a container is to drill for the lever screw. This technique will bypass problems associated with

lever or wheel pack malfunctions. It can be used successfully on all S&G, Diebold, Federal, and LaGard locks. The procedure will not work on the Mosler 302. A **diagram** illustrates the proper drill point to remove the lever screw.

It will be recalled that the fence is attached to a pivoting lever that is directly linked to the bolt. If the head of the lever screw is removed, the lever and fence can be shifted out of the way and the bolt manually retracted. A ¼" or 3/8" hole is made at the precise drill point location of the center of the screw; then, an ice pick or similar tool is used to move the bolt.

Once the screw has been removed, the bolt is easily shifted. Remember that a detent spring and ball may be used to retain the bolt in a locked or unlocked position. Thus, added pressure may be required for movement of the assembly. The failure of the remaining screw shaft and head to completely separate from the bolt can be a complicating factor. Thus, all parts of the screw must be removed in order to free the lock bolt. One solution is to grind the drill tip to a flat surface, resembling an end-mill.

35_7.2.4.6.1 Drill Point Location and Procedure

Generally, the bolt center and dial centerlines are linear. Thus, the drill point for the lever screw will be located at 0, 25, 50, or 75, depending upon handing and mounting. This in turn determines the location of the bolt in reference to the dial.

Mounting	Radial Position of Lever Screw
RH	75
LH	25
VU	0
VD	50

We shall use a Right Handed S&G 6730 to illustrate the procedure. The lever screw is 1 11/16" from dial center. Once the lock is penetrated and the backside of the bolt can be observed, a ¼" HSS bit is used to remove the brass lever screw. The drill becomes a grinder to disintegrate the body of the screw, with the goal of eliminating the linkage between the bolt and lever. Once the screw has been neutralized, an ice pick, screwdriver, or probe is utilized to move the bolt to the open position.

35_7.2.4.7 Locking Cam or Lever

If it is impossible to drill for the lever screw, the alternative is the locking cam or lever. This will remove the obstruction that prevents the bolt from retracting, and may result in a piece of the lever being destroyed during the process.

35_7.2.4.8 Lock Case Mounting Screws

Lock case mounting screws are generally not protected by hard plate. Thus, they can provide a drill point for the introduction of a probe to view critical components. There are usually predrilled holes in the barrier material to accommodate mounting screws. Containers are usually constructed by welding a mild steel mounting plate to the barrier material that is affixed directly to the inside surface of the door. Holes are drilled and tapped through the hard plate and into the door. Using the relatively soft screws as a channel through the hard plate can reduce the difficulty of gaining a probe point.

In the S&G 6730, the mounting screws are located 1 3/32" from the center of the dial. Two screws can be drilled. These are located at 10 (upper screw) and 39 (lower screw). The two locations, however, will not provide a direct observation of the wheel pack. As with the lever screw, these drill points require precision in defining their location.

35_7.2.4.8.1 Difficulties and Hazards

There are problems in selecting this drill point. Thus:

- **Screw centers are difficult to drill and maintain using a ¼" bit. A template is recommended;**
- **The screw-head can become a nuisance once the threads are removed. The head can fall into the**

lock body or wheel pack, especially in standing safes where the upper mounting screw has been drilled. The head can also become lodged in one or more of the gates, or against the wall of the lock case. In such case, a magnet can be used to move the head out of the way;

- A direct view of the wheels is not available;
- A scope is required;
- A fixed drill rig is required.

35_7.2.4.9 Relockers

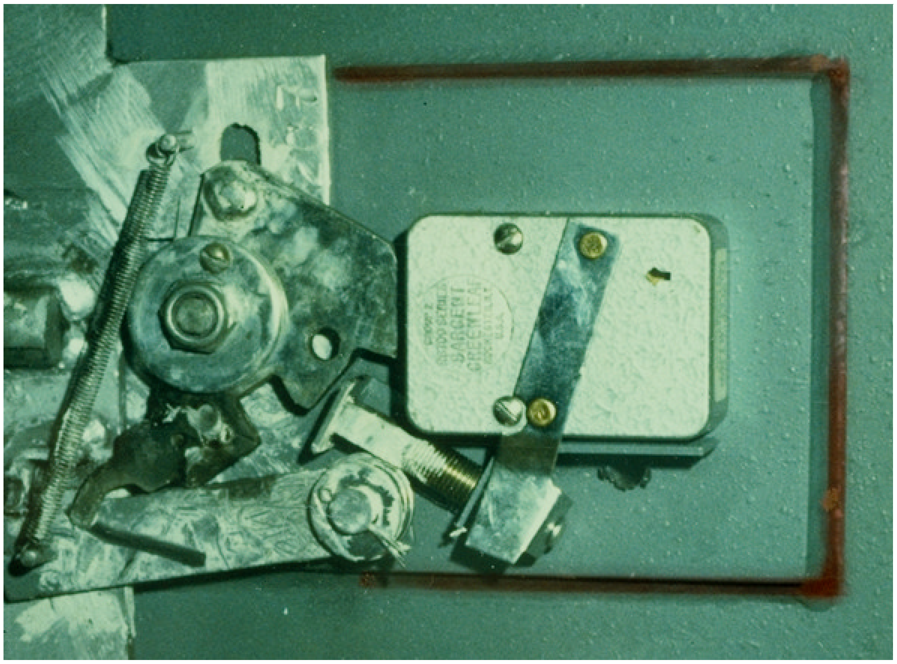


Figure LSS+3547 (left, ISP 95-3563, right ISP 96-3563). Drilled relockers and zoom view.

Relockers may be found in both the safe lock and container body. Their function is to provide a secondary block to the operation of the boltwork, once they are triggered. Certain types of relockers were described in **Chapter 33** and **34.** This section will contain a more detailed discussion as relates to neutralization and bypass. Depending upon their mechanical design and physical placement, they can be defeated by drilling, followed by manipulation and application of directed force such as punching.

Some relockers will cross-lock, meaning that the relocker is deadlocked after being fired. In such cases, pulling on the connecting cable will have no effect. This type of design is routinely employed in high-security safes. A relocker is said to be "active" when the locking mechanism is in a retracted state and until the connecting cord or cable is broken. Once this event occurs, the bolt releases.

Whenever a safe or vault is serviced, extreme caution should be exercised to insure that relockers are not engaged. If, for example, the lock case cover is loose after maintenance, a very difficult lockout problem is created if the door is closed. Whenever a lock is serviced for any reason, two critical rules

apply:

- **Insure that the lock case cover is secured tightly to the container;**
- **Always test the lock and boltwork system with the door open.**

35_7.2.4.9.1 External Relockers

These devices are spring- or gravity-activated projections that are incorporated within safe and vault doors to block the operation of primary bolts. Heat, temperature, vibration, shock, penetration in specific areas, or alteration of the door or lock triggers them.

35_7.2.4.9.1.1 Thermal or Fusible Links

A heat-sensitive link can be triggered by a rise in ambient temperature, caused by a torch, lance, or similar device. Generally, fusible links are constructed of two pieces of metal that are soldered together and spring biased. Once the threshold temperature is reached, a spring-loaded bolt will be released to block primary locking mechanisms.

35_7.2.4.9.1.2 Glass Plate Relockers

A pane of specially designed glass is located to protect critical components in the door. Drilling, shock, or vibration will shatter the glass and release tensioned lines that are attached to spring-loaded projections.

35_7.2.4.9.1.3 Lock Case Relockers

Relock triggers can be incorporated within the lock or external to it. Internal triggers are described elsewhere in this section.

35_7.2.4.9.1.4 External to the Lock Case

These devices are mounted outside of the lock case and are triggered by the alteration, removal, or destruction of the cover. They are specifically designed to guard against many forms of attack, including punching. Punching the spindle is perhaps the most common method to attack safes. In older containers and those having lower security ratings, the entire

lock, including the wheel pack, was knocked out of the way using this practice. The lever would be physically manipulated to the unlocked position. Manufacturers, in an effort to secure the container against the practice, have incorporated many design features within the lock and container. These include:

- **Place the drive cam in a position so that driving the spindle forward will not remove the wheel pack or allow the lever to fall;**
- **Place relockers in the lock case that are actuated by the removal of the lock;**
- **Integrate relockers into the handle by the use of shear pins and shafts that will break from excessive force or torque;**
- **Install relockers within the door that are triggered by any change in the lock case position or shape.**

35_7.2.4.9.2 Internal Relock Trigger

The relock trigger prevents the bolt from retracting when the thermal plug has melted or the lock case cover has been altered, distorted, destroyed, or is loose. As noted in **Chapter 34**, the relocker can also become active when the dial is knocked off and the spindle punched. It can also trigger from vibration. This can result from slamming the door or as the lock cover screws back themselves out over time.

The purpose of selecting this drill point is to disengage the relocker, **not to destroy it**. Thus, a hole is made in order to remove the obstruction that keeps the bolt from retracting. If the relock trigger has fired, the combination will run but the dial cannot be fully turned to retract the bolt.

35_7.2.4.9.2.1 Procedure to Disengage Relocker

There are many different designs for relock triggers, although they all perform essentially the same function. When the cover is firmly seated to the lock case, the trigger pin is depressed. Removal or movement of the cover will cause the spring-biased pin to pop up. This will engage a corresponding recess in the bolt, deadlocking it in the locked position.

We shall use the S&G 6730 for the purpose of illustration. In the 6730, the trigger is located at the lower right side of the

lock case (at about 60), 1 1/8” from dial center. To minimize the chance of severing the trigger arm, drill 1¼” from dial center, although this position will not afford a direct view of the arm. The goal for this drill point is to be in a position to move the relock lever toward the front of the container. This is accomplished using a wire snare while tension is applied to the dial in order to retract the bolt.

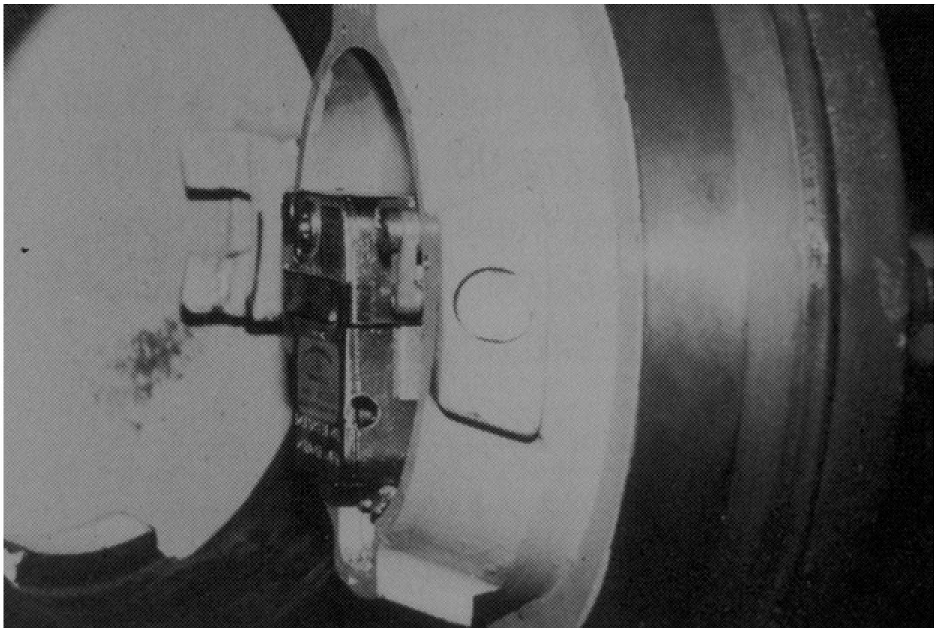
35_7.2.4.9.2.2 Relock Trigger Designs

Depending upon the manufacturer, relock triggers will have different mechanical designs. They are all engineered to block or stop the bolt from being retracted if there is an attempt to compromise the lock case. Based upon the configuration, the drill point should allow disengagement by either pushing or pulling the locking device from the bolt. Thus:

- **Mosler uses a brass pin, biased by a spring steel tab, measuring ¼” wide that is mounted on the back of the lock case;**
- **Yale employs a brass tab;**
- **LaGard provides a formed wire spring that is retained by a notched boss on the interior of the case cover. If the cover is removed or broken, the spring releases;**
- **S&G has a pivoting lever;**
- **S&G MP locks use a compound relocker, activated by the removal of the driver. This can be caused by the spindle being punched, or release of the cover. The result will be raising the trigger and releasing a locking pin into the bolt.**

35_7.2.4.9.3 Drill for a Relocker: Required Information

Information regarding the drilling of relock triggers is presented elsewhere in this section. In every case, drilling to neutralize a fired relocker requires detailed information regarding:



- **The type of relocker (internal or external);**
- **Mechanical configuration;**
- **Round or square projection;**

- **How the relocker is triggered;**
- **What is engaged, locked, blocked, or cross-locked by each relocker;**
- **How many relockers have been triggered;**
- **The location of each triggered relocker;**
- **Precise drill points for each relocker;**
- **Can deadlocking result from a fired relocker. For example, in the triggered and extended position, the projection may no longer be in alignment with the body of the relocker. This situation makes it extremely difficult to retract the secondary locking bolt;**
- **Every component that is affected by the triggered relocker;**
- **Additional complications that may be caused by attempts to neutralize each relocker. For example, a relocker that blocks the rotation of the handle cam has been fired. Forcing the handle, the shear screw, pin, or rivet will delink the handle cam from the shear plate, thus preventing the bolts from being actuated;**
- **What options exists for bypassing or neutralizing the relocker. Often, the only option is to drill a hole at the location of the relocker and then use a punch to destroy the bolt carrier to displace the relocker from the bolt.**

35_7.2.4.10 Spindle Shaft

The spindle shaft may be drilled in order to gain access to the handle cam. The bolt can be actuated once the cam is depressed and moved out of the way.

35_7.2.4.11 Viewing Hole: Front, Top, Sides, or Back of Safe

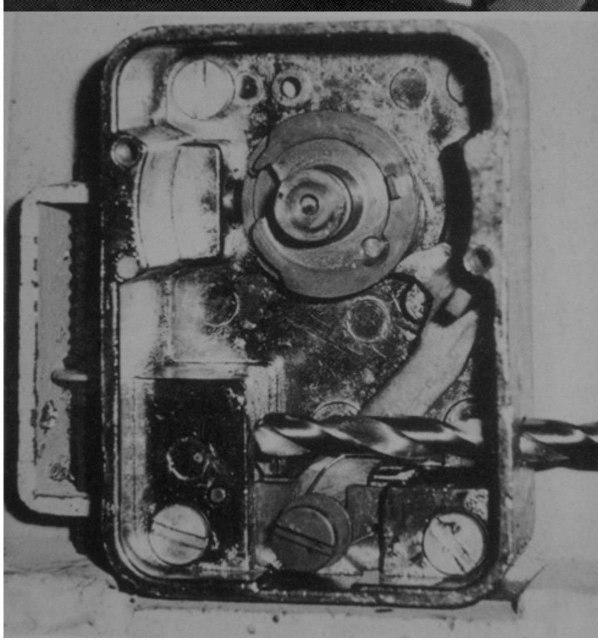


Figure LSS+3548 (Left, ISP 20-2963; right, 21-2963) Mosler MR-302 point of penetration.

Many doors are hardened or contain barrier material that cannot be easily penetrated. In such cases, a drill point can be selected to provide a view from the front, top, sides, or back of the safe. Each drill point will provide an observation of critical locking components. With respect to the front of the

door, the drill point will be inside or outside of the dial ring.

35_7.2.4.11.1 Lock Case

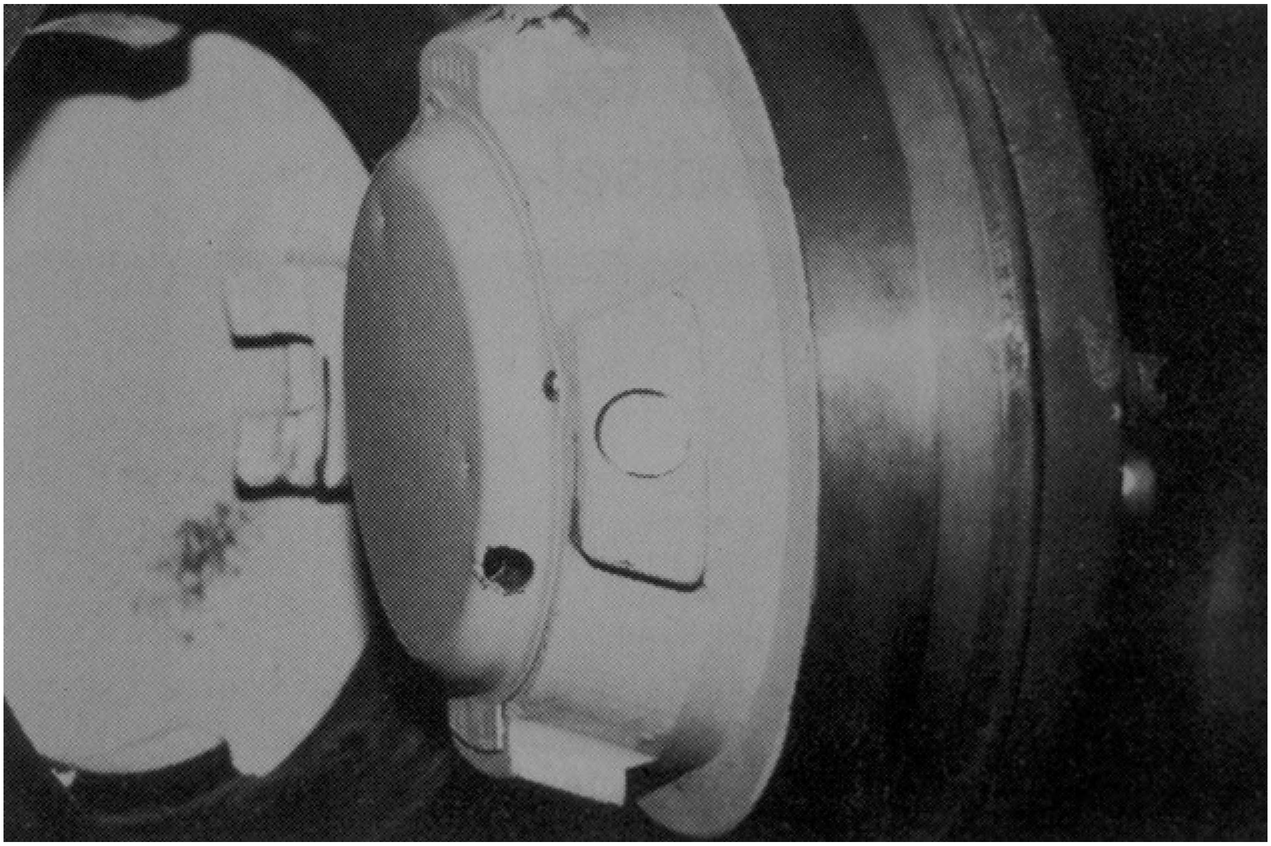

Figure LSS+3549 (ISP 19-2963) Hole drilled through cover plate.

A hole may be made through the front of the door or the side, top, bottom, or back of the container to scope the lock case in order to observe the fence and gates. The position of the hole will depend upon whether a borescope is available or a direct sighting must be made. If a borescope is not available, a hole must be placed at the edge of the wheel pack. In this instance, a view can be obtained around the radius (half the diameter) of the wheel.

Drilling for a **direct view** will allow observation of the fence and gate together. In such a case, no translation is required to correlate gate position with drop in. A drill rig must be used for this procedure in order to insure a precision tolerance of ±.125”-.375”. In older safes, the ability to view can be more difficult. This results from the use of gray wheels and a

polycarbonate fence. In locks such as the Mosler 120 and 302, or S&G 6709, the view of the fence is obstructed. In these mechanisms, the wheel post is on the case cover and the lever is mounted on the bottom of the case.

The direct view procedure will allow the combination to be determined by rotating each gate to alignment in the order that the number sequence is normally entered. That is, each wheel is rotated in the L-R-L or R-L-R order while viewing the gates. Each is aligned under the fence until the wheel pack is properly positioned in order to allow the lever to fall into the drive cam. The S&G 6730 is probably the most widely used lock for security containers. It will be used as a reference here. Critical information to obtain a direct view includes:

- **The wheel diameter (1.75″ for S&G);**
- **Location of the edge of the wheel pack from dial center (.875″ from dial center);**
- **Location of the fence (97 radiant on the dial);**
- **Drill point (97 x .875).**

The drilling procedure was described in detail earlier in this chapter. This technique can also be used to physically move each wheel into the proper position when drive pins or flys are broken.

35_7.2.4.11.2 Side Drilling the Lock Case

Side drilling of the safe will bypass glass relockers, except in some high-security containers, such as made by Chubb.

Figure LSS+3550 (ISP 18-2963) Side drilling and scoping the lock case.

35_7.2.4.11.3 Angle Drilling into the Lock Case

Figure LSS+3551 (ISP 8-2963 left; 10-2963 right). Example of floor safe that has been angle drilled to view wheel pack. Courtesy of Illinois State Police, Bill Sherlock.

Angle drilling can prevent damage to the locking mechanism. In addition, some locks cannot be directly drilled at a perpendicular angle to the door because the dial cannot be removed. Such is the case with the Yale OC5 friction fence lock, for example. To drill properly, first the door thickness is determined. Then, the drill point is set so that the top of the lock case is penetrated at an angle without touching the wheel pack. If done correctly, the edge of the wheel pack and driver will be observable.

35_7.2.4.12 Drilling Through the Top and Back of the Container

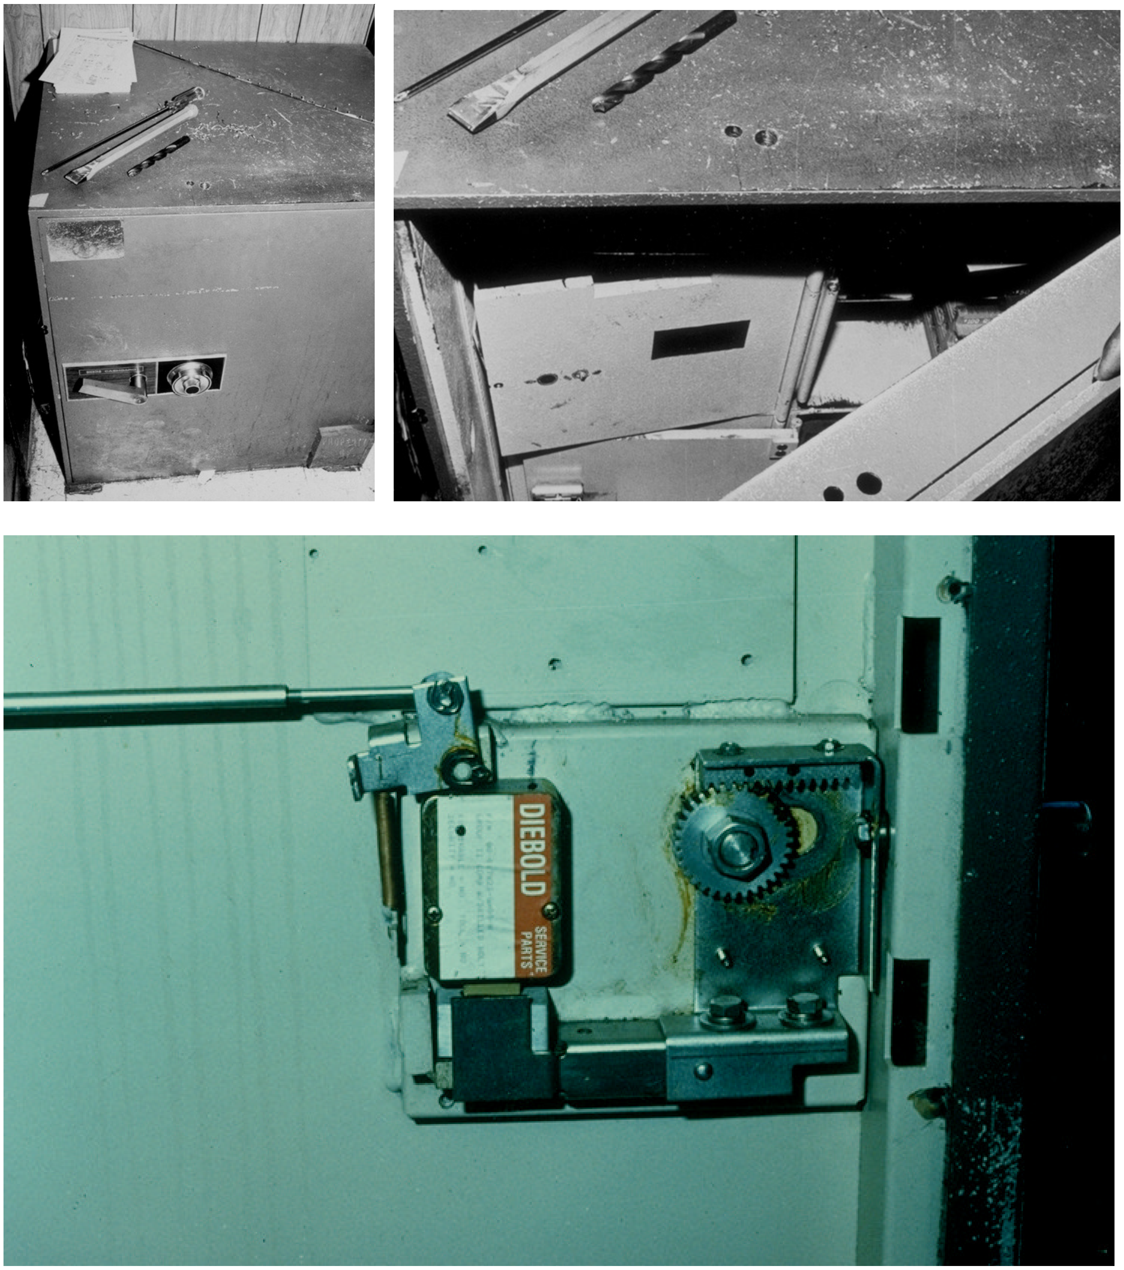

Figure LSS+3552 (Top left ISP 14-2963; right 15-2963; bottom, 16-2963). Burglary of a drug store chain, drilled from the top of safe to lock box to view the wheel pack. Courtesy of Illinois State Police, Bill Sherlock.

Drilling may be accomplished through the top and back of the container in order to penetrate the lock case. The procedure for each of these locations is essentially identical. The drill

point is determined from the dimensions of the lock and the location of the dial. It is placed to avoid contact with the internal components, yet provide an unobstructed view of the wheels. One or more holes may be placed in the back of the safe in order to read the lock or disassemble it.

35_7.2.4.12.1 Disassembly of the Lock

Several holes may be made in the rear of the container to allow disassembly of the lock. Generally of very limited utility, this procedure requires that a view hole, light hole, and manipulation hole be made to allow direct access to the back of the lock. Obviously, no obstructions can be present for this technique to work. Once access to the lock case has been provided, a long screwdriver is used to remove the cover. The combination is then dialed and the relock trigger depressed, to allow the bolt to retract.

35_7.2.4.12.2 Change-Key Hole

A hole in the back or side of the container can afford a direct view of the change-key hole, using a borescope. Through this limited opening, the wheel pack can be observed. The complexity of the procedure will depend upon whether the lock is front or rear drive. Remember, the image in the borescope may be reversed, adding another level of difficulty to the operation.

35_7.2.4.13 Square Section of Holes

Several holes in a square pattern can be made by drilling or by using a torch. Once the pattern has been completed, a sledgehammer is used to punch the remaining metal inward. The area should be large enough to allow for the insertion of a hand or mechanical device to remove contents.

35_7.2.4.14 Wheel Pack

Drill a precise hole to allow alignment of the gates under the fence. In some locks, notably Mosler and Federal, this is not possible because they face toward the cover. The evidence technician should note this fact. If a Mosler or Federal were drilled improperly, it would indicate a lack of knowledge on the part of the burglar.

35_7.2.4.15 Wiring Holes

Often, there are one-inch wiring inlets at the rear of a container for alarm circuit access. Generally, these holes will not provide a direct view of the bolt mechanism or lock, but may be worth considering if there are no other options.

35_8.0 Forced-Entry: Required Information and Data

Containers and their locks are predominantly mechanical and thus, subject to failure. Each safe may have special design issues that must be understood prior to drilling. Accurate information in advance of a forced-entry can determine whether the effort will be straightforward or complicated, difficult, and time consuming.

The analysis of a security container and its lock prior to attempting an entry occurs in two distinct stages. First, all of the known information regarding the safe or vault is gathered from the owner, user, or industry reference sources. This type of data will give the technician a clue as to how to proceed; he will know the required tools and the difficulty of entry.

If the lock or boltwork is inoperative, causing a lockout condition, then diagnostic analysis must be attempted in order to focus upon the proper target of attack. In such a case, all possible information must be gathered regarding operational difficulty or malfunctions prior to the lockout.

The conscientious safe technician will, whenever possible, keep detailed notes regarding the containers that he routinely services. This information should be kept in a secure location and coded with respect to a particular safe. Information that can and should be gathered **prior** to a lockout condition should be based upon drawings, photographs, diagrams, blueprints, or notes. The information should include:

- **Location of relockers;**
- **Data regarding the safe, boltwork, and lock;**
- **Photograph of the boltwork mechanism on the door;**
- **Location of bolts;**
- **Door measurements;**

- **Lock specifications;**
- **Drill points and hole placement.**

35_8.1 Photographs

Photographs, in order to be accurate, must include a method to determine scale. Two rulers, one vertical and one horizontal, should be placed next to critical components when taking photos. This will allow a 1:1 correlation for measurement and distance calculations. Remember that the lock case and bolt size can be used in old photographs to determine other dimensions within the picture. The length and width of the door may be similarly utilized as a reference. Photographs should be produced using either a macro or 52 mm lens with the film plane parallel to the object being recorded.

Before attempting the forced-entry of any lock or container, the technician must obtain as much information as possible about the target. Drilling or other forms of destructive entry requires a great deal more prior knowledge than if the lock is to be manipulated. Proper and accurate planning of the attack is crucial. This “reconnaissance” is essential, for many reasons:

- **Increase the likelihood of success;**
- **Reduce the time required for entry;**
- **Eliminate or reduce the potential for multiple-entry attempts due to errors in procedure;**
- **Minimize required repairs after entry has been effected;**
- **Minimize the damage done to the container;**
- **Reduce the likelihood of firing relockers or other protective devices that will create lockout conditions, and which may be extremely difficult to resolve;**
- **Minimize the dangers inherent in any forced-entry;**
- **Minimize the effects of penetration upon the security rating of the container;**
- **Reduce subsequent risk of penetration of the same container;**
- **Reduce the cost of repair or replacement of components;**
- **Reduce the sophistication or number of tools required to effect an opening.**

35_8.2 Information Regarding the Lock and Container

It is highly recommended that the technician take the necessary time to gather all available information before making the decision as to how entry is to be made. Sitting in front of the safe for a period of time and weighing courses of action can reap large dividends in terms of simplified openings. As noted elsewhere in this chapter, relocking devices can pose the greatest threat to a successful opening. If the proper information is not gathered or available prior to making the decision as to how a container will be bypassed, then it is likely that relock devices will be triggered. Once activated, the container may be extremely difficult to open. **The best way to deal with relockers is not to set them off.** Data regarding the following factors can be critical in making the decision to drill a container:

- **Barrier material and Rockwell rating;**
- **Best location to penetrate the lock case for an unrestricted view of the wheel pack without causing damage to the mechanism;**
- **Body thickness;**
- **Bolt diameter;**
- **Boltwork direction;**
- **Boltwork mechanical design;**
- **Boltwork location;**
- **Check for a stuck fly;**
- **Check the dial for excessive in-and-out play;**
- **Check the dial ring for tightness;**
- **Check the door for play;**
- **Combination or key lock;**
- **Comparison with similar containers and methods of construction;**
- **Contact point location;**
- **Container size;**
- **Cross-locking on relockers;**
- **Determine the drop in point;**
- **Identification of lock by design of dial and dial ring;**

- **Dial location;**
- **Diameter of the wheels;**
- **Direction of bolt extension from lock case. A right handed lock means that the bolt will extend from the left side of the lock as viewed from the dial, outside of the container;**
- **Direction of handle rotation to retract;**
- **Distance between opening handle and dial;**
- **Door size;**
- **Door cover plates;**
- **Drive cam diameter;**
- **Electronic locks often have bypass codes in case of lockout;**
- **Experience with particular container;**
- **Handle design;**
- **Hinge design: bypass capability;**
- **Is it possible to enter the container;**
- **Is the lock in working order;**
- **Is the safe insulated;**
- **Key lock, number of levers;**
- **Key lock, special tools for bypass available;**
- **Lever system in lock: universal, geared, gravity drop, biased, or straight tail piece;**
- **Lock identification, as outlined in Chapter 33;**
- **Manipulation of lock: is it possible;**
- **Manufacturer and model of safe and lock;**
- **Measurement: door face to bolt center;**
- **Measurement: door thickness;**
- **Measurement: door thickness to combination lock;**
- **Mounting of the lock;**
- **Movement of safe: is it on casters or wheels;**
- **Opening handle shape and position;**
- **Optimum place to enter the lock case;**
- **Original color of container;**
- **Rating for fire or burglary. Burglary protection will use more difficult barrier material to penetrate;**
- **Relock devices;**
- **Reverse the rotation, oscillating the dial at drop**

in;
- **Run the combination, oscillating the dial at the drop in;**
- **Thermal links;**
- **Thickness of each barrier level;**
- **Tools required;**
- **Tools which are unavailable;**
- **UL or other rating;**
- **Use of glass plates;**
- **Verify that all wheels are being picked up simultaneously;**
- **Verify that the spindle is intact and communicating motion to the wheels;**
- **Weight of container;**
- **What is the security classification of the lock: Group 1, 2, or unlisted;**
- **Wheel material: metal or plastic;**
- **When was the safe and lock last serviced;**
- **When was the spindle last lubricated.**

35_8.3 Preliminary Information about a Malfunction or Lockout

A lockout will most likely occur because the lock or mechanical components of the container were not serviced properly. Even a small amount of dirt or debris in the bolt receptacle or a coin or paper fragment in the door can cause the problem. The customer should not be relied upon to provide or volunteer the cause of the difficulty. If the safe must be opened as the result of a malfunction, a determination as to the nature of the problem should be attempted. There are at least fifty causes of lockout. In less than ten percent of those, drilling or other forms of forced-entry are actually required.

The following information about the target safe should be gathered and an analysis of both the lock and container should be undertaken prior to developing a plan of entry. Proper diagnoses of one or more of the following symptoms can often negate the requirement for drilling or other means of forced-entry:

- **#3 wheel is drifting to a higher or lower number;**
- **Bent lever;**

- **Bolt retraction not possible: relock trigger engaged;**
- **Drive pin broken;**
- **Broken fly;**
- **Cam is bound by corrosion;**
- **Cam gate slide is inoperative in an MP lock;**
- **Combination check;**
- **Dial binding, wobble, or hard to turn: spindle or drive cam problem;**
- **Dial has fallen or been knocked off, spindle intact;**
- **Dial is free spinning: broken drive pins, flys, or loss of contact between drive pin and fly;**
- **Dial is turned sharply: feel drive pins pickup flys and verify all are active and working;**
- **Dial knocked off, spindle punched;**
- **Dial off center: does it bind;**
- **Dial or spindle slippage;**
- **Dial ring loose;**
- **Dial ring marking centered;**
- **Dial stuck: was excessive force used, resulting in broken drive pin;**
- **Dial turns hard, usually due to water damage;**
- **Dial turns smoothly;**
- **Dirty and/or worn flys;**
- **Drive pin slippage;**
- **Drop in area: rap dial with soft-face mallet to compute and determine how far off from standard reference. May have been twisted with pliers by the user;**
- **End play on dial, driver not picking up wheels;**
- **End pressure on boltwork, causing lever to hang;**
- **Fly is stuck, can cause error of up to ten numbers in combination;**
- **Handle swings freely, shear pin broken;**
- **Lever spring is broken or fallen off;**
- **Levers bound by pressure from lock bolt;**
- **Levers bound or jammed;**
- **Lock case screw has fallen out, jamming lock;**
- **Locking cam is bound;**

- **Mounting screws loose;**
- **Obtain written combination from owner or user and have it entered in an attempt to open the lock;**
- **Operational difficulties in entering combination prior to lockout;**
- **Parts seized by dirt or moisture;**
- **Relocker set off, usually by back cover falling or being knocked loose;**
- **Relockers engaged, resulting from burglary attempt or dial handle broken;**
- **Spline key has fallen out, dial unscrews from center;**
- **Spline key is loose;**
- **Spline key is missing;**
- **Stuck fly;**
- **Unlocked wheel;**
- **Verify that correct combination is entered properly;**
- **Verify that the dial and dial ring have not been shifted from impact or loose spline key;**
- **Wear of components;**
- **Wheel mesh slippage, locked into new combination (not unlocked wheel);**
- **Wheel mesh unlocked (generally closest wheel to drive cam);**
- **Wheel pack binding: often #1 wheel. Mounting screws may have worked loose and engaged wheel pack.**

35_8.4 Diagnostics of the Lock and Container

There are as many variations in factors leading to a lockout as there are different brands of safes and locks. The following preliminary evaluation of symptoms, once identified, is generally the starting point in the drilling assessment process. The result should focus upon the proper course of action to open the container. Drilling should only be chosen as a last resort, based upon careful analysis of all known data regarding a lockout.

Analysis of all problems relating to the combination lock will begin with the dial. If it can be turned, then the problem will relate to those parts that control alignment of the gates. If the dial cannot be turned, then those components that control

rotation should be examined. The following analysis provides a summary of issues. It should serve as a guide, pointing the reader to more detailed maintenance reference manuals.

35_8.4.1 The Dial Turns, Yet the Lock Will Not Open with Correct Combination

Proper entry of the combination will not open the lock. The cam is at the drop in point, but the fence will not fall into position. The dial is oscillated ±5 numbers with no effect. It is believed that the spindle is intact, the contact points can be determined, and the wheels are being picked up during rotation.

Probable Solutions

There are several possible causes:

- **Correct combination not entered;**
- **Damage to drive pins or flys;**
- **Stuck fly;**
- **Unlocked wheel;**
- **Wheel slippage;**
- **Loose spline key.**

35_8.4.2 Correct Combination not Actually Entered

The correct numbers may not have been entered or remembered by the person attempting to open the safe. There are many possibilities relating to the entry of an improper sequence of numbers. A wheel may also have become disengaged or slipped, causing the problem. The following data should be verified regarding the entry of the correct combination:

- **The written combination should be provided to the safe technician;**
- **Determine if the person attempting to open the safe is the individual who normally does so and that he understands the correct opening procedure;**
- **Observe the entry of the combination. Are the correct numbers and sequence being used. Is the index marker being utilized correctly;**
- **Have maintenance problems been potentially created by the method of combination entry. For example,**

are rapid jerks or changes of direction employed when rotating the dial. This can cause drive pins and flys to break;

- **Is the dial seated tightly. Is it damaged. Could its marker position have been altered through impact with doors, furniture, or other objects;**
- **Can the dial ring be easily rotated;**
- **Can each wheel be felt as it is picked up. Can each drive pin and fly be felt as they interact;**
- **Is it believed that the spindle has been twisted from excessive torque. If so, the combination will be increased, equivalent to the rotation. One method to determine possible twist is to compare the actual location of the physical drop with factory specifications.**

35_8.4.3 Unlocked Wheel

It is possible that a wheel in a changeable lock has become disengaged or released, as if to be programmed. This malfunction is difficult to detect, because the wheel pack will act normally. A wheel that has become unlocked can randomly move from one position to another, thus erratically changing the spline-gate position.

Usually, it is the wheel closest to the drive cam that is causing the problem. This is because it receives the most wear and abuse. The problem is more pronounced with metal wheels and will rarely be seen with plastic discs. The change in gate position can be detected through manipulation. In practice, each wheel is isolated and run to the drop in point. Once the wheel is identified, it can be rotated to lower and higher numbers until an opening occurs.

35_8.4.4 Slipped Wheel

A wheel that has slipped is not the same as one that has become unlocked. Slippage can occur, mainly in the number three wheel, as the result of excessive torque. The best example was in early models of the LaGard 1980 series. It resulted from an undersized drive cam that was caught by a lever. It would not properly clear the gate after some wear had occurred. Upon locking the safe, the drive cam met the fly of the wheel. It would not move, however, because the fence restricted the gate. The result was that the teeth of the wheel were trapped, causing a change in the

wheel-gate relationship and thus, the combination. In all such cases, the combination must be translated to account for the difference between gate positions.

35_8.4.5 Slippage of Drive Pin or Fly

While turning the dial, binding will occur at one location. The problem can result from:

- **Binding wheel;**
- **Binding wheel pack;**
- **Drive cam wear or excessive tolerance that provides a gap between the wheel pack. Attempt to pull on the dial while the combination is entered in an effort to overcome the problem. It may also be possible to "walk" the fly around the wheel. This is done by continuing to back step from where the fly looses contact, then moving the wheel forward. The combination can also be run in reverse.**

35_8.4.5.1 Stuck Fly

A stuck fly is one of the most common causes for a lockout. Rotating the dial four times left or right, then reversing the direction while continuing to turn, can isolate a wheel. Each wheel will be picked up at the same position where the direction of rotation initially changed. A stuck fly can be released by sharp turning of the dial, oscillation and tapping, or running the combination in reverse direction.

This condition can also cause the combination to change if the fly is stuck or released. A stuck fly will never change the combination more than ten numbers. Remember, however, that one stuck fly can affect the entire combination sequence.

35_8.4.6 Loose Spline Key

The spline key provides the critical reference link for the dial marker, spindle, and drive cam. If it is loose or worn, the combination can change. Generally, the loose key can be felt during dial oscillation. Usually, the combination can be determined by adding ½ number for left rotation and subtracting ½ number for right turning.

35_8.4.7 Dial cannot be Turned

There are many reasons that a dial either cannot be turned or difficulty is encountered during a revolution. Ultimately, the problem will relate to the concentricity of the dial, dial ring, spindle, drive cam, or individual wheels. A lever that is frozen or sluggish may also result in problems. The following information must be obtained in order to determine the problem:

- **Does the dial turn with difficulty in both directions. If so, there is a concentricity error in the dial, spindle, or drive cam. Sometimes, these errors can be remedied by tapping the dial with a mallet to correct for any bends. If the problem remains unsolved, the drive cam is bound within the wheel post. The brass spindle may have been twisted from excessive applied pressure;**
- **Has the dial become harder to turn, or does it stick at a certain position. Added torque may have been applied by the customer, causing a drive pin to be broken;**
- **Is it possible that one of the wheels or the wheel pack is binding. Care should be exercised if it is believed that this condition exists, because added torque can shear a spline key or break drive pins and flys. Generally, the first wheel (bottom) of the pack is most likely to bind. Often, bound wheels can be forced through the application of sharp bursts of energy. Running the combination in the reverse direction may solve the problem;**
- **Do the wheels turn in one direction, but not the other. If so, there may be a loose mounting screw that is causing the binding. Shock, vibration, or the use of gravity (turning the safe upside down) may solve the problem;**
- **Does the dial bind when turned, indicating that it is not "true" with the dial ring;**
- **Does the lever move freely. Moving slowly past the drop in area will reveal if the lever has any restriction of movement. Either there is end pressure on the bolt, or the lever is blocked from movement. This can be caused from an obstruction, such as a loose mounting screw. Shock or vibration around the lock can often clear the problem.**

35_9.0 Safe Opening Protocol: A Case Study

The following example provides an insight into the protocol that may be followed to open a TL-15 rated safe. The procedure will obviously vary depending upon many factors, including:

- **Known data about the safe;**
- **Information as to the probable cause of the lockout;**
- **Damage to the container from a burglary attempt;**
- **Damage to critical locking components through improper service, misuse, abuse, wear, or failure;**
- **External factors such as coins and paper jammed in the door that are compounding the lockout;**
- **Fired relockers;**
- **Boltwork linkage failure.**

A more comprehensive list of possible failures was presented earlier in the chapter.

35_9.1 Background Information

The known or inferred facts for our example include:

- **The lock was functional until the lockout;**
- **This is a TL-30 burglar safe;**
- **The safe has no observable physical damage, in that the handle, hinges, and dial are working properly and intact;**
- **The wheel pack seems to be rotating freely, and the drive pins and flys are working properly;**
- **There is a dial indication of the lever drop;**
- **The lock was manufactured by S&G;**
- **We can measure the thickness of the door;**
- **We know where all of the drill points are located, because we have identified the lock;**
- **We can make an educated guess as to the handing of the lock;**
- **We know the correlation for the translation of gate position, based upon handing;**
- **We know that the dial can be pulled because it is**

made of zamak;
- **We believe, from all indications, that the combination has been lost and that is why the lock will not open.**

We do not know:

- **The location or number of relockers;**
- **The number and location of locking bolts, or the mechanical linkage for the bolt system, and bolt retraction.**

35_9.2 Opening the Safe

The following steps are followed to open this safe:

- **Remove the dial with a dent-puller or a screw drilled through the center. Caution should be exercised because we know this safe carries a TL rating, and thus, the dial is pinned to the spindle. A better decision may be to utilize a hole saw to reduce the dial size;**
- **Select and mark the drill point, using coordinate measurements or a template. In this case, we will drill for the fence;**
- **Attach a fixed drill rig;**
- **Begin drilling a pilot hole, first using an HSS bit until hard plate is reached. Be certain that the drilling angle is perpendicular to the door;**
- **Enlarge the pilot hole to create a clearance hole that will allow the carbide bit to rotate freely. This is required so that the bit does not grab softer metal while spinning;**
- **Determine when hard plate is encountered by sensing when metal cutting has stopped and the drill motor speed increases;**
- **Identify the type of hard plate and whether the material is smooth or included. Did the drill jump just before reaching the barrier. If so, there is a rough surface that is indicative of alloy hard plate. A borescope or otoscope may be used to verify this information;**

- **Use a punch to fracture the carbide chips in order to create a means for the drill bit to grab the material;**
- **Set the drill motor for a speed of 1000 - 2000 RPM;**
- **Select the appropriate drill bit (carbide tipped for this safe);**
- **Alternate between punching and drilling;**
- **Conduct short drilling cycles of about thirty seconds, then inspect the drill bit for dulling. Replace the bit if necessary, and repeat the fracturing of included material on the hard plate surface. The hole should be cleaned often;**
- **Once the hard plate has been completely penetrated, switch back to a sharp HSS bit to go through the mounting plate and lock case;**
- **View the edge of the gates of the wheels and align for opening;**
- **Translate the wheel position to the drop in point;**
- **Reenter the translated combination and open the safe.**

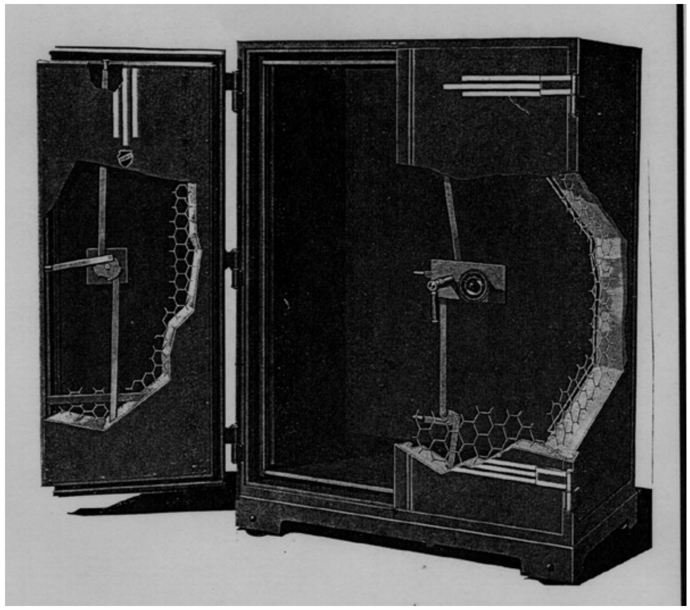
35_10.0 Forensic Evidence of Destructive Entry

35_10.1 Introduction

The investigation of illegal entry of safes, vaults, and safe-deposit boxes has been a primary focus in this text. Forensic evidence relating to the forced-entry of **locks** is discussed in **Chapters 23-27.** This section will provide general information regarding destructive forced-entry techniques as relates to physical evidence. It is not meant to be an exhaustive treatise, however, as the topic is well known. Forensic evidence is most often based upon tool mark identification.

A safe or vault that has been the subject of unauthorized entry can yield many clues to determine the modus operandi (MO) and identity of the perpetrator. In this section, the presence of evidence for both covert and forced-entry is discussed. Burglary methods, techniques to hide evidence of drilling, and information that can be derived from a crime scene are presented.

There are three primary classifications of safe burglars: opportunity, amateur without any specific knowledge, and expert. It is incumbent upon the crime scene investigator, whether forensic or criminal, to attempt a determination as to the motive and competence of the perpetrator.



Safe Burglary by Opportunity: The offender usually commits a burglary and finds a safe on the premises. Tools used for entry are also utilized in an attempt to open the safe. Generally, hinges, the dial, or handle are the subjects of attack. The burglary is rarely successful.

Safe Burglary without Expert Knowledge of the Safe: In this instance, the offender knows there is a safe on the premises prior to entry, but he has no knowledge of the make or model, nor of specific entry techniques. He attacks the safe in several different areas with tools that are usually not sufficient to allow bypass. The office area is often looted because of the failure to obtain the contents of the safe.

Professional Safe Burglar: This individual has detailed information about the safe; its location, design, make, model, and security rating. He carries with him the appropriate tools, and leaves the tools at the scene so that he cannot be traced to them through tool marks or trace materials. The professional does not loot the office; he is there to open the safe take its contents, and make a successful exit.

As has been noted throughout this book, there are two primary safe classifications: fire and burglary. Within those groups, there are several subgroups, primarily within the burglary classification. These include money safes, encased/clad money safe, and floor safe. Within the fire rating are included **record safes**, **combination safes**, and **composite safe (Chubb Planet)**. The combination safe is generally constructed with a fire-resistant exterior, with a burglary-resistant interior container.

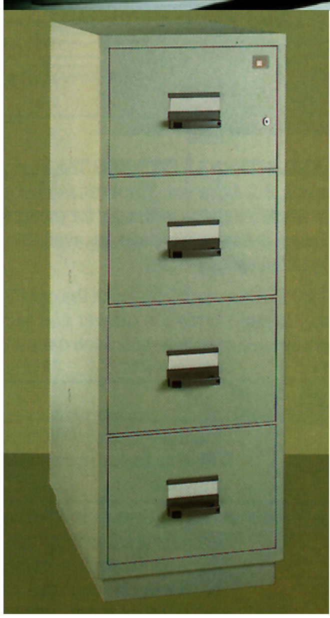


**Figure LSS+3505 Examples of fire and record safes. Shown (left) is the Chubb Planet composite
container that is burglary and fire resistant and described elsewhere in this text. A record
safe is constructed primarily to resist fire and provides only minimal burglary protection.**

**Figure LSS+3506 Example of a high-security money safe produced by Chubb. Money safes
are designed to protect valuables and cash from theft. Their design usually requires
thick steel doors and walls. Intricate locking mechanisms including relockers are
the practice.**

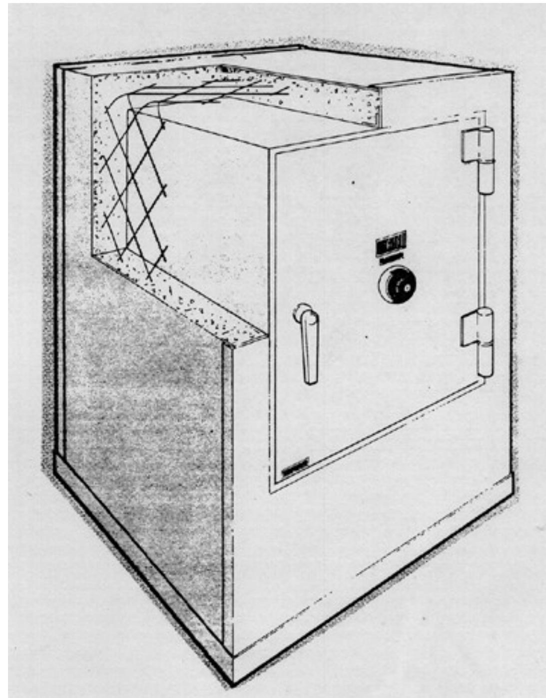

Figure LSS+3507 The cash container and encased/clad money safe. A money safe encased in concrete, then clad in steel or a money safe encased in concrete provides greater difficulty to burglars in removing the physical container from the premises. Encasing in concrete can also raise the safe to a more convenient working level.

35_10.2 Investigative Checklist

There can be many reasons for a forensic investigation of a safe or vault. In one instance, a routine security inspection is performed to insure the integrity of locks and containers. At the opposite extreme, a crime scene may have been declared with the goal of identifying a perpetrator. In the first case, there is no indication that a break-in has occurred until an inspection yields such evidence. At the crime scene, the method of entry may be obvious; only the burglar is unknown.

So, where does the investigation begin? The answer to that question involves many factors. They include:

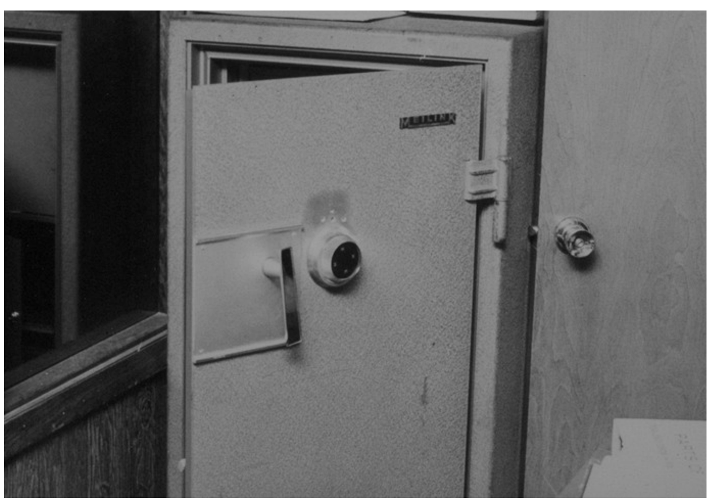
- **Evidence at the scene;**
- **Prior knowledge of the investigator regarding a suspect's techniques of entry;**

- **Similar crimes;**
- **Target of the burglary;**
- **Complexity of the crime;**
- **Methods of entry and the types of evidence created, including tool marks;**
- **Time required and allowed for entry;**
- **Location;**
- **Access;**
- **Type of lock and enclosure;**
- **Barrier materials;**
- **Competence of the perpetrator;**
- **Sophistication of the tools employed;**
- **Potential that the burglary was simulated.**

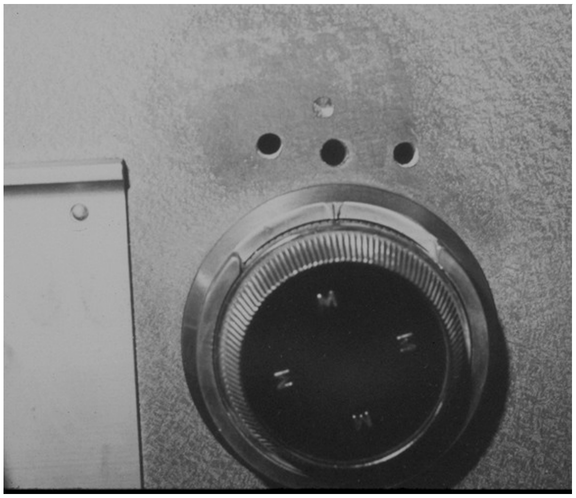
Each of these factors will in part dictate the kinds of evidence that is created or left at the crime scene. The following checklist provides a master index of facts or evidence that can be deduced, inferred, or proven. No such list can ever be complete due to the unique nature of each occurrence. However, the material will suggest avenues of inquiry and documentation that can form the basis of any investigation.

35_10.2.1 Preliminary Questions

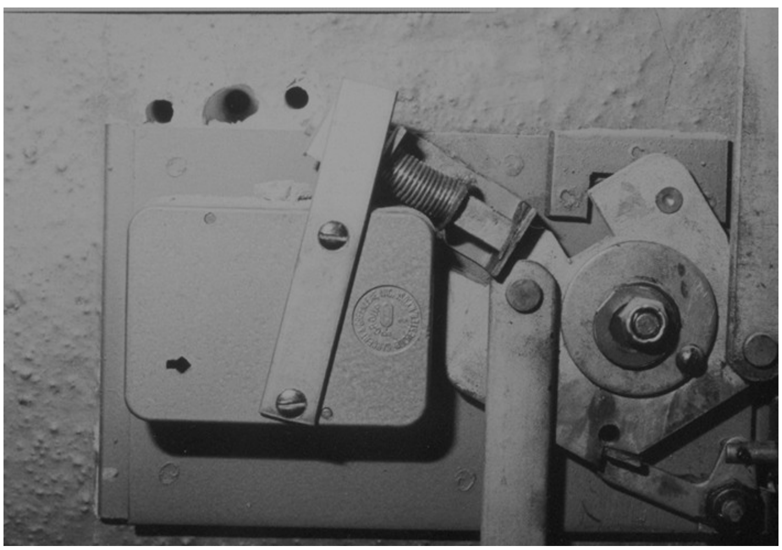
- **What is the appearance of the safe;**
- **Was the safe opened by forcible attack;**
- **Is the handle firmly attached;**
- **Does the dial rotate;**
- **Is there a dial;**
- **What did the burglar have to determine, in order to successfully open the safe;**
- **Are there any similar crimes or open cases;**
- **Was the lock left on the factory combination;**
- **Is the MO recognized;**
- **How was entry effected;**
- **Can covert entry be confirmed;**
- **Was there an attempt to hide the fact or method of entry;**
- **Has the method of entry been disguised to cover different or more sophisticated techniques, other**



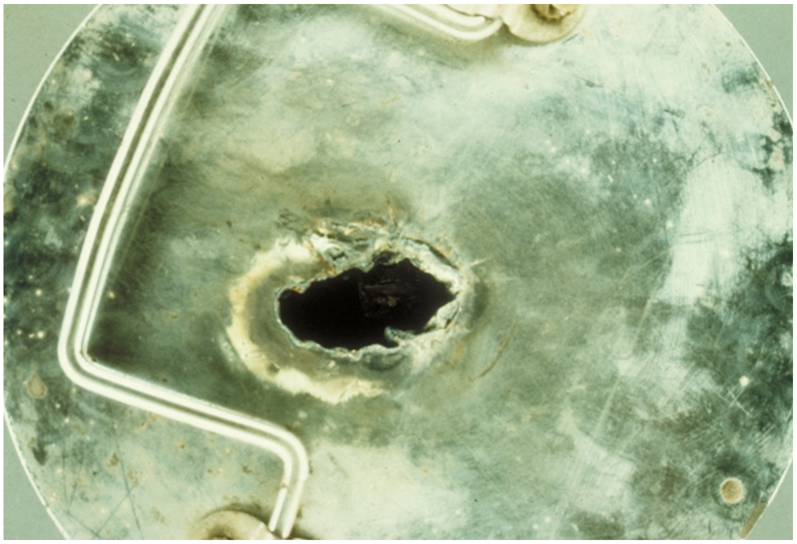
crimes, or the identity of the perpetrator;



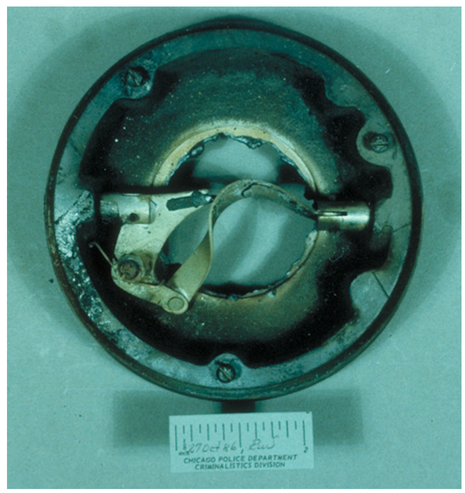
- **Have repairs been made to cover the fact of entry. If so, what is the skill level of the repair;**
- **Has prior work been done on the container that made it more susceptible to a subsequent forced-entry. Could the perpetrator have had prior knowledge of that repair;**
- **If prior repairs had been made that contributed to the present burglary, were those repairs accomplished according to specifications. GSA, for example, has stringent requirements whenever a container has been drilled and repaired. There is no such UL specification for repairs;**
- **Was the burglar interrupted, leaving tools at the scene or explosives not detonated;**
- **If explosives were utilized, have charges been left primed but not detonated, indicating interruption;**
- **Does it appear that explosives were set off improperly, indicating rough handling;**
- **Is there residue from explosives that could be detonated upon contact from crime scene technicians;**
- **Has the safe been moved, especially if on wheels;**
- **Are there wheel tracks on the floor;**
- **Does the size of a drilled hole equal that which would be required. The size can provide an idea as to the competence of the burglar;**
- **Does it appear that the job was abandoned when it should have been completed, indicating psychological pressure to escape by an amateur or lack of knowledge;**
- **Should the safe have been easy to open but was not, indicating lack of knowledge;**
- **Was there an attempt to remove a brass or steel dial on an old lock, indicating lack of expertise;**
- **If an older safe was opened, could vibration have been utilized to rotate the wheels to gate alignment. The type of lock must be checked;**
- **Are combination locks correctly installed;**
- **Are hinges correctly installed;**
- **Is there an oil-like deposit on everything in the area of the burglary indicating the use of a thermic**

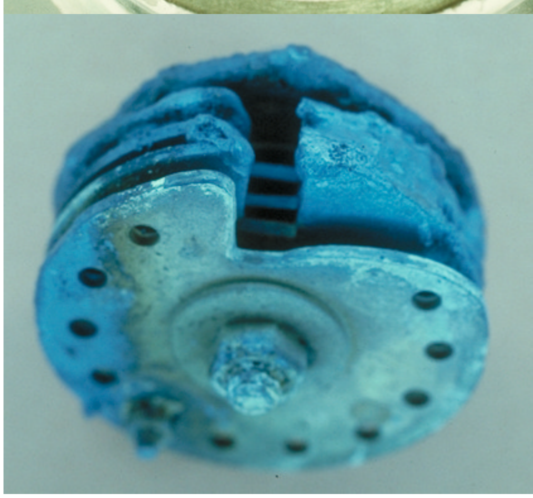


lance;



- **Is there evidence of drilling, especially through or under the dial ring. Disassembly of the lock may be required because of replacement or repainting;**
- **Are there lever marks on the face of the door;**
- **How much did the safe or door weigh, indicating how many burglars may have been involved;**
- **Was the door removed or altered to cover use of correct combination, or manipulation;**
- **Has the safe been recently serviced. Were drawings made by the service technician to provide precise drill points;**
- **Has a new cover plate been installed, indicating that one has been replaced after drilling;**
- **Take the door and lock apart to inspect for marks;**
- **Has the safe been recently moved;**
- **Are electric locks utilized on secure doors. If the power is interrupted, what is the result;**
- **Are high-security padlocks in use, such as the S&G 8088 or 8077. These have been designed to government specifications to provide an indication of entry. They are constructed with a shiny chrome-plated shell with shrouded dials.**





CHICAGO POLICE DEPARTMENT
CRIMINALISTICS DIVISION

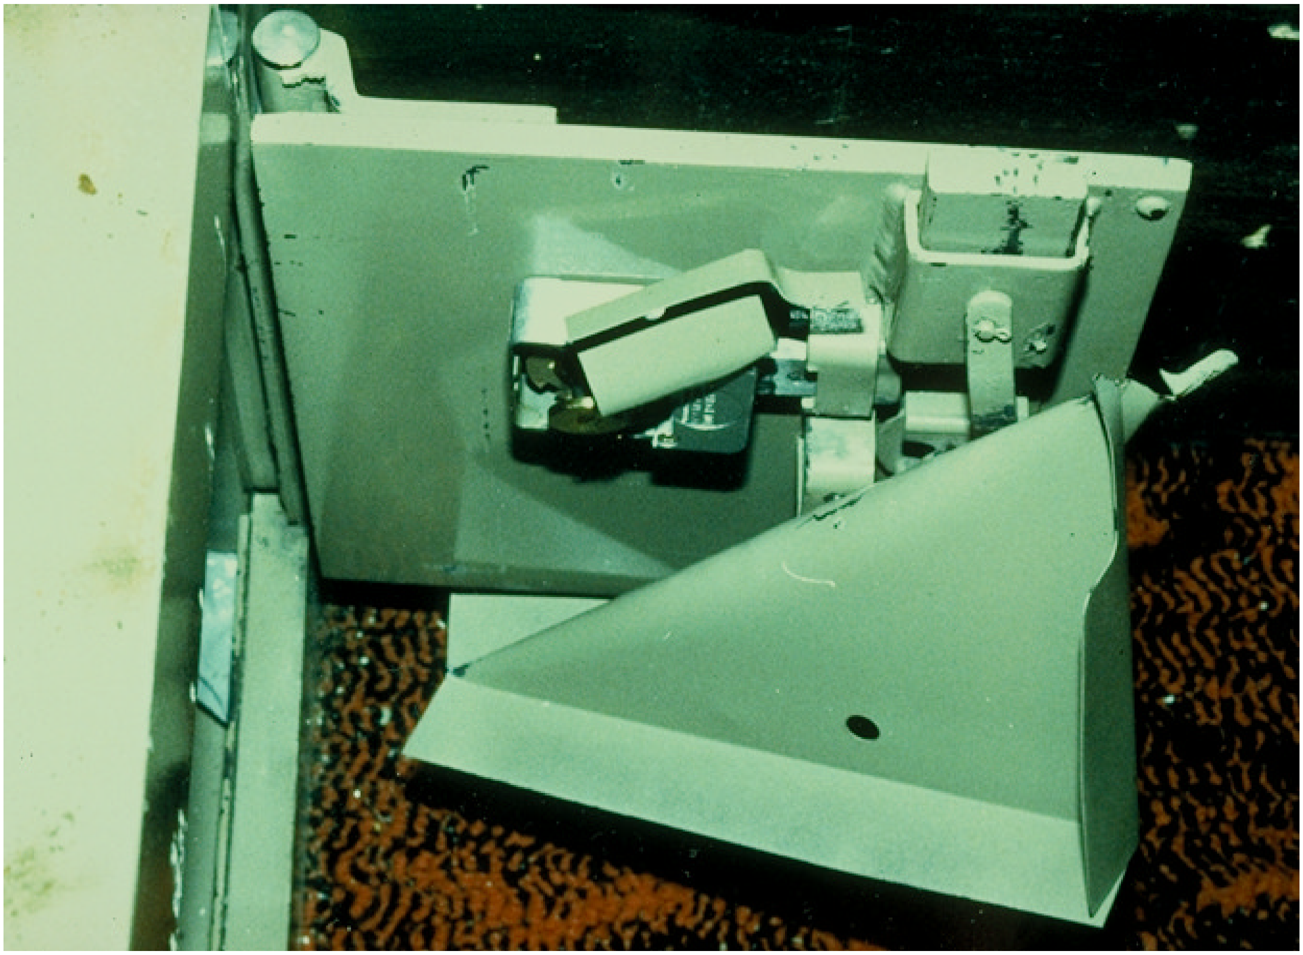


Figure LSS+3553 (PHOTO ID: Top left ISP 33-2963, center 34, right 35; second row left 36, right 37; third row left 38, center 39, right 40; bottom 41). Is there something that does not appear correct in the way the safe or its components appear. ISP 33, the Sears Tower in Chicago, is shown leaning at a severe angle, indicating that all is not what it appears. The same rule applies in safe burglaries; many are simulated but are in reality inside jobs. Examine carefully all of the evidence to be certain that how things appear actually reflect the facts. In all of the above photographs, records chests and floor safes have been subjected to simulated attacks. Courtesy of Illinois State Police, Bill Sherlock.

35_10.2.2 Fire Safes

- **If a fire safe has been burglarized, is there evidence of a prior burglary;**
- **If the contents of a fire safe have been destroyed**

by fire, is there evidence of a prior drilling to effect entry. If so, is there evidence of a repair and the replacement of insulation to factory specifications. One hole in a fire safe can destroy the contents if not repaired correctly. There may be an insurance liability issue if proper repairs were not completed;

- **Was a torch utilized to penetrate the safe. This would be indicated by external criteria, as well as moisture content of the materials contained in the container;**
- **Insulated safes can be easily moved and attacked from the bottom.**

35_10.2.3 Identification of the Perpetrator

- **Did an amateur or professional effect entry. Opening safes can be a highly technical operation, especially for a professional. There are many sophisticated mechanisms, and all are different. If a professional did the job, then the perpetrator may have had a background as a locksmith, safe technician, military technician, intelligence officer, or mechanic. Was the burglary of the safe a crime of opportunity that occurred during the burglary of the premises? Did the burglary appear to have specific knowledge of the safe and the tools that would be required for entry? Did the perpetrator have the correct tools to effect entry? Did the burglar leave his tools and all indicia that could link him to the crime;**
- **Did the method of entry or the use of tools indicate special knowledge that minimized the damage, expedited the opening, or demonstrated expertise;**
- **If explosives, drills, or cutters were used, it is likely that insulation material will attach to the perpetrator, his tools, or clothing. Keep samples of all materials from the scene. The presence of diatomaceous earth, Portland cement, vermiculite mica, gypsum, wood chips, paint, and other materials can identify the burglar. This is because most manufacturers utilize unique materials, mixtures, and particle size. Botanical experts may be**

employed with respect to the identification of certain compositions, especially if infected with a fungus;

- **Record all tool marks;**
- **Search for fingerprints;**
- **Search for blood;**
- **Search for fragments of skin on glass or other surfaces;**
- **Paint transfer may occur between tools and other surfaces that can allow for identification;**
- **Was the dial pulled off the safe, but entry not made through the front, but rather the side or back. This would indicate that the perpetrator had special knowledge and measured the distance from the face of the door to the back of the lock case, using a fine wire;**
- **Samples of metal chips from drilling hard plate and the oil residue from the drill can be matched with those found on a suspect;**
- **Examine the lock case for burned paint that was caused by excessive heat, dull bits, or a negative rake on the bit. Does it appear that a carbide bit was used to penetrate the lock case, rather than a sharp HSS bit;**
- **How much pressure was used during drilling. If there is a hole in the lock case, is there damage to the nose of the lever or wheels. Is any of the plastic wheel pack melted;**
- **Was the back cover of the lock case knocked loose;**
- **Was a thermal relock trigger fired and which was caused by heat from drilling;**
- **Was a second hole required because of incompetence;**
- **Were drill bits left at the scene that can be linked to a perpetrator;**
- **How was the dial removed. Did the removal of the dial indicate lack of experience or knowledge. Dials made of brass, bronze, and steel, Group 1 dials (S&G 8500, or TL rated), or certain manufacturers (Mosler 302, for example) cannot be pulled with a slam hammer or dial puller. If the dial is threaded or pinned, it likewise cannot be pulled;**
- **Drilling generates fine dust. Check the clothes,**

hair, and fingernails of a suspect;

- What information and prior knowledge was required to plan the attack;
- Was prior knowledge of the container required;
- Has the owner been having trouble opening the container, and has a locksmith recently been called;
- Were relockers engaged, indicating lack of expertise.

35_10.2.4 Other Physical Evidence

- Tool marks on any surface;
- Scrape marks on sides of safe and handle, indicating the use of a drill rig with chains;
- Magnetic images on face of safe;
- Metal chips on floor in order to determine the type of drill;
- Broken bits left at scene in order to indicate make and manufacturer of drill.

35_10.2.5 Tools

- Was a hole saw used to reduce the dial size. Was there any damage to the drive pins or flys. If not, the wheels may have been spun several times prior to drilling. This practice protects components from shock, thus indicating expertise of the burglar;
- Was entry effected by an amateur or professional;
- If the lock case was penetrated, does it appear that a sharp drill bit was utilized. A dull bit will force material ahead and form ridges or bubbles on the inside of the lock case wall that can bind or rub against the bottom wheel. Examine for such indicia;
- Did the burglar drill through the dial and hit the mounting screws. This would indicate a lack of knowledge, especially with regard to the bottom screw, because of the potential of dropping the screw-head into the wheel pack;
- Were mounting screws drilled in an effort to bypass hard plate to reach the lock case;

- **Were professional tools employed to manipulate internal components. Often, burglars will remove the dial and punch the spindle. Then, tools are used to align the gates and defeat relockers. Tool marks may be present in the lock case or on the wheels;**
- **Drilling can be dangerous, especially if a bit breaks. This can cause the motor to fly and hurt someone. Is there evidence of personal injury;**
- **Are there multiple drill marks on the face of the door, indicating lack of proper tools and that the work was performed by an amateur;**
- **Was a professional drill press utilized;**
- **If a magnetic drill press or template was attached, then magnetic fingerprint powder, copy toner, or spray material will show magnetized spots on the surface of the safe;**
- **Was a robot dialer, such as the ITL, utilized. Are there any clamp or suction marks on the dial;**
- **Was a diamond-tipped drill bit utilized. If so, was it run at low RPM and light pressure, indicating expertise;**
- **Are there any broken bits left at the scene, indicating difficulty in penetrating hard plate or lack of expertise;**
- **Does it appear that expensive tools were required to effect entry. Do such tools leave distinctive marks;**
- **Were tools broken, indicating lack of experience;**
- **Was an incorrect drill bit utilized;**
- **Was an improper drilling technique utilized;**
- **Was an incorrect cutting tip for an oxyacetylene torch used;**
- **If a torch was used for penetration, was the door welded shut due to excessive heat;**
- **How precise were drill points. Exact location would indicate the use of a drill template and expertise;**
- **Was the dial removed, indicating lack of experience.**

35_10.2.5.1 Tools in the Possession of Suspects

The characterization of an implement as a "burglary tool" is somewhat illusive. However, the following devices will generally meet the statutory criteria, depending upon where found, combination of tools, circumstantial evidence and direct evidence of use:

- **Bellows;**
- **Borescope or special viewing device;**
- **Containers of gunpowder;**
- **Drills;**
- **Explosives;**
- **Fur muff, carpet, or other sound baffling material;**
- **Fuses;**
- **Hole-saws;**
- **Jimmies, in various lengths;**
- **Levers;**
- **Lights;**
- **Maps and blueprints;**
- **Rubber hose;**
- **Spatula to open window fasteners;**
- **Specialty pulling tools;**
- **Tubes for blowing powder into openings;**
- **Wedges;**
- **Wrenches.**

35_10.2.6 Drilling

- **What was the drilling technique;**
- **Did the perpetrator have prior knowledge of the container;**
- **Did the perpetrator understand the proper use of his tools;**
- **Did the perpetrator bring the proper tools to do the job;**
- **Did the perpetrator utilize tools in an incompetent manner;**
- **What was the accuracy;**
- **Was a drill template used;**
- **Was the hole drilled at an improper angle;**

- **Were relockers triggered, indicating lack of knowledge;**
- **Were holes drilled in the wrong place;**
- **Was there damage done to the lock;**
- **Was the diameter of the hole too great or too small;**
- **Were bits stuck in the hole;**
- **Was a magnetic template used on the face of the safe;**
- **Was special knowledge required for a particular type of lock to drill it properly;**
- **If hard plate in a burglary-resistant container was drilled was the drilling angle 90°. If not, the perpetrator may not have had prior knowledge of the construction of the container.**

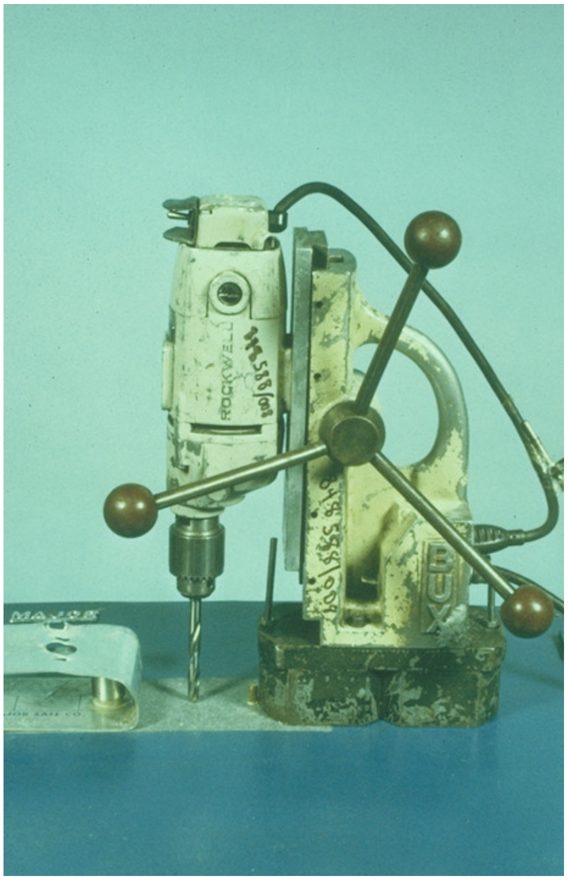

Figure LSS+3554 (left, ISP 90-3563; center, ISP 92-3563; right ISP 93-3563). In 90, the burglar uses a drill without much knowledge of the safe. In 91, 92, this was a safe at a fast food restaurant chain, showing that the thief had no idea where to drill. In 93, a mock drill point is shown to demonstrate lack of competence upon the part of the burglar. Courtesy of Illinois State Police, Bill Sherlock.

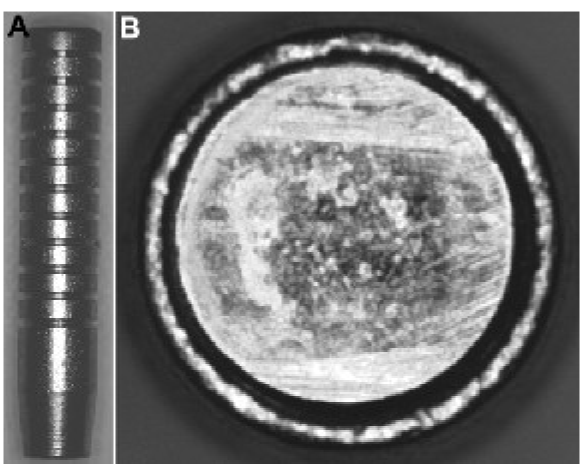
35_10.2.7 Modus Operandi

- **What is the primary method of operation: apparent and real;**
- **If the container was drilled, for what purpose;**
- **Does the technique indicate expertise. If so, why;**
- **Was the lock drilled under the dial ring, then replaced to mask the fact of entry;**
- **If drilling was under the dial ring, is the lock unique or difficult to obtain;**

- **If an electronic lock such as the Mas-Hamilton X-07 was replaced, was special knowledge required in order that the combination not be disturbed;**
- **Did the perpetrator have sufficient time to use his knowledge and tools successfully;**
- **Did the perpetrator have the proper tools to complete the task;**
- **Did the perpetrator have sufficient knowledge about the safe.**

3563-15 Individual must have knowledge



3563-16 Tool knowledge of the burglar

3563-17 Time limit for burglary

3563-1819 Proficiency in burglarizing types of safes

35_10.2.8 Prior Repairs to the Door

Government organizations have strict requirements with regard to the repair of containers. High-security GSA containers, for example, are not designed to be money containers or fire chests; they are essentially file cabinets. They are specifically designed **not** to be repaired because the fact of penetration needs to be discovered.

Improperly completed repairs can result in different ramifications that can affect the investigation of entry. These include:

- **Within a fire safe, destruction of contents due to channeling of high temperatures to the interior;**
- **Insurance liability issues;**
- **Ease in subsequent penetrations at the same point of entry;**
- **Loss of security rating or UL classification.**

The basic rule of repair is to make it more difficult to effect subsequent entry at the same drill point. Repair criteria and protocols have been standardized and require the following procedures:

- **Ream the hole;**
- **Fit the pin into the hole for precise mating. The pin should completely conceal the edges;**
- **Clean the hole;**
- **Fill the hole using a tapered, hardened tool steel pin and large ball bearing. Be sure that it is a tight fit. A hole may also be filled with pro-epoxy 20 to act as a binding agent. It may also be welded with a plug;**
- **A hole may be filled using a setscrew. This requires that the opening be tapped about three quarters through. A grade-8 bolt is screwed into the hole, with torque applied;**
- **Weld the hole from each side, first placing ball bearings, broken files, and other materials in the center;**
- **Grind smooth the weld, trimming any protrusions;**
- **Use a rubber rotary disc, emery, or fine grit to remove all grinding marks;**
- **Paint over the hole or refinish the door so that the repair is invisible. Then use oil and fine emery cloth to polish. Automobile trunk paint can be used;**
- **Texture the finish;**
- **Replace the dial ring, if necessary.**

35_10.2.8.1 Evidence of Current Repair

- **Was a repair made to cover the fact of entry;**

- **Was the lock replaced and reprogrammed;**
- **Has any portion of the lock been replaced recently;**
- **Is there any indicia of repair in the form of physical evidence, such as metal filings, paint flecks, or drilling tails;**
- **Is there evidence of drilling in the form of a tapered pin, plug, epoxy, solder, or other filling compound;**
- **Has the safe been repaired on previous occasions;**
- **Was solder used to fill a hole, rather than a tapered pin;**
- **Has the dial ring been burnished or cleaned with a file, wire brush, sand paper or steel wool;**
- **Examine the paint finish for differences in texture or color;**
- **Has the index marker been altered or refilled with paint;**
- **Can the type of paint be identified, if used to retouch a dial or door surface;**
- **Look for drill indications and the use of plugs or pins, especially under the dial. Examine very carefully because such indications can be masked, making them difficult to observe;**
- **Examine similar containers as a comparison;**
- **Check for a new dial. It may be necessary to remove the dial and check for replacement;**
- **The dial ring is attached with screws. Check to see if they have been replaced;**
- **Repairs to government containers require a certification describing the alteration. There is no such regulation in the commercial sector. Federal rules also require that no indication be present that the lock had been penetrated.**
- **Although there is no UL specification for repair once a container has been penetrated, it cannot be fixed and retain its label.**

35_10.2.9   Use of Explosives

- **How much explosive was used;**
- **Was substantially too much explosive utilized,**

indicating lack of expertise. In the alternative, was just enough material utilized, indicating prior experience and expertise;

- **Have similar entries been performed using the same explosive, or technique.**

35_10.3 Tool Mark Evidence

Many types of implements can create tool marks. Jamb spreaders, crowbars, pry bars, wedges, screwdrivers, hacksaw blades, punches, and like tools will also leave marks on doors, locks, and frames. See **Chapters 23-27** for a detailed discussion regarding tool marks.

CHAPTER THIRTY-SIX: COVERT ENTRY

Non-Destructive Methods of Entry

Master Exhibit Summary

A discussion of Mas-Hamilton and the Soft Drill, by Harry Sher

Background on Mas-Hamilton and the development of the Soft Drill, by Harry Sher

36_1.0 Introduction

This chapter is about the techniques used to open safes and vaults, of which movies are made. Much of what the public believes to be true about manipulation and other forms of covert or surreptitious entry is in reality only partially accurate. However, as the reader will learn, very sophisticated techniques are available for opening the most secure containers without leaving any evidence.

In this chapter, the various methods to bypass combination locks without damage or evidence of doing so are examined. Without question, some of the techniques are very sophisticated. There is no doubt that as the technology of digital image and sound capture is integrated into future robotics designs, the ability to compromise today's mechanical locks will mandate that electronic devices be utilized for any secure container. Some forms of silent entry require sophisticated and expensive equipment and very specialized knowledge. Radiographic imaging is such a science. Other techniques are less complex but equally effective. All of the principal methods of non-destructive entry are surveyed in this chapter, prior to a detailed analysis of traditional manipulation techniques.

The chapter concludes by exploring the art, science, and technology of manipulation. The technique, in one form or another, has existed since the advent of the modern combination lock itself. Today, there are professional safe technicians, government agents, and criminals who are extremely adept at opening a lock by feel and sound. Notwithstanding the belief by some British safe manufacturers to the contrary, manipulation done by a skilled technician can allow most locks to be compromised. Manipulation requires a great deal of training and experience to open safes consistently and successfully. As will be shown, other forms of non-destructive entry do not require such expertise. The ITL robot dialer, for example, will open virtually any Group 2 lock if programmed properly and left for a sufficient period.

This chapter is not intended as a detailed treatise on covert

non-destructive bypass. It will provide a working knowledge of the subject, sufficient for the conduct of forensic investigations or as a reference for further study by the safe and vault technician. Our prime focus is manipulation and its underlying theories, thus providing a working knowledge of the subject for the reader. Lockmasters, MBA (Mark Bates), Bennie Wells and Martin Newton (UK), Ken Dunckel and Skip Eckert (U.S.), and other recognized experts provide intensive training schools, consultation, and reference materials on the subject. The reader is also directed to **Chapter 38** for an expanded discussion of certain physical security devices.

36_1.1 Factors Affecting Entry Method

Every covert entry situation is different. Which technique is selected will depend upon many factors. These include:

- **Primary classification of lock: mechanical or electronic;**
- **Type of mechanical lock: combination or lever;**
- **Type of electronic lock: high-security equivalent to Group 1, such as Mas-Hamilton, S&G, LaGard, or lower security rating equivalent to Group 2, or no security rating;**
- **Security and UL rating of the lock;**
- **Security rating and design of the container;**
- **Special entry tools available for specific type of lock;**
- **Prior reconnaissance of lock and container;**
- **Access parameters:**
  - **Maintenance and lockout condition;**
  - **Law enforcement operation with warrant, not covert;**
  - **Law enforcement covert operation;**
  - **Covert intelligence operation;**
  - **Limited window of opportunity;**
  - **No time limit of access;**
  - **Secure site, no problem leaving automated equipment;**
  - **Non-secure site;**
  - **Operation may be performed with several attempts at different times;**

  - **Operation must be performed in one session;**
  - **Mission is critical as to when it must be accomplished;**
  - **Mission is non-critical in nature; time not an issue;**
  - **Physical danger involved in the operation;**
- **Access to facility requires special entry team and use of covert techniques;**
- **Likelihood of success for specific techniques;**
- **Equipment and special tools required for bypass;**
- **Number of operatives required for bypass of container.**

36_2.1 Covert Methods of Entry: A Survey

There are many covert methods of entry available to the safe technician, intelligence agent, investigator, and burglar. This Section will summarize the principal techniques used for opening safes and vaults in a non-destructive manner. For a discussion of specific techniques relating to key locks, see **Chapter 29.** An analysis of the diamond theft in Antwerp, Belgium also provides an insight into the compromise of combination locks. See section **40_5.0.** There are at least twenty recognized methods to bypass the lock on a security container. The use of a particular technique will be based upon one or more factors, conditions, or circumstances as outlined above. The principal methods of entry include:

- **Capture of individual, bypass, or master codes;**
- **Capture of remote authorization or log in;**
- **Decoding the lock;**
- **Deduction of combination through physical means:**
  - **Paper marking;**
  - **Fingerprints;**
  - **Audio capture;**
- **Employee compromise;**
- **Position of dial after entry of combination;**
- **Factory tryout combinations;**
- **Impressioning the lock;**
- **Manipulation, using sound, feel, and touch;**
- **Picking the lock;**

- **Radio frequency energy interception;**
- **Radio frequency interference or disturbance;**
- **Radiographic imaging;**
- **Reversal of day locking;**
- **Robot dialing;**
- **Simulated burglary or maintenance to secure information;**
- **Observation of combination through surveillance;**
- **Vibration;**
- **Wear of internal components;**
- **User negligence;**
- **Use of the Mas-Hamilton Soft Drill manipulation system.**

36_2.1.1 Capture of Individual, Bypass, or Master Codes

Minimum-security safes used in hotels, lockers, public places, businesses, and homes utilize computer-based systems in conjunction with various authentication technologies. Magnetic stripe credit cards and magnetic spot (barium ferrite) cards are perhaps the most popular, although other schemes are also in use. Many of these systems can be compromised by decoding cards, locks, or memory devices within the CPU.

The author has worked many investigations involving these types of containers. In several instances, it was possible to remove non-volatile memory from a safe, decode the master password, and create a magnetic stripe credit card that would open all containers within a massive complex. All this was accomplished covertly and within a few minutes. Once the location of bypass codes within a memory device is determined, it can be a relatively simple matter to decode and re-encode that information. See www.security.org for specific security alerts for these types of devices.

36_2.1.2 Capture of Remote Authorization or Log-in

Fast-food restaurants, truck stops, and other locations with a high incidence of armed robbery have begun using remote-controlled cash containers. These systems require a host or control center to transmit an authorization via dial-up telephone circuit before the safe can be opened. If this

information exchange is captured and decrypted, the process can be simulated.

36_2.1.3 Decoding the Lock

The subject of decoding was fully presented in **Chapter 31** with regard to mechanical key locks. This technique is equally applicable to lever locks that are popular for use on safes. Decoding involves the analyses and extrapolation of information derived from individual levers, wafers, or tumblers. The data can be obtained in a variety of ways, including the use of an impressioning compound, optical viewing device, feeler gauges, or specially designed instruments.

John Falle produces an extremely sophisticated array of decoding tools, together with training for the professional safe technician and intelligence operative. His **pin lock** and **lever lock decoders** are legend within the military, government, and intelligence communities. Using them, virtually any lever lock can be bypassed covertly. As described in **Chapter 31**, these tools determine with absolute precision the position and travel of each lever to the fence or shear line. Some devices are so sophisticated that they will allow the highest security locks to be opened within a few minutes without trace of entry. These instruments can then decode and replicate each bitting position of a key in order to produce a duplicate.

36_2.1.4 Deduction of Combination Through Physical Means

A combination can be deduced through a variety of physical techniques without leaving a trace. Touch-sensitive materials, such as fingerprint powder and ultraviolet indicators, can provide useful information about a target lock and specific details of how it was opened. UV powder, for example, can display which keys of a touch pad were depressed when the lock was opened.

Use of ultra violet to determine which keys have been depressed on a keypad. Courtesy of Don Shiles.

36_2.1.4.1 Marking Material

Marking material such as foil, wax, or paper can be secreted under the dial to indicate stop-points for each revolution during entry of the combination.

36_2.1.4.2 Fingerprints

Fingerprints can be captured and later observed with ultra violet markers and an illumination source. This technique is especially useful for push button locks.

36_2.1.4.3 Audio Capture

This procedure is useful with combination locks that generate audible clicks for each number division. A microphone is hidden in close proximity to the lock to record the entry of the number sequence. If the dial is zeroed or set to a known marker position, then the recording can be interpolated and the combination decoded.

36_2.1.5 Position of Dial or Entry of Combination

The final number of the combination can often be observed, because it is common practice to leave the dial set at this position during the day. Once one of the numbers has been compromised, it is much easier to manipulate the lock or open it with a robot dialer. Dial marker position can be acquired through casual viewing, or with the aid of remote video, pinhole cameras, or borescopes. High-resolution cameras make possible the capture of such information from several feet away. In some cases, it is also possible to observe an authorized individual actually opening a safe. In this manner, the complete number sequence can be obtained.

36_2.1.6 Employee Compromise

Information regarding combinations may be obtained from employees, with or without their knowledge. An unauthorized person can obtain the data and compromise security.

36_2.1.7 Factory Tryout Combinations

Many safe manufacturers generate random combinations by computer. Often, number sequences are linked to the serial number for a particular container. Some vendors have adopted default sequences to open all locks shipped in their original configuration. Unfortunately, many unskilled technicians will install a new lock or container without reprogramming the factory combination. There is a comprehensive list of these number

sequences for all major locks on **www.security.org**. In the event that original combinations have not been altered, the manufacturer will usually provide the information as well as drill points to authorized technicians.

36_2.1.8 Impressioning the lock

Mechanical key locks can be impressioned, as well as decoded and picked. The subject was thoroughly reviewed in **Chapters 29-30-31.** Even a nine-lever high-security mechanism can be compromised in this manner.

36_2.1.9 Manipulation by Sound, Feel, and Touch

The art and science of manipulation is more thoroughly discussed later in this chapter. The technique involves the use of sight, touch, and hearing, combined with a detailed knowledge of the lock. A competent technician can often open a Group 2 lock in less than four minutes. The procedure is actually quite simple and relies upon the failure of lock manufacturers to achieve perfect tolerances between wheels, lever fence, and gates. Production imperfections are exploited to determine the gate position of each wheel.

36_2.1.10 Observation and Surveillance

While the container is being opened, direct observation or remote surveillance of an employee can yield the combination sequence. With the availability of extremely small video devices, a camera can often be placed in such a position as to afford a direct view of the dial. High-resolution cameras make possible the capture of such information from several feet away. This information can be recorded or directly seen. Borescopes may also be utilized as pinhole cameras. Techniques for obtaining information through surveillance include:

- **Secrete persons or cameras in ceilings;**
- **Observe safe being opened at close range;**
- **Audio or video plants in order to derive the combination or information about it. Devices will include video, film cameras, or audio recorders, long-range lenses, telescopes, or binoculars.**

36_2.1.11 Picking the Lock

As described in **Chapter 29**, almost all lever locks can be picked. The process involves the manipulation of each lever until all are aligned with the fence. Regardless of the security rating and anti-pick features, the vast majority of these mechanisms can be compromised.

36_2.1.12 Radio Frequency Energy Interception

Most electronic locks emit some form of electromagnetic energy at radio frequencies. In some cases, a spectrum analyzer and data recorder can be used to decode information about the combination. Certain systems will also utilize passive and active code devices embedded in keys or electronic cards. Although minute levels are present, there is data being transmitted to the central processing unit from such devices. Capture and decoding of this data will yield information that can be of value.

36_2.1.13 Radiographic Imaging

General techniques of radiographic imaging have been described elsewhere in this text. X-ray is used to observe internal components of a lock, normally shielded by metal surfaces. A radiation point source, using x-ray, gamma ray, beta ray, neutron bombardment, or ultrasound can be used to create a shadow and image of a wheel pack, and display the relationship of the wheels to the fence. Even low-density wheels made of delrin or similar materials can be photographed with neutron bombardment techniques.

Traditionally, a radiation source would be placed at the back of the safe, with film in front of the lock. Although focusing is a major problem, with proper training and expertise the photographs can yield sufficient data to allow a determination of the gate position of each wheel. Harry Miller, of S&G, was the first to experiment with radiation resistant locks in 1947. Group 1R locks were patented about the same time, and incorporated delrin wheels made of low-density material, to combat the threat. Initially, it was thought that the introduction of scattering and shielding material into a lock would make radiographic imaging unreliable as a decoding technique.

With the advent of the portable isotope in 1953, the United States government became concerned about the potential for compromise of high-security locks. At that time, the isotope could be contained in a small lead container weighing no more

than sixty pounds. With a three to five million volt power supply, the equipment was safe to use and ideally suited to radiographic imaging of locks. Miller found that a three-wheel lock could be decoded by exposing each wheel movement separately. A correlation would then be made with each individual piece of film.

The differences in photographic density that resulted from the effects of the high-density metallic tumblers and voids at the location of the gates could be correlated to different dial positions. The typical method to decode locks using radiation would require that a film magazine first be placed in a special holder that was attached to the dial. This would allow the dial and film to rotate in unison. The radiation source would be placed at the rear of the safe. If the dial and film holder were synchronized and rotated at a uniform rate while being radiated, it would be possible to decode the gate positions.

Even in low-density locks containing scattering material, a uniform background on the film is produced except for the gate locations of the wheels. With suitable markers on the film, the combination can be established as one of six possible sets of numbers. Miller found that the use of stationary scattering and shielding material and low-density tumblers did not afford adequate protection against compromise. SAIC and other manufacturers produce portable radiation devices that are suitable for field operations, and can provide valuable information in order to open safes and vaults.

After extensive testing, Harry Miller patented the first lock to use lead bearings behind the dial in order to deflect any radiated source (2970217, **3024640(408)**). In 1962, Miller incorporated several unique features in his lock to distort x-ray and like radiation energy patterns. This would prevent decoding of the combination. Today, his technique is rarely employed due to the use of DuPont delrin wheels.

Ultrasound, as a less sophisticated alternative, has also been utilized but found unreliable in most cases. A multiplicity of air gaps in differing materials within the lock produce results that are usually inconsistent.

36_2.1.14 Reversal of Day-Locking

Upon opening a safe, many employees will not fully rotate the dial to scramble the wheel pack. Rather, they will turn the dial

a few numbers, just sufficient to move the lever above the gates. However, the interrelationship between each wheel and the position of the pack remains undisturbed. To open the safe, all that is required is to turn the dial back to the drop in point, thus defeating all security measures of the lock and container.

36_2.1.15 Robot Dialing

ITL (Canada) originally introduced the computer-controlled robot dialer. These devices are designed to physically link a stepper solenoid and a computer to the dial. Upon proper programming, they will exploit the tolerance errors for a particular lock in an attempt to determine the true combination. Every possible number sequence will be dialed and tested until the proper sequence is found.

Locks can be opened in less than 45 minutes if one of the three numbers of an opening sequence is known for a 100-segment dial. Otherwise, up to about twenty-nine hours may be required to run every permutation. The equipment and process is more fully examined later in this chapter. See the Wilson patent, granted in 1984, for a method of automatically dialing combinations (**4433563(409)**).

36_2.1.16 Simulated Burglary or Maintenance

A simulated burglary or action that causes maintenance to be performed can be used as a subterfuge to learn the combination. Thus, a malfunction may be feigned in order that a locksmith is called. Information can then be obtained from that person about the safe.

36_2.1.17 Strong RF Field Disturbance

In some poorly designed electronic combination locks, a strong RF field may be employed to scramble the CPU, logic unit, or bolt mechanism. The result can be a corruption of data in memory, or the inducement of voltages that are sufficient to trigger solenoids or other bolt control devices. The author has employed this technique using high-power portable transmitters to accelerate timing lockouts, defeat combination locks, or alter the clock frequency on processors.

36_2.1.18 User Negligence

Convenience often takes precedence over security. Selection of

combinations based upon birth dates, social security numbers, telephone numbers, easily remembered sequences, or patterns are too often used. The burglar can sometimes guess these and open the lock.

36_2.1.19 Vibration

Although not a significant problem today, older combination locks can be opened through the introduction of constant vibration. This was a particular problem aboard ships, where engine tremors were transmitted throughout the vessel. In time, each of the wheels would be self-rotated to where the gates were in the position to allow the fence to drop. The problem was solved with the introduction of balanced wheels.

In practice, many older safes can be opened by the following procedure utilizing vibration:

- **Determine the location of the tip of the fence;**
- **Tilt the entire safe so the fence location constitutes the most vertical position of he lock;**
- **Set the dial to the drop in point;**
- **Tape the dial to prevent rotation;**
- **Attach a transducer to the dial. The transducer must be excited with a low frequency, high energy sound wave. Thirty cycles per second, or within that range should be sufficient;**
- **Apply energy for at least ten minutes, and each of wheels should be vibrated so that the gate is positioned under the fence;**
- **The lock should open.**

36_2.1.20 Wearing of Internal Components

In some inferior quality UL Group 2 locks, the dial can be spun at high RPM with a drill motor for several hours in an effort to create excessive wear upon components. This will lessen critical tolerances or cause seizure. Likewise, a high-speed router capable of operating at 20,000 RPM can explode a wheel pack or separate the individual wheels. The U.S. government has a specification for Group 1 locks that requires the mechanism to be impervious to this form of attack, for a minimum of eight hours at 600 RPM. The lock must still function after that time and be resistant to manipulation. S&G, in response to this specification, have changed the lubrication to allow perfect

operation after eight hours. There **is** a risk that thermal relockers may fire due to heat build-up.

This particular technique was foreseen in the design of the Mas-Hamilton X-07 and is guarded against through both hardware and software. In that lock, there is a threshold of dialing attempts within a predetermined timing window. If the number is exceeded, the lock will shut down.

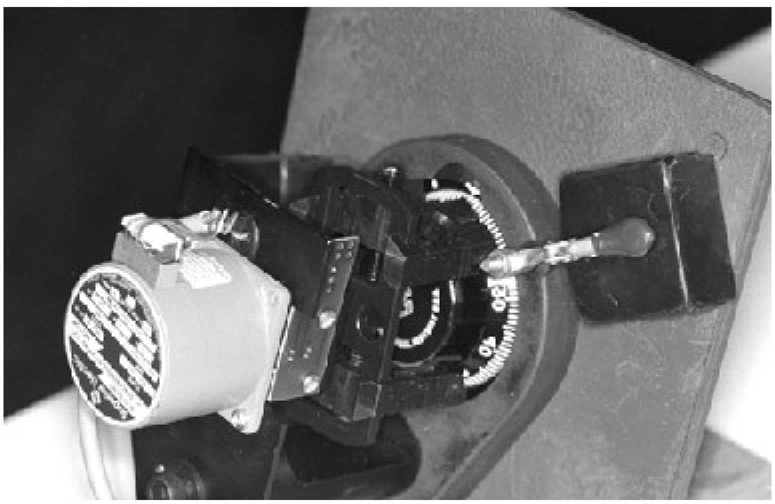
36_3.0 High-Technology Bypass of Combination Locks

The following material describes the current high-technology devices for opening combination locks. A discussion of instruments used for key locks is presented in **Chapters 29-31.** Certain methods for opening GSA enclosures have been omitted intentionally. The following information has been gathered from manufacturers, government agencies, and the United States and British patent offices.

36_3.1 Tools for Determining Safe Lock Component Positions

36_3.1.1 Direct-Drive Locks

Simple tools have been designed and patented for determining the gate positions in direct-drive combination locks (**4056956(410)**). Generally, these instruments measure the movement of the handle when torque is applied. In these mechanisms, the tailpiece position will change slightly when it is pressed against the gate of a wheel.

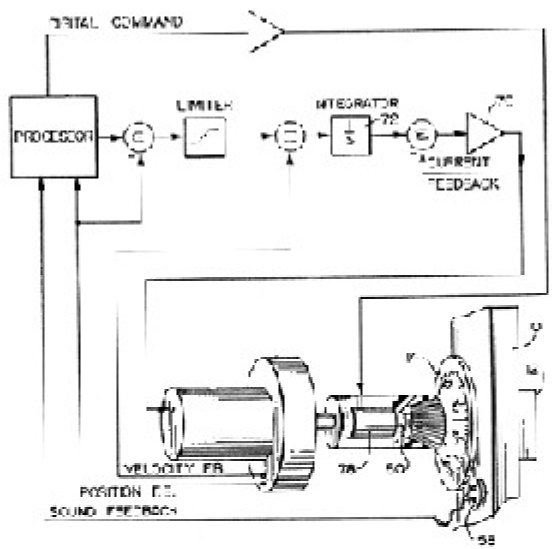


36_3.1.2 Robot Dialers

2963-42 The use of robot dialers

Computer-based automatic control mechanisms can be attached to the dial of a Group 2 combination lock to open it. They can be programmed to sense gate position, or the location of the drive cam with respect to the fence. They will detect when all wheels are aligned and the lock can be opened. The reader may be interested to read a description of an **automaton** robot dialer that was developed more than one hundred fifty years ago to

manipulate lever tumbler locks. This is described in the Hobbs book, contained within this Infobase. Robot dialers are designed to perform two distinct functions. Either they can open the lock by exploiting tolerance errors and testing each permutation of the combination, or they can replicate the actions required in manual manipulation.



There have been many patents issued for such devices and related technology (534650, 1064608, **2974517(411)**, 3222922, 3633388, 3694637, 4017851, **4056956(412)**, 4126821, 4319223, 4377847, **4433563(413)**, 4591774, 4769583, 4777603, **4803860(414)**, **4905490(415)**). Recent inventions reflecting current technology are described in this chapter. See **www.security.org**.

Devices currently under development or being tested will bring sophisticated enhancements to the relatively imprecise present manipulation process. Instrumentation that senses and process audio and video will be available that will open Group 1 and Group 2 locks, with the exception of the X-07.

The Mas-Hamilton X-07 is virtually impervious to manipulation attempts and robot dialing. It is estimated that it would take the ITL approximately 190 days to open the X-07 in single mode, and 250 years if dual mode has been implemented. At the University of California (Irvine), for example, a robot was constructed as part of an engineering project to open safes. The device utilized sophisticated audio and noise analyses with an electro-optical link. The link eliminated noise coupling that created artifacts during processing. It is estimated that when the unit is developed, it will weigh five pounds and be

completely portable.

36_3.1.2.1 Automatic Permutation Sequencing

A number of decoders have been developed for automatically sequencing a lock to test all possible combinations until an opening occurs. In 1958, Jacobs (**2974517(416)**) developed a machine to exploit vibration as a means for manipulating open a lock. The problems associated with vibration were discussed in **Chapters 34-35**, specifically with regard to safes located on ships. It will be recalled that wheels within the wheel pack would vibrate to a position wherein their gates were aligned with the fence. This problem was corrected with the introduction of balanced wheels. Jacobs developed a device to impart random vibration and oscillations in order to induce movement of each wheel until the lock opened.

In 1984, Wilson (**4433563(417)**) developed a device that could be programmed for a specific algorithm, depending upon the fence-gate tolerances of a given lock. His instrument would ignore "illegal" combinations such as in the forbidden zone, thereby reducing the time required to find the correct sequence. The tool could be programmed to skip overlapping numbers, also making the process faster. Finally, the wheels would only be turned to test the next number in the series, rather than redialing the entire number sequence. This allowed a fully automated system that would sense when the correct combination was determined, although the device was incapable of determining

the gate position of each wheel independently.

In 1991, Heinzman was granted a patent (**5017851(418)**) for an opening device that could store many combinations for different safes within a complex. This completely portable unit could be programmed for a variety of modes, depending upon individual requirements. The instrument did not determine gate positions, but rather it could be used as a secure memory device to allow one individual to access many locks.

36_3.1.2.1.1 ITL Robot Dialer

ITL (Vancouver, Canada) produced the first microprocessor-based portable robot dialer available in the commercial market. This device is described in detail here because of its unique design and utility to the professional safe technician.

Robot dialers can perform one of two functions: **permutation sequencing, or manipulation.** The ITL unit is programmed to sequence a particular lock through all possible number permutations until the mechanism is opened. Using the ITL, a lock can be compromised in between four and forty hours, depending upon many factors. If one of three numbers has been determined through manipulation or other means, then the process can require less than one hour.

The device dials a predetermined sequence of combinations, based upon the following information that is entered into the computer:

- **Type of lock;**
- **Number of wheels;**
- **Location of drop in point;**
- **Precise location of left and right contact point;**
- **Position of the zero-marker position or other defined location;**
- **Tolerance or overlap between numbers;**
- **Forbidden zone and unusable numbers;**
- **Known numbers in combination;**
- **Range of numbers to test;**
- **Sequence of numbers per individual wheel.**

Lock manufacturers, to test their products and determine reliability, also utilize robot dialers. These devices provide a means to study how locks perform when users enter combinations.

Programs can vary speed, motion, and delays during the entry process. In this way, failures can be detected and corrected based upon individual user profiles.

36_3.1.2.1.1.1 ITL 9000 Operation

The ITL can be set to dial any sequence of numbers for each individual wheel. A different combination will be dialed every second until a torque change is sensed, indicating that the lock has been opened. Presently, these units will only function with a single-action combination lock that retracts the bolt through the dial action.

The dialer is comprised of a stepper-motor that is mechanically linked to the dial and controlled by a portable CPU. The entire assembly is magnetically coupled to the safe-body for stability. This device will operate in an unattended mode; once the lock is opened, the dialer stops and displays the last number entered.

36_3.1.2.1.1.2 Theory of Operation

All permutation sequencing robot dialer designs are based upon the same principle: mechanical combination locks have tolerance errors between individual wheels that are inherent in the manufacturing process. Dialers exploit these errors by reducing the number of permutations that must be tested in order to determine the correct combination. The gate tolerance for Group 1 locks is ±.75-0.875 from the target number; in a Group 2 lock, it can be up to ±1.25. UL allows ±1.25 from the edge of the target; S&G, from the center of the gate. Each manufacturer takes full advantage of these specifications.

The tolerance for a given lock will determine the actual number of permutations, and thus security. This factor is also affected by wear and will be altered over time. If the fence is close to the gate, it can be vibrated into position, thereby further exploiting tolerance errors. Every 100-division three-wheel lock has 1,000,000 theoretical permutations. The actual number may be less than 240,000, correcting for tolerance errors and unusable numbers. The time required for a dialer to open a lock is based upon a simple calculation. It is a function of the number of real permutations, divided by non-overlapping unique positions and the amount of time required to dial each permutation.

Smart dialers, such as the ITL, will move each individual wheel to the next number to be tested in about one second. Thus, the

combination is actually entered sequentially on an individual wheel basis at high speed. In this manner, these devices can test hundreds of thousands of number sequences in a relatively short period. The actual time required for each test is based upon the coefficient of friction of the wheels.

The probability percentage of opening a lock will increase as more numbers are tested. Thus, in a lock with 240,000 actual permutations, the probability of opening the lock on the first tested combination is extremely low. The curve, however, is linear as one progresses through the number sequences, plotting numbers against time. In a Group 1 lock, there is a probability that a lock can be opened in twenty hours, assuming that the dialer is capable of working on this type of mechanism.

36_3.1.2.2 Instruments for Determining Contact Points

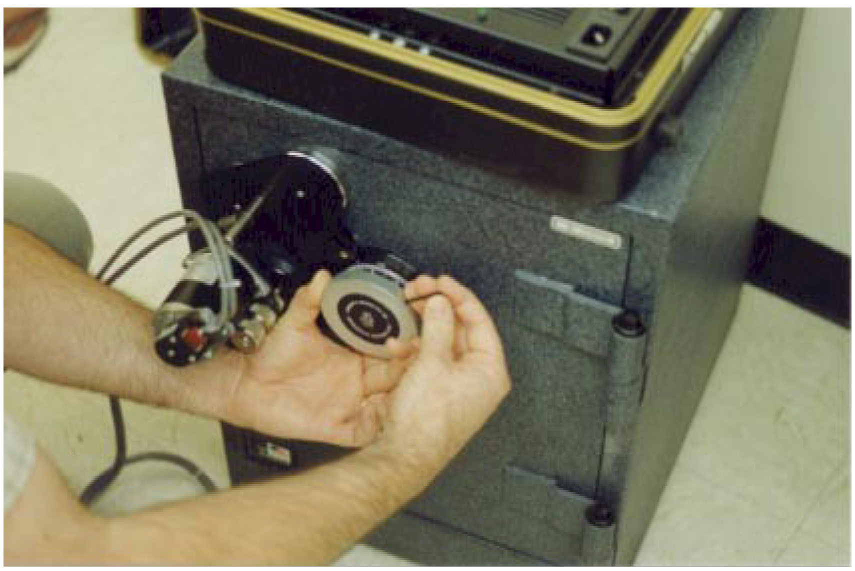
Manipulation is a precise art, requiring a great deal of skill. Simple aids have been developed such as magnifiers, filtered audio amplifiers, scales, and special illuminators. All of these devices are utilized in an attempt to define contact points.

As the reader shall learn, more sophisticated automated devices have also been proposed and developed. Combination lock decoders have been designed to sense dial positions and contact points in an attempt to automate the manipulation process (**4905490(419)**). For example, one major lock manufacturer has produced an instrument that utilizes electro-optical sensing, coupled with extremely sensitive and filtered audio to indicate the position of contact points.

Moore, in 1989 (**4803860(420)**), received a patent for an electronic device to assist in the manipulation process by obtaining accurate contact readings. His invention employed an optical scanner integrated with an audio detection and discrimination system to quantify the information normally interpreted by the safe technician during manipulation. This system, however, did not take advantage of microprocessors or memory technology. The Moore device was not intended to replace the technician or the required detailed knowledge of the manipulation process. Rather, it was designed to enhance the ability of a skilled professional to manipulate open a safe.

In one invention (**4905490(421)**), Wilson designed a device that would accurately sense dial position within one tenth of a digit,

and open many locks within one hour, including Group 1 devices. The invention relied upon the manufacturing tolerance errors that occurred in the production of wheels and the fact that they can never have precisely identical diameters. The inventor used the physical contact between the nose of the lever and each wheel to provide data that could be interpolated by his decoder.



The physical and electronic design of the decoder is typical of the state of the art. A frame is secured to the container in a fixed position, and a gripper links the dial to the servomotor and associated control circuitry. A rotary encoder is coupled to the servo in order to indicate the exact position and velocity of the dial. Also connected to the lock and the processor is a sensitive sound transducer to provide an indication of contact points.

In the Wilson invention, the processor and control circuitry can be programmed with a manipulation algorithm for each lock in order to decode the opening combination. The device will continue to dial thorough all permutations until the lock opens.

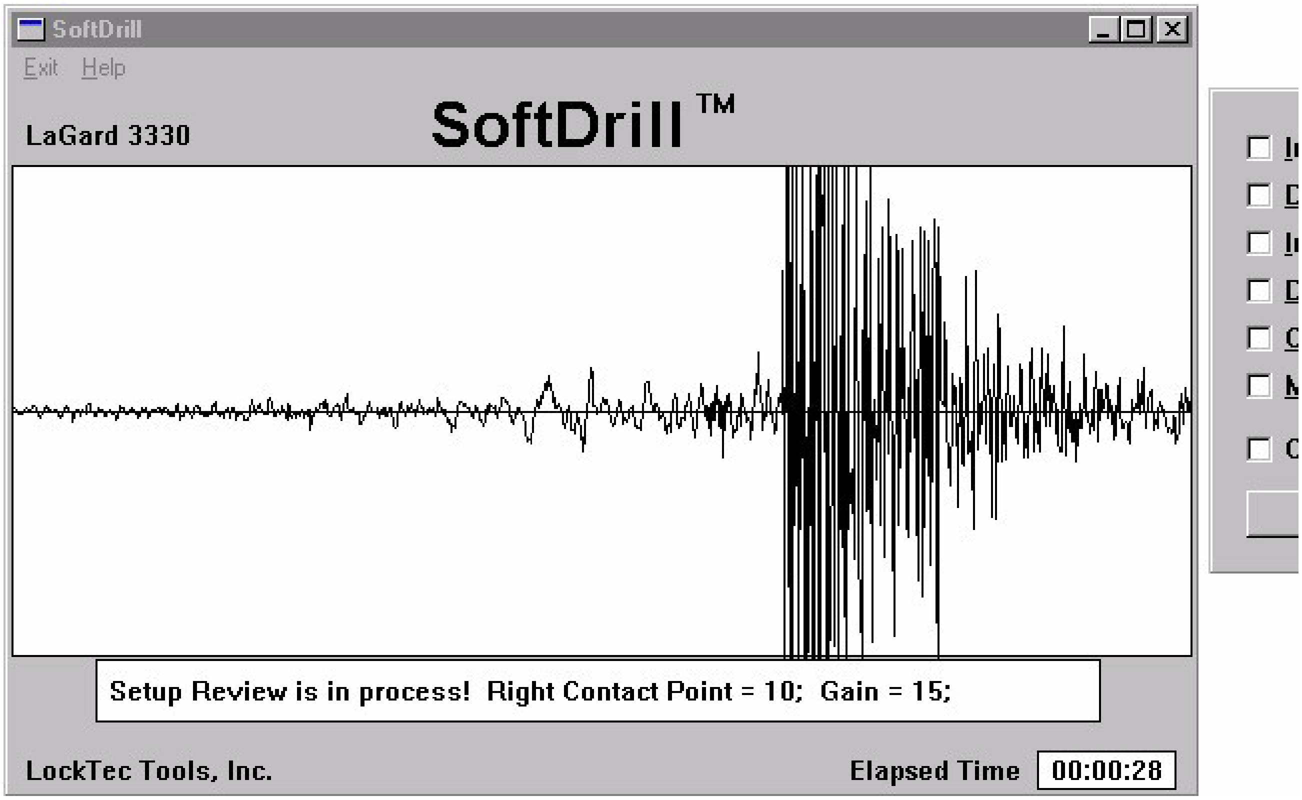
LSS201: Mark Bates on the Soft Drill



A discussion of Mas-Hamilton and the Soft Drill, by Harry Sher

Background on Mas-Hamilton and the development of the Soft Drill, by Harry Sher

Since the printing of the Second Edition of ***Locks, Safes, and Security***, Mas-Hamilton has introduced the **Soft Drill** (r) system for manipulating certain Group 2 combination locks. The technology is based upon mechanical and acoustic sensors that can replicate traditional manipulations techniques. Complete documentation of this system is contained in this section, together with a multimedia demonstration of the opening of a S&G 6730.

Presently, software is available to open the S&G 6730 series and the LaGard 3330. The Soft Drill system provides a sophisticated integration of computerized sensing technology with extremely advanced hardware to detect sound and movement to replace manual manipulation. This system is not a robot dialer, but rather a stand-alone process to determine the correct combination and open certain locks.

36_3.2 Defenses to Bypass Techniques

For almost every bypass technique, certain defenses can be implemented by manufacturers and security officers. The following discussion surveys countermeasures against methods of covert entry.

36_3.2.1 Improper Possession of Combination

James Sargent developed the time lock to prevent entry into a container unless the proper combination was used at the correct time. Today, electronic and mechanical time locks protect virtually every high-security safe and vault. They are even used in cash containers at locations with high robbery potential. Time locks are extremely effective in preventing certain types of robberies.

36_3.2.2 Observation of Entry of Combination

Utilize top-reading spyproof dials and covers (2836052).

36_3.2.3 Back-Dialing

Follow the correct security procedure or employ automated locking if the mechanism remains in an open state for more than a few minutes. An employee should always turn the dial at least one full revolution when securing a container. Certain combination locks will automatically reset after being in an unlocked state more than a few minutes.

36_3.2.4 Manipulation

High quality UL Group 2 locks or higher security Group 1 devices can be utilized.

36_3.2.5 Automatic Robot Dialers

Utilize dual-function Group 2 locks or Group 1 locks that are specifically protected against this form of attack. Electronic devices such as the X-07 are immune to dialers.

36_3.2.6 Fingerprints or Other Physical Indicia of Combination

Use special dust covers or random keypad numbering, such as provided by Hirsch.

36_3.2.7 Radiographic Attack

Use of radiation for imaging can be prevented or severely hampered by several techniques. These include:

- **Use of Group 1R locks;**
- **Use of low-density wheels;**
- **Incorporation of lead bearings within the lock and dial assembly (3024640(434)).**

36_3.2.8 Reset of Combination in Zero-Change Lock

The combination in a zero-change lock can be reset without knowing the original number sequence. This can be accomplished

without the knowledge of the owner of the safe. The countermeasure is to utilize a regular change lock.

36_3.2.9 Use of Factory-Default Combination

Change the combination when the lock is installed.

36_4.0 Opening Locks by Manipulation

36_4.1 Introduction

Opening safes by manipulation has been characterized in countless movies as a skill easily acquired by spies and criminals. A little bit of sandpaper, light touch of the dial, listen to the clicks, and in a few seconds the container is opened. All quite elementary!

In reality, manipulation is an art, technology, and a science. The process allows a lock to be opened without any prior knowledge as to the combination and absent any trace of entry. It is a silent skill that will cause no damage to the lock or container. It does not require force, extra tools, or special equipment. Moreover, it has existed for about four thousand years in various forms.

Knowledge of the techniques of manipulation is mandatory for any professional safe technician. The process makes drilling and other forms of forced-entry unnecessary, and it can be invaluable in analyzing the cause of lockouts. However, manipulation will not work in all cases. Damage, wear, malfunction, or design parameters can obscure contact indications.

The forensic examiner and security officer is concerned about manipulation, as it is used for surreptitious entry involving sophisticated thefts. Although over ninety-eight percent of all entries are accomplished by force, major thefts, especially of classified information, are often carried out using this technique.

With the proper skill and knowledge, the procedures outlined below can allow a technician to open most Group 2 locks in relatively little time. However, there are no shortcuts. The art must be learned, based upon a detailed working knowledge of locks. To properly manipulate can require a great deal of time and patience, and adherence to a strict regimen. The talent is

not easily acquired, nor will it work for every lock. Each opening will present a new challenge and potential problems.

In the following discussion, the underlying theories and principles of manipulation will be explored, together with proper procedures and guidelines to allow for a successful and expedient opening. The materials are not intended as an exhaustive treatise on the subject; many books and courses teach the art in far greater detail.

The principles of manipulation are logical, straightforward, and easy to learn. They can be succinctly stated in just a few pages. The translation of that knowledge into a useable skill that will ultimately open a locked safe is another matter. Just knowing the principles does not mean that a particular technician can open a lock.

Our discussion concentrates on theory, rather than an in-depth examination of all of the different variables that can occur for specific types of locks. In the view of the author, it is more important that the reader acquire a sound theoretical basis for the principles of manipulation. Many references provide detailed information regarding opening procedures for each type of mechanism. Gaining proficiency in the art is far less challenging with a thorough understanding of the underlying theory of the technique.

36_4.2 Listen to the Lock: It Will Speak to You

The portrayal in film of combination locks being opened by listening to telltale clicks is pure Hollywood. The "clicks" provide no useable information. In fact, the lock within most of the high-security safes is usually very quiet during movement, as they are often shielded by up to 8" of metal.

"Listening to the lock" means letting it provide information about itself as the dial is moved and various diagnostic procedures are performed. If the mechanism is thoroughly understood and one pays attention to its clues and signals, it will disclose how it can be opened. This will be a one-way conversation to be sure, for there is nothing that can be **told to** the lock. To be effective, the technician must be "at one" with the internal mechanism, and in harmony with it.

36_4.3 Prerequisites to Successful Manipulation

Three primary skills are required for successful manipulation:

- **Visualization of internal components;**
- **Sensory skills;**
- **Logic and judgment.**

36_4.3.1 Visualization

Visualization is the ability to translate sensory information obtained from sound and touch into mental images of internal components. The process must be based upon a detailed understanding of the lock and the integration of that knowledge with sensory data. The technician must know the placement of every internal part and understand its function and purpose. A cutaway model is ideal for this purpose, especially for the novice. It can provide a reference during manipulation and is recommended to be included as part of a basic tool kit.

36_4.3.2 Sensory Skills

During manipulation the technician must process sensory input from the lock in the form of sight, sound, and touch. This information must be integrated into a mental image of the internal components.

36_4.3.2.1 Visual Skills

Manipulation is based upon minute variances in the position of the dial marker, at the left and right contact points. The ability to accurately discern this information is critical. The problem is often complicated by imprecise markings with respect to their width, consistency, and placement.

Dial markings must be observable to a resolution of .05 (1/20) of one marker or division. That means that in order to obtain sufficient data, the dial must actually be divided into two thousand segments. Accurate and consistent extrapolation of marker information is an absolute necessity.

The technician must be able to adequately observe markings. Poor eyesight, inadequate lighting, distortion in eye wear, or obstructions to vision will cause the manipulation process to fail. Visual aids are available to enhance the ability to accurately discern small variances in measurement. These devices are discussed at the end of this chapter, and should be used to

expedite the process of manipulation.

36_4.3.2.2 Touch

A delicate sense of touch is essential for determination of contact points. This requires two separate functions: **motion** and sensing of **obstruction.** The dial motion must be constant within the contact area until the left and right side of the gate physically stops the nose. The amount of motion and torque must be slight; just enough for the nose to make physical contact, but not enough to lift it. A slight, even, and consistent sliding movement is required.

The second component of touch involves the determination as to the exact point where the physical contact occurs. This is a quite delicate sensation and is often enhanced with a filtered audio amplifier. The drive cam is moved ever so slightly at the left and right contact points in an effort to determine when the nose **touches** the gate, but goes no further. This location is the contact point. Any further movement will skew the reading.

The goal is to precisely locate and measure the exact position of the drive cam boundaries, using the nose of the lever as the reference. One simply wants to **abut** the lever against the left and right side of the drive cam channel without disturbing its vertical position. This concept is critical, because **manipulation relies upon the vertical position of the nose within the channel.** Any lifting of the nose, caused by excessive torque, will make the readings worthless.

36_4.3.2.3 Logic and Judgment

Logic and judgment cannot be taught but must be acquired through experience. They are essential to successful manipulation, because they control how a lock is to be opened. Logic and judgment dictate simple rules with respect to opening locks:

- **Do not rely upon preconceived ideas;**
- **Do not rely upon unproven or unsubstantiated data;**
- **Only rely upon information from the lock;**
- **Be flexible in formulating approaches to opening the lock.**

36_4.4 Theory of Manipulation: An Overview

Virtually every UL Group 2 listed lock can be opened by manipulation. This category includes about ninety percent of the devices used on **B** or **C** rated containers, as well as **TL-15** and **TL-30** rated safes. Regardless of the mechanical design, the fundamental theory by which a lock is bypassed is essentially identical. Design deficiencies or tolerance errors in machined components permit all combination locks to be manipulated.

Almost every Group 2 lock will yield the required information to allow bypass, because their design and operating principles are quite similar. Although the placement of components may vary, the way that they interact to accomplish locking is the same. In manipulation, the safe technician is searching for minute discrepancies or irregularities based upon manufacturing tolerances for each part, in order to deduce the combination. The ways in which engineering and manufacturing problems are exploited is the subject of the remainder of this chapter.

Manipulation theory is based upon the following principles and design criteria. Each must exist, with respect to critical locking components, in order that the lock will yield information:

- **The establishment of the individual sequence of numbers that comprises the combination of the lock must be based upon the gate position of each wheel as referenced to the spline;**
- **The combination must be determined solely by the mechanical position of each wheel with respect to the fence;**
- **Bolt retraction must be based upon the position of the lever fence with respect to the gate in each wheel;**
- **The fence must fully enter the drive cam gate in order that the bolt can be withdrawn;**
- **The circumference of each wheel must vary, if only minutely, in order that individual wheels can be isolated;**
- **There must be a definable correlation between the position of the lever fence in the drive cam and each wheel gate;**
- **As the fence is aligned in succession with the gate of each wheel, the distance between the left and**

right contact points of the drive cam will diminish;
- **Each individual wheel must be rotated to precisely the correct position to allow gate alignment;**
- **The lever fence must attempt to enter each of the gates simultaneously in order to allow bolt retraction;**
- **The width of each gate must be uniform with respect to each wheel;**
- **There must be a direct mechanical relationship or link between the fence and contact points when the drive cam is rotated to the drop in point. Any obstruction or shrouding of the gate area, such as found in Group 1 locks, will defeat the manipulation process because measurements cannot be obtained as to the width of the gate for an individual wheel;**
- **The contact points must be formed by the left and right edges of the drive cam gate.**

36_4.4.1 Design Deficiencies

Deficiencies can be defined as mechanical configurations inherent in the design of the lock that make the process of manipulation both possible and easier to accomplish. A few examples illustrate the problem.

In older combination locks, the fence was allowed to rest on all of the discs all of the time. This created a critical weakness that allowed direct sensing of gate position. False discs were incorporated in the design, but that technique was neutralized with a high-speed drill or other procedure. Keeping the lever fence clear of the individual discs prevented direct sensory access to the wheel pack.

The direct-drive fence provides another example. Because of its design, it is a great deal simpler to bypass than the traditional lever fence. This is because pressure can be applied directly to the wheels through the bolt in order to determine contact points.

36_4.4.2 Tolerance Errors

Tolerance and clearance errors in machining and manufacturing processes must occur and will create the minute differences in individual components. A certain degree of clearance is required in order that parts can move freely. Thus, for example, the

inside diameter of the wheels must be approximately .005” larger than the wheel post to allow unrestricted motion. Without such errors, manipulation would be impossible. The process involves the sensing of these variances in order to ascertain the position of the lever with relation to the contact points. One or more of the following tolerance errors can provide enough data about the lock for manipulation to occur:

- **Differences in the width of the gating of each wheel and drive cam;**
- **Differences in the wheel post diameter;**
- **Differences in the diameter of the lever screw and mating hole;**
- **Differences in the eccentricity of each of the wheels;**
- **High or low wheel;**
- **Variances in the distance between the nose of the lever and the fence;**
- **Differences in the diameter of the drive cam;**
- **Shape and square of each gate and fence;**
- **Angle of the fence, referenced to the lever and top of the wheel pack (should be precisely 90º from the edge of all wheels);**
- **Fence protrusion warped;**
- **Fence tip warped;**
- **Lever body not exactly parallel to the plane of the wheels.**

36_4.5 Locks Subject to Manipulation

Certain locks can be manipulated; others cannot. Some have been specifically designed to be manipulation resistant and are employed in high-security applications. Other locks, by virtue of their design, are extremely receptive to the process.

36_4.5.1 Locks that are Easy to Manipulate

There are certain inexpensive locks that can be manipulated quickly and without much training because of their mechanical design. Burglary and fire safes sold in large retail outlets, for example, will generally offer poor resistance to manipulation because their mechanical designs are rudimentary and tolerances inexact. In one very popular but poorly designed mechanisms, only

the sequence, rather than the combinations for each wheel, can be reset. In such cases, permutations of a combination can be entered based upon the sequence of digits. This can result in the lock being opened quickly.

Likewise, some extremely popular and inexpensive round safes that are designed for mounting in floors can be opened in less than five minutes. They can be identified easily, because they usually contain two wheels and a drive cam. The manipulation procedure is illustrative of the simplicity with which such locks can be opened, although to the unknowledgeable they may appear secure. In these kinds of safes, once the drive cam gate area is determined, the wheels are rotated **AWR** or **AWL** every 2.5 or 5 numbers with a return to the right-contact point. The contact area will be .5 less for the correct gate position. Testing and parking of each wheel can isolate the gate.

Surplus government safes can often be opened easily by knowing that most agencies have a requirement that locks must be neutralized to a standard combination. GSA should be consulted to determine current practice.

36_4.5.2 Manipulation-Resistant Locks

A UL Group 1 or Group 1R designation means that a lock has been specially designed and engineered to be manipulation-resistant. The principal difference between Group 1 and Group 2 mechanisms relates to the tolerance errors identified later in this chapter.

In Group 1 locks, maintaining the tolerance between components becomes of critical importance. In addition, certain mechanical design changes have been incorporated to isolate the lever nose from the drive cam. The higher security Group 1 devices (1R) have the same basic design, with the exception that the wheel pack is made of delrin or similar low-density material. UL specifications require that these locks shall resist manipulation or penetration for a period of time, measured in man-hours. As will be noted, however, companies have developed machines capable of automatically opening some of these high-security locks. **Chapter 37** provides information about UL and other standards relating to manipulation resistance of combination locks.

S&G, LaGard, Mosler, Diebold, American Security Products and others have all produced such mechanisms, although S&G appears to be the most widely used in government service. In fact, in May 1989, the GSA specified that only S&G 8400 and 8500 series locks

were acceptable for use on certain high-security containers. Subsequently, Mas-Hamilton received approval as the sole vendor for its X-07 electronic lock for safes containing top secret information.

Harry Miller (S&G) is credited with inventing and patenting the MP 6700 in 1948, and then the MP 6730. These were the first MP locks ever produced. Several improvements were made to the design in the R6700 (1962) and the T8400 (patented in 1965). The current version of this lock is the 8550 M.P.

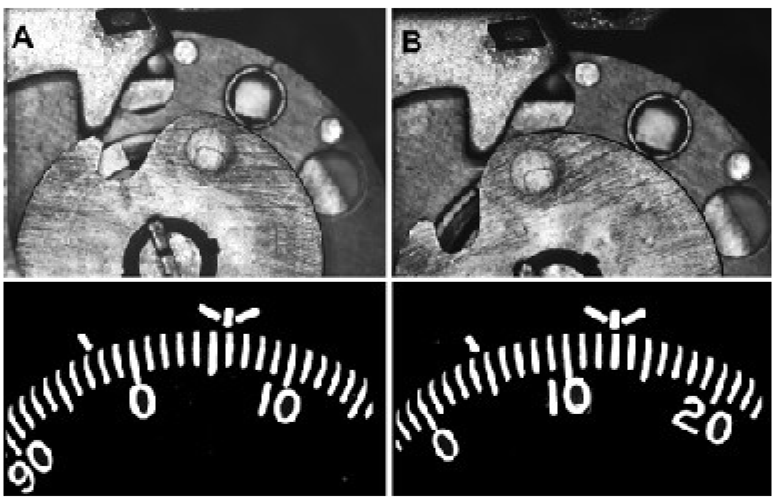
The unique butterfly lever in the center of the dial of earlier models can readily identify the manufacturer. This thumbscrew mechanism prevented manipulation by controlling access to the gate of the drive cam through an inner-spindle. After the last number had been entered, the dial was set to zero, held in one position, and the thumbscrew turned to its stop. The lock could then be opened. In the later model 8550, there is no longer a thumbscrew and internal spindle mechanism. Rather, the dial is set to the zero index marker after the last number is entered. The dial is then physically depressed which releases an accelerator spring, thus allowing the lever to drop into the drive cam gate.

Mosler produced the **MR-302(435)** and **MRK302** (key change) MP locks, based upon a patent issued to Potzick in 1963. It had the same features as the S&G with respect to a shutter that protected the drive cam.

LaGard introduced their version of the MP lock, known as the 1980-A RL, in 1980. This was actually a modified 1800 series Group 2 mechanism and incorporated plastics to prevent radiographic imaging and a "lever trigger plate" to thwart manipulation. It consisted of a pivoting arm that was connected to the nose by a spring. As in the S&G design, the lever was blocked from the drive cam except when the gate was directly under the lever.

Some Group 1 locks can be manipulated, but with extreme difficulty. In order to open them, a machinist dial indicator must be mounted on the safe, with its tip touching the outermost portion of the dial. This device will be utilized for taking readings, with the lowest indication **possibly** identifying a gate.

Manipulation procedure is similar to Group 2 locks, with the exception that each time a reading is obtained, the dial must be



set to 100 and then depressed in order to permit the fence to contact the wheels. The dial is allowed to retract until the lever makes contact with the beveled edge of the drive cam.

36_4.6 Definitions

Certain terms and concepts relating to manipulation are unique within the safe and vault profession. These require definition in order to enhance an understanding of the detailed theory and process of manipulation which is explained later in this chapter.

36_4.6.1 Contact Area

The contact area is identified as the range of movement of the nose between contact points.

36_4.6.2 Contact Points

The contact point describes the physical interaction between the nose of the lever and the edges of the drive cam gate. The points are further defined as either left or right; they denote which side of the drop in area is being sensed. Although the nose is the component that actually “contacts” the drive cam gate, its depth of penetration into that gate is a function of the position of the ridge of the fence as it touches each wheel.

36_4.6.3 Drop-In Area

The nose must enter the drive cam gate to allow contact readings to be obtained during manipulation. The place where the nose **first** enters the recessed portion of the cam is defined as the drop in area.

36_4.6.4 Manipulation

Manipulation is the process by which a combination lock can be opened through information derived from visual, auditory, and tactile senses because of design deficiencies and tolerance errors within the lock. Manipulation is both an art and a science.

36_4.6.5 Parallax Error

Manipulation is based upon minute variances in the position of critical components. Quantification of such measurements can be especially difficult, especially if normal dial markings are utilized. The problem is compounded, based upon the viewing angle. Because fractional partitions of dial marker positions are utilized as a standard, the method and angle of viewing must remain constant. Otherwise, the data derived from each contact reading will not be reliable.

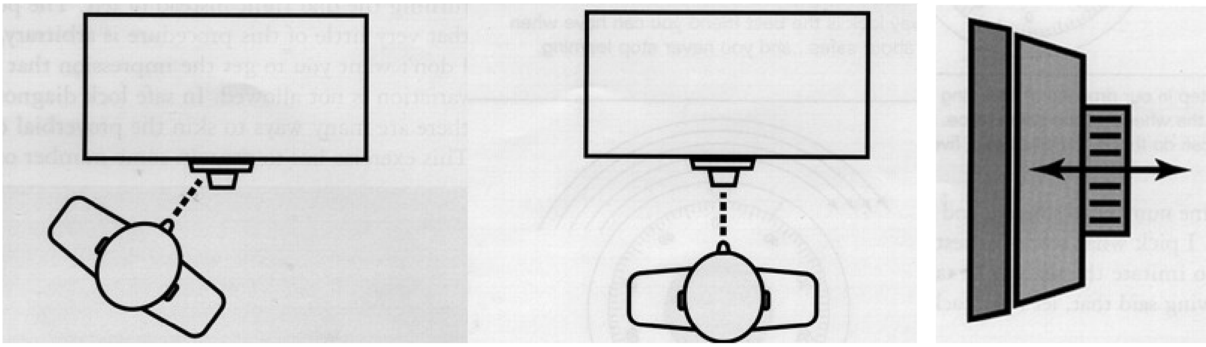


**Figure LSS+3603 Parallax error must be eliminate in the manipulation process if
accurate readings are to be obtained. Dial markings must be viewed perpendicular
to the dial, without adding the distortion of a viewing angle.**

A parallax error will occur if the operator does not look straight at the lock when taking readings. The problem is not limited to safe technicians but is inherent to anyone attempting to take measurements based upon a specific angle of view. Photographers who utilized older cameras that required two images to be overlaid for focusing often experienced the same difficulty.

36_4.6.6 Right and Left Contact Points

The process of manipulation requires continued testing of the relationship between the nose of the lever and its position within the drive cam gate. Information regarding that relationship is derived from the physical contact between the nose and the left and right sides of the gate. Thus, the **left** contact point is defined as the location, referenced to the dial marker, when the dial is rotated to the **right** and is engaged by the gate. The right contact point would constitute the opposition position.

36_4.6.7 Shadowing

This common problem is encountered during manipulation. It relates to **blocking** by an adjacent wheel, thereby obscuring a contact reading. The condition occurs when one disc is higher or lower than the wheel that is being read. In effect, the adjacent wheel will prevent the nose of the lever from dipping to its lowest depth, because it is being held up by the next wheel.

36_4.7 Detailed Theory of Manipulation

LSS201: Mark Bates on Manipulation

The process and theory of manipulation can be stated succinctly as a series of logical steps. These steps are based upon the premise that the fence, linked to the nose of the lever, will drop further and further into the gating of the wheel pack and drive cam as each gate is properly aligned. The purpose, then, of manipulation is to discover the low spots on the wheels. The assumption is that these spots either are a gate or dip in the edge of the wheel that will allow the fence to make contact with the edge of the next lowest wheel. Simply stated, the technician must keep working toward the lowest point within each wheel. **All gates must be correctly identified, in the proper sequence, to open the lock.**

The fence will continue to drop farther, so long as the correct sequence of wheels and their gating is determined. Thus, although gate positions can be tentatively identified for each wheel independently, the process requires that the **proper sequence** be established, based upon the **diameter** of each wheel, or other tolerance error.

Remember that manipulation is only possible because of tolerance errors or design deficiencies. The most crucial tolerance error is the **concentricity** of each wheel. In order to identify their order within the wheel pack, there must be a slight variance in the diameter of each. **This error allows the nose to drop farther into the drive cam as each gate location is identified.**

36_4.7.1 Manipulation: A Detailed Procedural Overview

The information that follows outlines the conceptual steps required to open a three-wheel lock by manipulation. Manipulation aids may be employed, based upon personal preference. The following procedure is premised upon the theory that as each wheel is aligned with the fence, the nose of the lever will enter the drive cam gate to a deeper level. As this occurs, the distance that the nose can be moved by dial rotation between the right and left side of the gate channel will decrease. This will cause the contact points, as referenced to the dial marker, to decrease in a linear fashion or become **closer together.** The summary procedure to manipulate a three-wheel lock requires the following steps:

- **Determine the type of lock;**
- **Determine the exact number of wheels;**
- **Determine the drop in area within the drive cam;**
- **Determine the contact points and take the first contact area reading;**
- **Graph each contact point as it is read;**
- **Test all numbers for number-one wheel, based upon 1.25, 2, 2.5 segment spacing, and log contact readings;**
- **Determine gate position for number-one wheel;**
- **Locate the true gate position of one wheel;**
- **Run test numbers and identify whether the wheel is the first, second, or third in the sequence of the combination;**
- **Set number-one wheel, then test all numbers for number-two wheel, and log contact readings;**
- **Determine gate position for number-two wheel;**
- **Identify the true gate position of a second wheel;**
- **Determine the position of that wheel within the wheel pack;**
- **Set number-one and number-two wheel, then test all numbers for number-three wheel, and log contact readings;**
- **Identify the true gate position of a third wheel;**
- **Determine the position of that wheel within the wheel pack;**
- **Enter the correct combination and open the lock;**
- **If the lock will not open, use vibration and oscillation of each wheel when testing each number. This is called "walking the dog" and requires the rapid rotation of the dial back and forth to drop the fence into the gate when its position is slightly off-center.**

Manipulation can be an extremely tedious process. In high tolerance locks, the procedure may require several hours to successfully complete.

36_4.7.2 Rules for Manipulation

The following mechanical relationships, procedures, and rules have been developed and refined during the past fifty years and are applicable to all mechanical combination locks. Adherence to these standards will help to assure success in deriving the combination for any lock.

- **Do not rely upon any input from anyone regarding a safe to be opened. The combination must be derived solely through manipulation techniques;**
- **Run all diagnostics prior to making a determination to manipulate or drill;**
- **Dial the lock as prescribed by the manufacturer. If the lock dials to the right, then do it that way during manipulation;**
- **The lock must be in operating order to be manipulated;**
- **Resetting the wheel pack, beginning with all wheels left (AWL) or all wheels right (AWR), is optional prior to manipulation;**
- **There must be a 1:1 ratio between movement of the dial and drive cam;**
- **The contact area must be defined precisely prior to manipulation;**
- **A decrease in the elevation of the nose of the lever within the drive cam gate must result in a lessening of the contact area;**
- **Contact points must be precisely determined for each test position;**
- **The left contact point is less significant than the right;**
- **Use the right contact for fast manipulation and to provide precision information about the dimension of the gate channel;**
- **If wheel number two is the first one to be identified, then wheel number three should be the next number tested;**
- **Determination of the position of flys can vary by ±1.5;**
- **The resistance of a wheel will change as a fly is engaged for the next wheel;**
- **The contact area can change between two locks produced by the same manufacturer;**

- **Movement of the detent ball and spring may cause an error in readings of 1 to 2 numbers, thus requiring the bolt to be stabilized. This can often be accomplished by placing pressure on the handle;**
- **Out-of-round wheels can cause a problem in contact readings, which can be remedied by a process known as shadowing. The operator can bypass this difficulty by moving one wheel around to the left of the fence;**
- **Oscillation of wheels is very important during manipulation in order to drop the fence into the gate when it is slightly off-center. This is accomplished by rapidly rotating the dial back and forth within the contact area;**
- **Gates will generally have a width of 4 to 8 numbers;**
- **Rarely will the correct combination be found by manipulation, although the lock will open. Thus, do not provide the information derived in this manner to the customer. The lock should be reprogrammed or taken apart in order that the correct number sequence is precisely determined;**
- **False gates can assist in determining true gate position. Look for the greatest depth.**

36_4.7.3 Identification of the Contact Area

The most common mechanical design for a Group 2 lock is the **drop lever**, which can be readily identified by its contact points. The S&G 6730, LaGard 3330, Ilco 67, and many others are based upon this configuration. We shall use an S&G 6730 for our example.

The contact area lies between the left and right contact points and equals the dimension (width) of the drive cam gate. In order to locate its position, turn AWL four times and stop at 50 (assuming the number 50 is not part of the combination). Next, turn the dial to the right. Within the **first revolution**, stop at 10. Now, if the dial is gently rotated between 90 and 20, the edge of the left and right side of the gate will obstruct and stop the dial from moving. These obstructions are the contact points, from which all measurements are taken. Sensing contact points can be simplified by grasping the dial with one finger and the tip of the thumb. Optimally, very little finger contact should be maintained between the technician and the lock.

36_4.7.3.1 Observing Contact Readings

Two technicians observing the same contact points will likely disagree as to their exact fractional number. This is due to individual visualization and extrapolation differences and is not relevant so long as the method utilized by each craftsman remains consistent. Thus, viewing of the dial marker must be done straight on, without creating a parallax error. Numbers should be recorded in .10 divisions of markers.

The use of standard dial markings can pose problems because of their irregularity. To assure consistent readings, the edge of engraved lines should be used for fractional determinations of .25 or less. Centering between divisions provides ½ markings.

36_4.7.3.2 Quantifying Contact Point Measurements

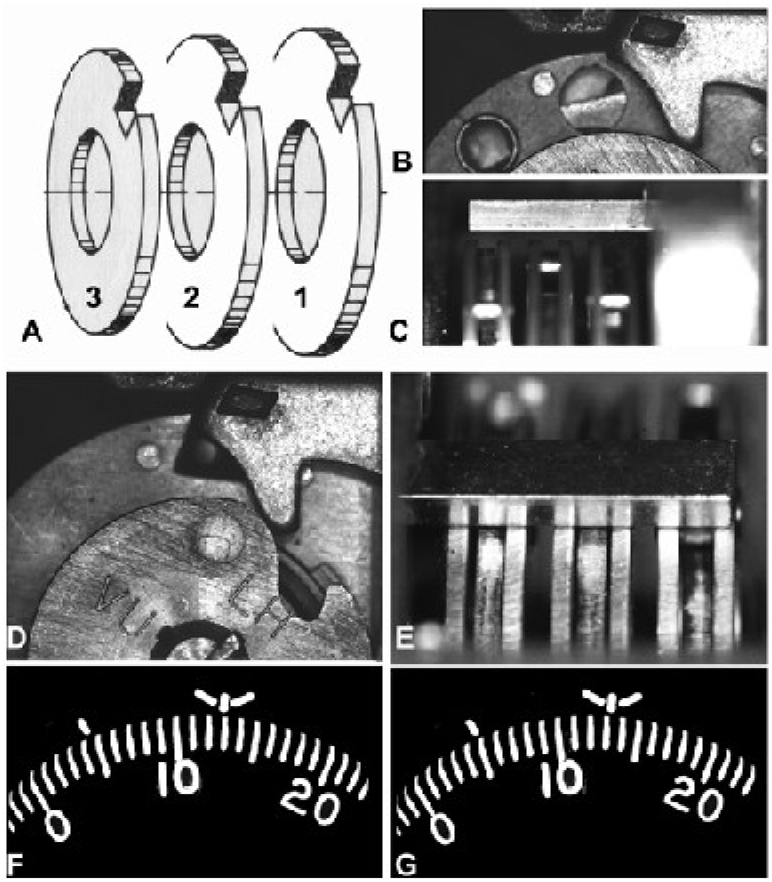
Manipulation is based upon the precise reading of the right and left contact points for each test position of a wheel and its gate. Accuracy in these readings must be to within .05 of a dial marker division for optimum result. Each of the contact points is charted to determine low and high spots.

The accurate and reliable sensing and recording of contact points can pose considerable difficulty. This can lead to lengthy delays in a successful opening or a complete failure. Because of issues relating to the measurement of contact points, manipulation may not work every time, for all types of locks.

Many causes can be attributed to the failure to obtain reliable and precise readings. These include:

- **Inaccuracies in the consistency, placement, spacing, width, or printing of dial markers by the manufacturer;**

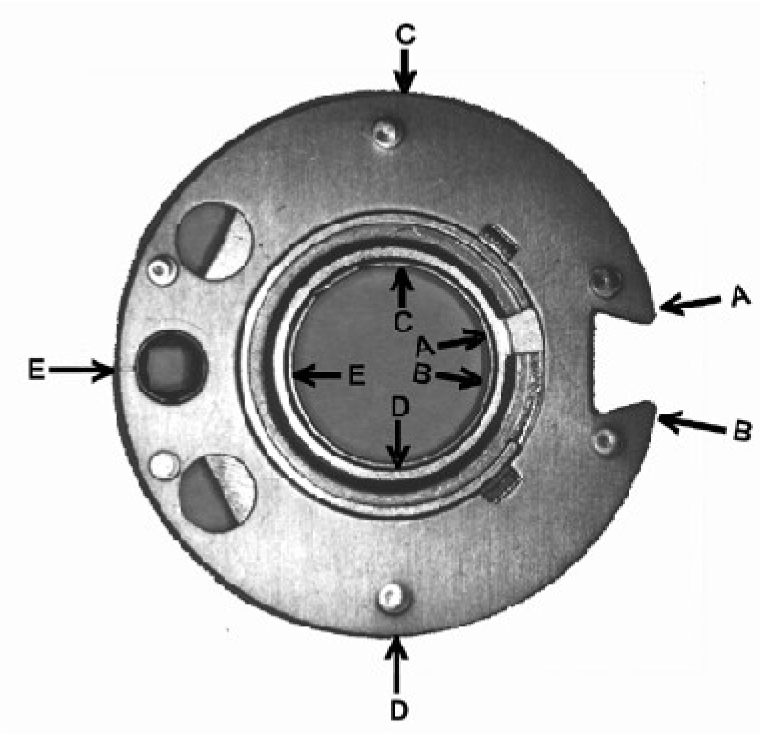
- **Poor lighting conditions;**
- **Vision problems;**
- **Close mechanical tolerances;**
- **Improper rotation motion of the dial and a failure to use even-handed pressure and steady rate;**
- **Loose, sluggish, or sticky dials;**
- **Manipulation-proof locks;**
- **Locks with anti-manipulation protective mechanisms;**
- **Different degrees of wear within individual gates.**



Both right and left contact points can be used for measurement. Experts disagree as to which is more significant, although the primary indicator is generally thought to be the right contact. There is a difference in the quality of information provided by each contact point. The **left** provides the best "indication" of position, while the **right** offers more quantitative data.

The best **indication** of presence and position is the left reading (dial turned to right). The contour of the drive cam gate causes the physical contact between nose and entry area to be more pronounced. This is due to the relatively sharp angle on the left side. The design of the right side of the gate channel offers detailed information regarding slight changes in the depth of the nose and results from the linear angle of the slope. For this reason, the right contact can be used for more accurate charting and faster manipulation.

Reliance upon the right contact point is premised upon a lock having a right-hand design. Most mechanisms, with the exception of vault doors, are constructed right hand, although mounting may be in any orientation. In the rare instance that the lock has been constructed left hand, the contact points are reversed. Prior to taking a reading, the dial should be oscillated across the drive cam gate to float or work the fence to its lowest point. This will provide a closer reading.



36_4.7.3.3 Geometry of the Contact Area

The geometry of the drive cam gate determines the significance of contact readings. The channel formed by the gate is precisely defined by the manufacturer, based upon criteria relating to interaction of the nose of the lever.

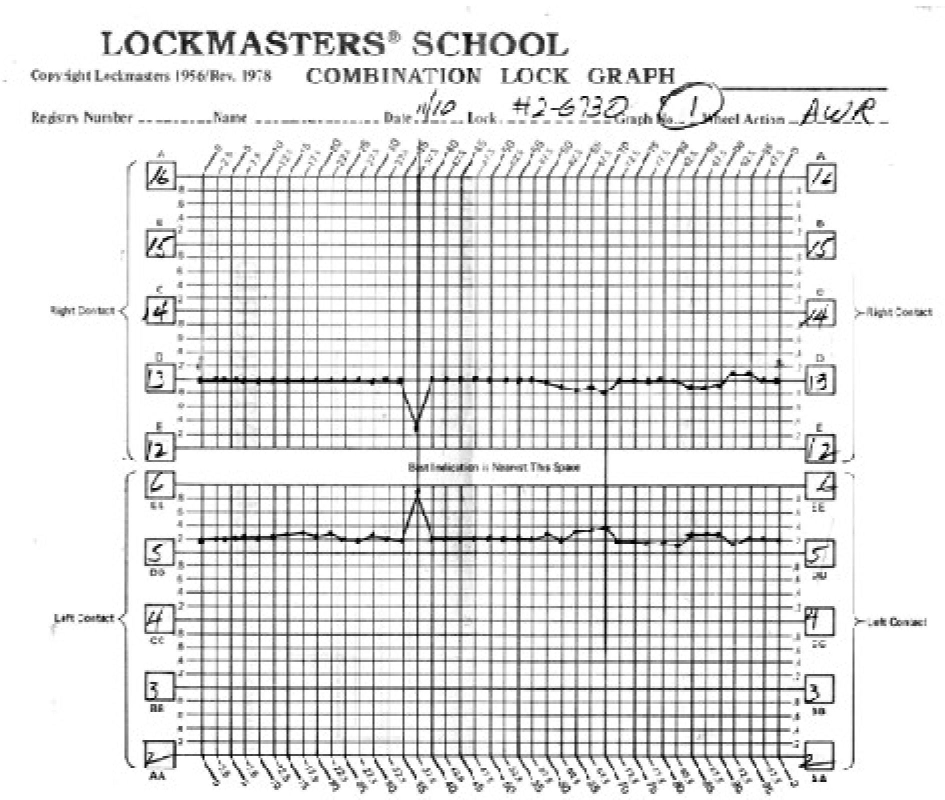
A right-hand design requires that the left contact be sharp and almost perpendicular to the edge of the wheel. For this reason, the left contact point provides a clearer indication that the nose has **touched** the gate. The right contact point provides more data with respect to the depth and position of the nose within the channel. The reading, however, is more difficult to obtain. This is because the nose is striking the channel at an angle that narrows toward the center of the cam. There is not as much metal contact between the two components and, hence, not as definitive an indication as with the left contact points.

Contact readings are a representation of the width of the drive cam gate and offer a linear reflection of the true contour of the edge of the wheel. Manipulation is possible because the width of the gate must change as the gate channel nears the center of the drive cam. A change in dimension between contact points can be directly correlated to the vertical position of the lever.

In most modern locks, the fence does not ever contact the edge of the wheels until the drive cam gate is within the contact area. It is only in this position that measurements can be obtained. For this reason, the dial must always be returned to that area during the sequencing of test numbers.

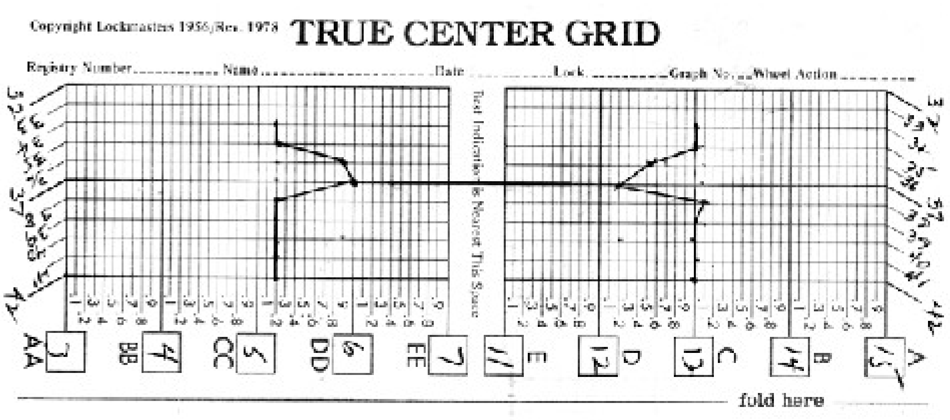
The process of manipulation is actually comprised of a series of measurements of the drive came gate. A description that compares the drive cam geometry and measurement correlation illustrates the ideal sequence of events that must occur in order that the lock can be opened. This example assumes that each wheel is tested **in descending order** with respect to concentricity errors. In the ideal world of manipulation, the number-one wheel would have the greatest diameter, the number-two wheel slightly smaller, and the number-one wheel even smaller. Of course, this is rarely the case.

36_4.7.3.3.1 Drive Cam Geometry and Contact Measurement Correlation



A manufacturer must adhere to several drive cam design parameters if the lock is to operate smoothly and reliably. The dimensions, rotation angles, motion requirements, and component placement

within the lock establish these measurements. The opening to the drive came gate is widest at its mouth, much like a funnel. It narrows toward the center. Fence movement and the resultant contact readings will diminish as gate positions are identified and the fence sinks deeper into the cam.



The right and left slopes of the gate are designed for smooth operation. The rounded sides at the mouth of the channel assure that the nose will not be trapped upon entry. Ramp angles are required to properly eject the lever when the mechanism is locked.

36_4.7.3.4 Charting Contact Points

Readings can be charted or remembered as they are tested. For the beginner, it is recommended that contact points be charted in 2.5 number increments around the dial. The process of charting requires that the technician make an extrapolation of fractional dial marker divisions. Either paper or a computer will produce a graphic display that represents the contour of the wheel and the width of the drive cam gate. If done correctly, it is a simple matter to interpret gate positions for each wheel from a narrowing of the contact area.

In practice, the readings for each number position is plotted on specially formatted chart paper provided by Lockmasters or other companies. When all 40 positions (for 2.5 number divisions) have been noted, the dots are connected for left and right contact points. A narrowing between the two, at any position, will indicate the possible location of a gate. Both sharp and gradual declines and rises can be significant. It is the lowest point that will indicate a possible gate position. In some cases, readings will have to be repeated after studying charts in order to determine which of several indications are "true." It is simply a process of elimination to find which wheel provides the best indication.

36_4.7.3.5 Determining Which Wheel is Indicating

In most cases, the number-three wheel usually indicates first. This, however, is not always true and is based upon issues relating to tolerance. There are simple procedures for correlating a gate to a specific wheel after a series of readings have shown the presence of a low spot. In order to make the determination, the gate position must be tested through a process of "parking" the other two wheels with a test combination. To correlate gate position to a specific wheel, a matrix is created wherein two of three wheels are parked at the known gate reading. The third wheel is then tested with a bogus combination to determine if it is the one that is "indicating."

36_4.8 Data Collection and Test Procedures Prior to Manipulation

The following materials outline the required steps that must be followed prior to attempting to manipulate a lock. They relate to obtaining needed information about the lock and its normal use. Any possible malfunctions that are causing a lockout must also be assessed.

36_4.8.1 Introduction

Manipulation is required in two situations. In the first instance, a lockout occurs due to mechanical malfunction. In other cases, the correct combination is unknown, not available, or will not open the lock. This situation might include covert entry, execution of legal warrants, burglary, or a lost combination.

Prior to attempting manipulation, information must be gathered and certain tests performed. In many cases, such procedures can eliminate the necessity to fully manipulate the lock altogether. Data required to assess and diagnose lockouts was examined elsewhere in this chapter. Other information about the lock and its operator can often be helpful and is detailed below.

36_4.8.2 Data Regarding the Lock

The process of manipulation must begin by learning everything that the lock can tell about itself. This information is essential and can determine whether the technique will be successful. With a detailed understanding about the mechanical components and their interrelationship, the following information should be obtained before attempting to open the lock:

- **Manufacturer;**
- **UL classification: Group 1 or Group 2;**
- **Is it possible that the lock contains four or more wheels;**
- **Contact area and contact points;**
- **Design of the drive cam area;**
- **Has the manufacturer changed the spline position on any locks;**
- **Drop in point location;**
- **Number of wheels, derived through transmission of motion;**
- **Wheel pickups: fixed or moveable flys and whether they are functioning properly;**
- **Type of wheels (moveable fly, screw change);**
- **Loose spline key;**
- **Stuck fly;**
- **Unlocked wheels;**
- **End pressure on the bolt;**
- **Loose back cover;**
- **Identify low areas on wheel pack;**
- **Identify "out of round" wheels, commonly referred to as eccentricity errors;**
- **Note unlikely number positions that take into account the forbidden zone, ascending or descending order, consecutive numbers, and adjacent numbers**

within ten digits.

36_4.8.3 Information about the User of the Lock

Information about the regular operator of a lock can possibly yield clues as to the combination, based upon work habits. The following questions should be asked in an effort to derive the correct number sequence:

- **Was the operator a methodical person;**
- **Did the operator establish a combination based upon a rigid pattern of numbers;**
- **Was the operator imaginative;**
- **What was his date of birth;**
- **What was the date that the combination was set;**
- **Did the operator have a favorite or lucky number.**

36_4.8.4 Lockouts, Diagnostics, and Manipulation

The process of manipulation encompasses more than just the technique for opening a lock. It is a methodical scientific procedure for determining malfunctions and potential causes of a lockout. In this section, the use of manipulation as a diagnostic tool is discussed. "Manipulation" is a combination of skill, knowledge, and analytical ability that provides the platform or vehicle through which locks can be opened. For the safe technician, these skills are generally called into service when there is a lockout. For the intelligence agent or law enforcement officer, opening the safe is secondary to obtaining access to the contents.

The important thing to remember is that "manipulation" is the use of sight, sound, and touch to learn information about the lock. It is also a **diagnostic tool.** A comprehensive discussion of lockout problems and related diagnostics was presented in **Chapter 35**. Whether the lock is to be opened simply to obtain access to contents or due to a lockout, virtually the same mental processes are required. Prior to engaging in manipulation, a preliminary analyses of basic facts and issues is necessary in order to assess the following:

- **Why is the safe locked;**
- **When was the safe used last;**

- **Has the correct combination been entered;**
- **Have factory tryout combinations been tried, including the following: 25-50-25, 50-25-50, 10-20-30, 20-40-60, 20-60-40,40-20-60, 40-60-20, 60-20-40, 60-40-20;**
- **Have all multiples of 10 and 50 been factored into test combinations;**
- **Consider the lighting that illuminates the dial. Is it dim, making the zero marker difficult to see and thereby resulting in potential entry errors;**
- **Is the combination written near the safe in plain sight on a bulletin board, adding machine tape, wall, door frames, top or sides of the safe, in personal phone books, or other places nearby;**
- **Are there scratch marks or inked-in index marks on the dial;**
- **Was the safe working properly when last opened;**
- **Is there a record of the correct combination stored anywhere;**
- **Are there any maintenance issues or problems that will prevent accurate contact indications during manipulation;**
- **Is there a preferable alternative to manipulation;**
- **Is there any reason why manipulation is not an acceptable course of action.**

If access to the contents of the safe or vault is the objective and there are no other known maintenance problems, then the lock can be manipulated. Of course, if a lockout exists, other factors come into play.

36_4.8.4.1 Mechanical Malfunctions

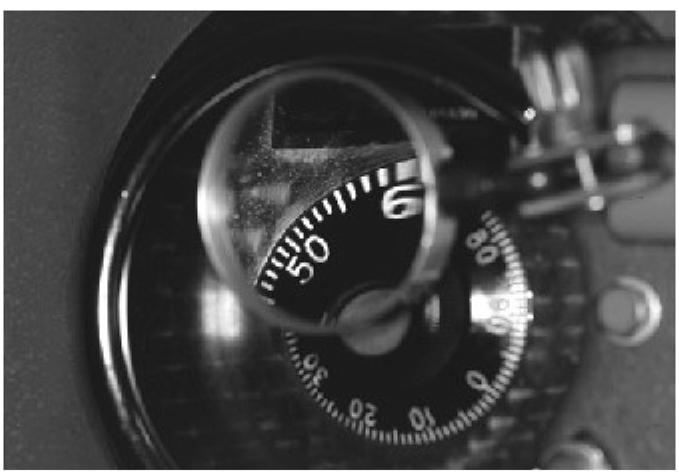
A lockout condition may require drilling. The following errors and malfunctions can render manipulation useless:

- **Errors in entering or changing combination, including maintenance errors involving changing three wheels on a four tumbler lock;**
- **Wheel related problems, including wheels becoming disengaged;**
- **Lever-related problems;**

- **Dial movement errors, including binding, seizure, non-linkage with drive cam, loose spline key, loose drive cam or broken dial;**
- **Fired relockers and relock triggers caused by shock, vibration, heat, concussion, and loose mounting screws;**
- **Stuck or broken drive pins and flys on wheel or cam;**
- **Improper or inoperative handle and bolt action;**
- **Failure of the correct combination to open the lock;**
- **Bolt linkage problems;**
- **Bolt end pressure;**
- **Improper drive cam rotation.**

36_4.8.5 Planning and Strategy

Before attempting to open a lock by manipulation, the technician should devise the methodology by which he will proceed. This will take into account the following issues, based upon previously discussed diagnostics:



- **Which contact points will be read and charted: right, left, or both;**
- **Will wheels initially be moved left or right;**
- **Will one, two, or all three wheels be moved initially;**
- **What increments will be utilized for testing the contact points: 1, 1.25, 2, 2.5;**
- **What compensation will be made for fixed flys.**

36_5.0 Aids to Manual Manipulation

Many aids to manipulation can enhance learning of the art, as well as the visualization and sensing process. These devices and materials allow greater precision in the measurement of contact points by using audio and visual representations. Especially for older technicians, these tools can be extremely effective. They include:

- **Optical aids for magnifying marker positions, including magnetically attached magnifying glasses, glasses or optivisor that is worn by the technician;**
- **Illuminator;**

- **Pointer extensions that are attached to the safe dial;**
- **Handle wheel meters with long wire and which are used to test against each number for movement;**
- **Replacement vernier dial markings that create a more precise set of indicators;**
- **Audio amplification devices;**
- **Oscilloscope with audio amplifier and storage capabilities;**
- **Video capture devices, including macro camera heads that can be used to observe contact points more precisely;**
- **Software programs that can be used in conjunction with camera heads to capture and analyze contact point data, and to automatically chart contact area;**
- **Software programs useful for training;**
- **Cutaway combination locks;**
- **Torque measurement kits;**
- **Lubricant;**
- **Lint-free wiper rags;**
- **Mallets and dead blow hammers;**
- **Comfortable chair;**
- **Office supplies;**
- **Tool case;**
- **Basic hand tools;**
- **Specialty tools.**

36_6.0 Learning Manipulation

The art of manipulation is not mastered quickly; rather, it requires a great deal of practice with many different locks. Accomplishing successful openings is based upon many essential skills:

- **Logic and judgment;**
- **Visualization skills;**
- **Sense of touch;**
- **Steadiness of hand;**
- **Precise movement of the dial;**
- **Correlation of sounds to touch;**
- **Location of contact points;**
- **Understanding of the theory of manipulation;**
- **Self-confidence and positive attitude about opening locks;**
- **Eye, ear, and hand coordination;**
- **Ability to interpret and correlate information provided through the integration of sight, sound, and feel;**
- **Ability to perceive exceedingly slight movement of the dial marker with respect to the contact points;**
- **Patience;**
- **Intuition with respect to lockout problems;**
- **Detailed knowledge and understanding of the mechanical design of combination locks;**
- **Ability to visualize the movement and position of internal locking components;**
- **Ability to compute tolerances;**
- **Working knowledge of the concepts of contact points, forbidden zone, and drop in point;**
- **Detailed and working knowledge of common mechanical failures that can cause lockouts.**

There are many classroom and correspondence courses offered by **Lockmasters**, **MBA**, and other professionals. These can teach the basic procedures and theory of manipulation. Expertise and self-confidence, however, can only be gained by the actual opening of many locks. Classroom instruction is, in the view of the author, the most efficient way to begin learning the

techniques collectively called manipulation. Once instruction in theory has been completed, the real learning phase begins.

The author was trained at Lockmasters, using cutaway S&G 6730 locks with the fence bent slightly downward or upward. This technique would define which wheel would indicate first and was an extremely helpful learning tool. Once the contact points of a modified cutaway lock can be uniformly identified, another lock is modified to a lesser extent. The process is repeated until production models can be opened.

BOOK FOUR: METHODS OF PROTECTION

Security

CHAPTER THIRTY-SEVEN: WORLD STANDARDS

Standards and Testing

Master Exhibit Summary

Figure LSS+3701 UL Label
Figure LSS+3702 UL Label designations and nomenclature
Figure LSS+3703 SMNA Label designations
FF-L-2740 Federal Specification for Combination Locks

37_1.0 Introduction

All locks, safes, and enclosures are defined and classified by standards relating to their ability to resist attack by forced and surreptitious means. The rating process analyzes the security of a device from a number of different perspectives. These encompass and take into account the various methods of entry,

different levels of sophistication of tools and techniques, and overall resistance to bypass. This chapter provides an overview of the security classifications that have been developed and promulgated by the primary ratings organizations in the United States and Europe. Underwriters Laboratories (UL), the American National Standards Institute (ANSI), the American Society of Testing and Materials (ASTM), and Safe Manufacturers National Association (SMNA) have been primarily responsible for developing comprehensive evaluation criteria for security devices.

Within Europe, many different entities have traditionally rated locks and safes. A comprehensive set of standards has been developed over the last seven years by the Comite European de Normalisation (European Committee for Standardization), CEN, for all EU countries. All ratings organizations have adopted essentially the same methods to evaluate products to insure security for a defined level of protection. These protocols provide the most comprehensive and reliable method to gauge the indestructibility of a device for both the government and private sector.

This chapter is organized by rating organizations and the standards that have been promulgated by them for each type of device. Summaries of the current burglary and fire standards for UL and the CEN are detailed, together with applicable testing protocols. Extensive hyperlinks to world standards organizations including UL, ASTM, ISO, ANSI, and BSI can by found at www.security.org.

37_1.1 Testing and Classification of Safes, Vaults, and Related Hardware

Safes and vaults were originally tested by an organization known as the Safe Manufacturers National Association (SMNA) for insurance companies. Their labels can still be found on thousands of containers and are identified later in this chapter. SMNA was a service bureau of insurance companies that eventually gave way to UL as the primary testing organization. In the United States, the classification of security containers and devices is primarily the responsibility of Underwriters Laboratories and the General Services Administration (for military and federal government). In addition, the Insurance Services Offices (New York, New York) define and rate mercantile and bank safe insurance classifications.

The U.S. government relies upon UL standards in promulgating its specifications and requirements, although it is not bound by them. There are two subclassifications for UL ratings: **burglary** and **fire** resistance. In Europe, the CEN is now responsible for developing a rating and testing system for security devices in all EC countries. In England, the British Standards Institute (BSI) was previously responsible for the development of performance tests for locks and safes. Many other countries have their own standards organizations that perform similar tasks to UL and CEN.

37_2.0 Underwriters Laboratories

Underwriters Laboratories was founded in 1847 by William Henry Merrill, an electrical inspector in Chicago. Originally known as the Underwriters Electrical Bureau, its function was to perform tests regarding the safe use and operation of electricity. The name was changed to the Electrical Bureau of the National Board of Fire Underwriters, and finally to Underwriters Laboratories in 1901. From its inception, the mission of UL was that of an independent testing agency, having no financial ties to any manufacturer. Their goal was to develop standards for quality assurance and safety of products in order to protect the public.

The UL certification process is based upon three critical elements: development of an applicable standard, evaluation of a product according to the corresponding standard, and follow-up testing and other services at the manufacturer's location. A certification attests to the security of a product; it is relied upon by the public and risk underwriters. The names of manufacturers who have demonstrated an ability to produce products meeting UL requirements are published annually in the following product directories:

- **Building materials;**
- **Fire protection equipment;**
- **Fire resistance;**
- **Recognized component;**
- **Electrical appliance and utilization equipment;**
- **Electrical construction materials;**
- **Hazardous location equipment;**
- **General information from electrical construction materials and hazardous location equipment;**
- **Marine products;**

- **Automotive, burglary protection, and mechanical equipment;**
- **Gas and oil equipment.**

37_2.1 UL and Security Testing

It appears that the first time UL became involved in testing of security-related products was in 1921, when it was named as the official testing facility for burglar alarms and locking devices. Then, in 1923, the first safe was evaluated for burglary resistance. In 1925, the organization began testing vault doors.

Since that time, UL has developed many testing standards for locks and safes, including:

- **UL 140 Relocking devices for safes and vaults;**
- **UL 608 Burglar-resistant vault doors;**
- **UL 687 Burglar-resistant safes;**
- **UL 768 Combination locks;**
- **UL 437 Key locks;**
- **UL 786 Key locking systems;**
- **UL 887 Time lock;**
- **UL 2058 High-security electronic locks;**
- **UL 72 Tests for Fire Resistance of Record Protection Equipment.**

Today, UL is responsible for promulgating standards for testing mechanical and electronic locks, safes, vaults, time locks, relockers, and associated devices. A UL standard contains basic requirements for products covered by a certification. The observance of such requirements by a manufacturer is a condition of continued coverage. Although a product may comply with the text of a standard, that is no guarantee of certification. It is up to UL to determine if other features might impair the level of safety or security contemplated by the requirements.

The promulgation of standards are based upon sound engineering principles, research, records of tests, and field experience. UL, in consultation with and based upon information obtained from manufacturers, users, inspection authorities, and other having specialized experience, derives an appreciation of the problems of manufacture, installation, and use of a product to be tested.

Standards are always subject to revision as further experience and investigation may demonstrate as necessary or desirable.

Underwriters Laboratories does not assume or undertake any liability for reliance upon its product evaluation or standards. The opinions and findings of UL represent its best professional judgment. It is given with due consideration to the necessary limitations of practical operation and state of the art at the time the standard is processed.

37_2.2 UL Specifications for High-Security Locks and Safes

The term "high-security" has been defined throughout this book to describe locks and containers that present various levels of difficulty in covert and forced methods of entry (generally referred to as burglary). The term, of course, is relative and depends upon many factors. Underwriters Laboratories sets the performance standard within the United States for different classes of security. Once a product passes the tests associated with a specific classification, it is entitled to bear a label attesting to the fact.

Specific tests are developed based upon a perceived need for a certain level of protection. Such definitions change as methods of entry become more sophisticated. Thus, in the 1980s, the jewelry industry required tougher standards due to the economic prosperity of the time. The result: the **TL-30x6** classification was developed. This standard was originally contained in UL 687 (Standard for Safety for Burglary-Resistant Safes) issued in 1938. Since its original issuance, testing for the rating has changed dramatically.

For all classifications, a consensus is required from an independent advisory committee. Industry is consulted and then the proposed standard is submitted to ANSI for approval. Any UL rated device must meet the latest standard, which automatically expires in seven years.

37_2.3 UL Burglary Ratings for Safes and Vaults

Safes are classified for their resistance to forced-entry (burglary). See **Chapters 32** and **35** for methods for forcible entry. Certain security ratings are required for each type of use as determined by insurance companies and regulatory agencies.

Figure LSS+3701 An example of a UL label for a safe lock. Courtesy of Mark Bates, The National Locksmith Guide to Modern Safe Locks.

37_2.3.1 General Construction Requirements

Depending upon classification, one or more of the following general construction requirements apply to all burglary resistant safes. The UL specific paragraph number appears in parenthesis.

- **(1) UL 768 rated Group 2, 1 or 1R combination lock;**
- **(2) All iron and steel parts painted, plated, or equivalent to protect against corrosion;**
- **(3) 750 pounds minimum weight or anchors, with instructions for anchoring in a larger safe, concrete blocks or on the premises where used;**
- **(4) Materials other than solid metal may be used for body construction, provided that the material has resistance to attack equivalent to at least 1″ open hearth steel with a minimum tensile strength of 50,000 PSI;**
- **(5) Walls fastened in a manner equivalent to continuous ¼″ penetration weld of open-hearth steel with minimum tensile strength of 50,000 p.s.i.;**
- **(6) One hole ¼″ or less, to accommodate electrical conductors anywhere, except in the door, and arranged to have no direct view of the door or locking mechanism;**
- **(7) Clearance between the door and jamb not greater than .006″; or designed so that no direct access is provided through the door and jamb.**

37_2.3.2 General Performance Requirements:

Three forcible entry methods are specified in the ratings,

depending upon security classification:

- **Entry Means (A): Opening the door or making a rectangular shaped opening 6″ square in an area or a circular opening 2.76″ diameter entirely through the door or front face;**
- **Entry Means (B): Opening the door or making a rectangular shaped opening 2″ square in an area or a circular opening 1.6″ diameter entirely through the door or front face;**
- **Entry Means (C): Opening the door or making a rectangular shaped opening 2″ square in an area or a circular opening 1.6″ diameter entirely through the door or body.**

37_2.3.3 Tools of General Design Used for Forced-Entry

Tools used for forced-entry attempts include:

- **Common hand tools;**
- **Picking tools;**
- **Mechanical or portable electric tools;**
- **Grinding points;**
- **Carbide drills;**
- **Pressure-applying devices or mechanisms (drill rigs).**

37_2.4 Burglary-Resistant Safe Classifications

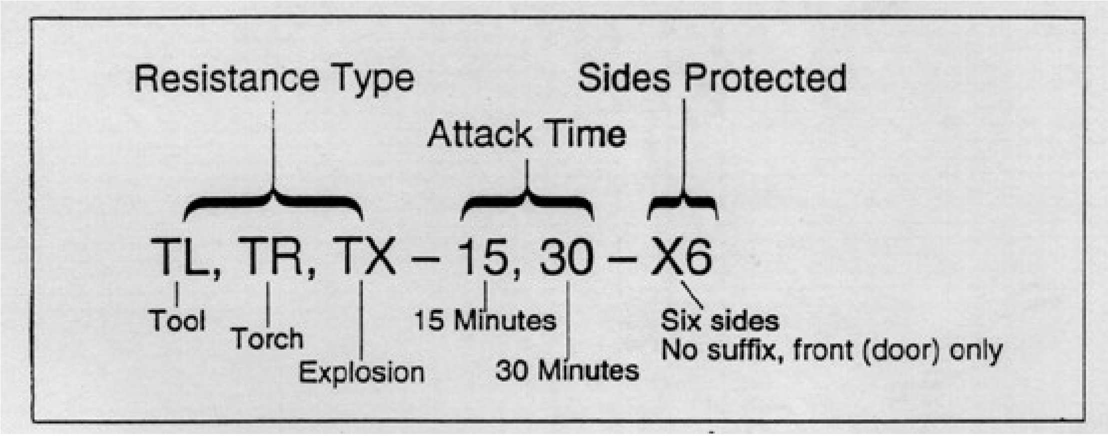


Figure LSS+3702 A UL label diagram denoting the designation for each component.

37_2.4.1 TL-15: Tool-Resistant Safe

A combination-locked steel chest or safe will offer a limited degree of protection against expert burglary by common hand or electrical tools. The safe will weigh at least 750 pounds or shall be equipped with anchors. All safes having this classification are equipped with a relocking device. The units are constructed of open-hearth steel, either cast or welded plate construction, combined with materials to resist carbide drills.

37_2.4.1.1 Specific Construction Requirements

Requirements (1) through (6).

37_2.4.1.2 Specific Performance Requirements

- **Successfully resist Entry Means (A) for a net working time of 15 minutes;**
- **Use of all general tools.**

37_2.4.2 TL-30: Tool-Resistant Safe

This is a combination-locked safe or chest, which offers a moderate degree of protection against expert burglary by common mechanical and electrical tools. The safe shall weigh at least 750 pounds and have adequate anchoring. In addition, the safes in this class are equipped with relocking devices and are constructed of open-hearth steel, either cast or welded plates, in combination with special materials to resist carbide drills and abrasive cutting tools. The door lugs should be of solid design, with the door machine ground to fit.

37_2.4.2.1 Specific Construction Requirements

Requirements (1) through (7).

37_2.4.2.2 Specific Performance Requirements

- **Successfully resist entry means (A) for a net working time of 30 minutes;**
- **Use of all general tools with the addition of**

abrasive cutting wheels and power saws.

37_2.4.3 TRTL-15x6: Torch- and Tool-Resistant Safe (six sides)

This rating signifies a combination-locked safe designed to offer protection against entry by common mechanical and electrical tools and cutting torches and any combination of these means.

37_2.4.3.1 Specific Construction Requirements

- **Requirements (2) through (7);**
- **Equipped with a UL 768 rated Group 1 or 1R combination lock.**

37_2.4.3.2 Specific Performance Requirements

- **Successfully resist entry means (C) for a net working time of 15 minutes;**
- **Use of all general tools, with the addition of abrasive cutting wheels, power saws, impact tools and oxy-fuel gas cutting or welding torch;**
- **Test gas limited to 1,000 cubic feet combined total oxygen and fuel gas.**

37_2.4.4 TRTL-30: Torch- and Tool-Resistant Safe

This is a combination-locked chest or safe designed to offer a moderate degree of protection against expert burglary by common mechanical and electrical tools and cutting torches. The safes are to be encased in no less than 3” of reinforced concrete or in a larger safe or other container. The safe should weigh at least 750 pounds. All containers within this class have a relocking device and are constructed of open-hearth steel, either cast or welded plate, combined with special materials to resist torches, carbide drills, and abrasive cutting tools. In addition, the door lugs are made of substantial design, and the door is machined to fit.

37_2.4.4.1 Specific Construction Requirements

- **Requirements (2), (4), (5), (6), (7);**
- **Equipped with a UL 768 rated Group 1 or 1R**

combination lock;

- **Encased in not less than 3″ of reinforced concrete or in a larger safe or other container;**
- **The safe as encased shall weigh at least 750 pounds.**

37_2.4.4.2 Specific Performance Requirements

- **Successfully resist entry means (B) for a net working time of 30 minutes;**
- **Use of all general tools with the addition of abrasive cutting wheels, power saws, impact tools and oxy-fuel gas cutting or welding torch;**
- **Test gas limited to 1,000 cubic feet combined total oxygen and fuel gas.**

37_2.4.5 TRTL-60: Torch- and Tool-Resistant Safe

This classification encompasses a combination-locked steel chest or safe which is designed to offer high resistance to expert burglary methods by common mechanical and electrical tools and cutting torches. Safes shall be encased in concrete and will weigh at least 750 pounds with the concrete. All safes in this class are made of open hearth steel, either cast or welded plate, in combination with special materials to resist torches, carbide drills, and abrasive cutting tools. The door lugs should be of solid design and the doors machine fit.

37_2.4.5.1 Specific Construction Requirements

- **Requirements (2) through (7);**
- **Equipped with a UL 768 rated Group 1 or 1R combination lock.**

37_2.4.5.2 Specific Performance Requirements

- **Successfully resist entry means (C) for a net working time of 60 minutes;**
- **Use of all general tools with the addition of abrasive cutting wheels, power saws, impact tools and oxy-fuel gas cutting or welding torch;**
- **Test gas limited to 1,000 cubic feet combined total oxygen and fuel gas.**

37_2.4.6 TRTL-30x6: Torch- and Tool-Resistant Safe (Six Sides)

This class signifies a combination-locked safe designed to offer protection against entry by common mechanical and electrical tools and cutting torches and any combination of these means. The container provides protection on all faces (top, bottom, sides).

37_2.4.6.1 Specific Construction Requirements

Same requirements as TRTL-60

37_2.4.6.2 Specific Performance Requirements

Same requirements as TRTL-60.

37_2.4.7 TXTL-60: Torch-, Explosive-, and Tool-Resistant Safes

Safes within this classification are combination locked and have relocking devices. They are of steel construction, and offer high resistance to expert burglary by common mechanical tools, cutting torches, high explosives, and any combination of these means within practical limits. Safes encased in concrete will weigh not less than 1,000 pounds. Cast open-hearth steel is combined with special materials to resist torches, carbide drills, and abrasive cutting tools. The thickness and strength of the material in the door, lugs, and the body, and the clearance between the door and jamb shall resist entry with mechanical tools, torches, and high explosives. The door lugs should be made of solid design and the door machine fit.

37_2.4.7.1 Specific Construction Requirements

- **Requirements (2), (4), (5), (6), (7);**
- **Equipped with a UL 768 rated Group 1 or 1R combination lock;**
- **Shall weigh at least 1,000 pounds.**

37_2.4.7.2 Specific Performance Requirements

- **Successfully resist entry means (C) for a net working time of 60 minutes;**
- **Use of all general tools with the addition of**

abrasive cutting wheels, power saws, impact tools, oxy-fuel gas cutting or welding torch, and may further include nitroglycerine or other high explosives;

- **The total quantity of explosive employed may not exceed eight ounces. Not more than four ounces is to be used in a single charge.**

37_2.4.8 KL Burglary-Resistant Container

Identification on safes of this classification are generally manufacturer's labels with the **KL** designation. Burglary classification (**KL**) signifies a key-locked safe designed to offer protection against entry by common mechanical and electrical tools and any combination thereof.

37_2.4.8.1 Specific Construction Requirements

Must meet general construction requirements (2) through (6). In addition the safe shall be equipped with a UL 437 rated two-key lock or changeable key lock with a minimum of one million changes.

37_2.4.8.2 Specific Performance Requirements

Successfully resist entry means (**A**) for a net working time of 15 minutes. Use of all general tools.

37_3.0 Specific Standards: UL 437 and UL 768

Standards promulgated by Underwriters Laboratories relating to locks, safes, and security are summarized in this section. Although many of the terms have been defined in other chapters, the specific UL definition is repeated in order to facilitate understanding. A glossary of terms appears at the end of the summary.

The following UL standards are summarized in this Section:

- **UL 768 Combination locks**
- **UL 437 Key locks**

37_3.1 UL 437 Standard for Key Locks

The primary standard for locks is **UL 437.** The requirements cover door locks, locking cylinders, security container key locks, and two-key locks.

37_3.1.1 Definitions

Underwriters Laboratories defines the different types of locks for which the specification applies.

Product: This refers to any type of lock or component defined within the standard:

Door Lock: This is a rim or mortise-type locking assembly that is used on doors to deter unauthorized opening by one or more of the following means:

- **Jimmying the door;**
- **Picking;**
- **Impressioning techniques;**
- **Driving the locking cylinder or assembly;**
- **Sawing or drilling the lock bolt;**
- **Pulling the lock cylinder;**
- **Other methods that involve the use of small hand tools.**

Locking Cylinder: A key cylinder that is used within door locks, alarm control switches, alarm shunt switches, utility locks, and similar devices to resist unauthorized opening by one or more of the following techniques:

- **Picking;**
- **Impressioning techniques;**
- **Forcing methods;**
- **Pulling;**
- **Drilling the cylinder.**

Security Container Key Lock: This is a lock that is designed for use on key-locked safes, collection safes, and similar security containers to resist methods of entry that include:

- **Picking;**

- **Impressioning;**
- **Drilling;**
- **Pulling;**
- **Punching;**
- **Forcing methods.**

37_3.1.2 General Construction and Operating Requirements

UL specifies a number of requirements that relate to the construction and operation of any lock that is certified under this standard. These include:

- **The product shall be constructed so that it may be readily and conveniently operated when the proper key or keys are used;**
- **The lock must be practicable for installation by a trained locksmith and able to be installed in a position or location that does not degrade its burglary-resistant qualities;**
- **Parts must maintain a high degree of tolerance and uniformity. This is especially important with regard to bittings.**

Locks tested under UL 437 must be constructed of brass, bronze, stainless steel, or equivalent corrosion-resistant material or shall have a protective finish that meets salt spray tests. There are a number of common standards relating to locks and security containers, including requirements relating to non-metallic parts, corrosion protection, and salt spray. These are described in UL 768.

37_3.1.3 Specific Requirements for Locks

37_3.1.3.1 Differs

Door locks and cylinders must be capable of at least 1000 key changes. Security containers must achieve significantly higher security levels, providing at least 1,000,000 differs for any design. Two-key locks require a minimum of 64 guard key changes and at least 15,000 customer key changes for any design.

37_3.1.3.2 Security Container Key-Locks

Specific requirements for locks that are utilized on security containers include:

- **Key shall be field changeable;**
- **The bolt lever must fit snugly on its post and shall be secured tightly;**
- **The fence face shall be perpendicular to the plane of the tumblers;**
- **The wheels, tumblers, levers, or pins shall run true and be at right angles to their mounting post;**
- **Within a combination lock, the clearance between the fence face and the tumbler wheels shall not be less than .025″ (0.64 mm) when the bolt lever is raised by means of a driver cam, and not less than .015″ (0.38 mm) when the bolt lever is raised by means other than a driver cam;**
- **Mechanical means must be provided that immobilizes the bolt if the lock is punched or pulled;**
- **The tolerance between plug and shell in a pin tumbler lock must be less than one cut depth.**

37_3.1.3.3 Endurance Test

The lock shall function as intended during 10,000 complete cycles of operation at a rate not exceeding 50 cycles per minute. A lock having a changeable core or field-changeable key design shall operate as intended after each of 50 changes of the core or key.

37_3.1.3.4 Attack Resistance Tests

Attack resistance tests encompass setup requirements, use of specified tools, timing, and entry methods.

37_3.1.3.4.1 Test Requirements

A number of tests have been defined to ascertain the attack resistance of a lock. UL 437 requires that a device cannot be opened or compromised as a result of the application or use of tools and techniques set forth in the standard and are summarized here.

Specific protocols have been devised with respect to mounting of samples to be tested. Door locks must be installed, in accordance with the lock manufacturer's instructions, in a 1-1/2" (38.1 mm) solid hardwood door of average size. The door is mounted in a 1-1/4" (38.1 mm) thick wood frame and reinforced as if actually installed. Door locks that are designed specifically for a certain door construction are to be tested in that mode.

The following test requirements apply for attack ratings:

- **The tools used for these tests include any common hand tools, hand or portable electric tools, drills, saw blades, puller mechanisms, and picking tools. For door locks only, pry bars up to three feet (.9 meter) long are also to be employed;**
- **Tools that are used on two-key locks must not include saws, puller mechanisms, or portable electric drills;**
- **Common hand tools are defined as chisels, screwdrivers no more than 15" (380 mm) long, hammers having three-pound (1.36 kg) head weight, jaw-gripping wrenches, and pliers;**
- **Puller devices are to be either a slam-hammer mechanism, having a maximum head weight of three pounds (1.36 kg), or a screw type;**
- **Picking tools are common or standard patterns, as well as those designed for use on a particular make or design of cylinder;**
- **Portable electric tools are identified as high-speed handheld drills that meet the following criteria:**
  - **Operate at a maximum of 1900 RPM;**
  - **Maximum ¼" (6.4 mm) chuck size;**
  - **Use high-speed drill bits;**
  - **Utilize electrically operated vibrating needles.**

37_3.1.3.4.2 Test Time for Attack Resistance

Net times in minutes are specified for each type of test and the lock upon which the procedure is to be performed. The sequence is not relevant, nor the number of methods to be applied. Samples

may be tested for several techniques, or a new specimen may be utilized for each procedure.

Test	Door Locks/ Cylinders	Security Container Key Locks	Two-Key Locks
	(Net working time in minutes)		
Picking	10	30	45
Impressioning	10	30	45
Forcing	5	30	5
Drilling	5	30	NA
Sawing	5	30	NA
Prying	5	30	NA
Pulling	5	30	NA
Driving	5	30	NA

37_3.1.3.5 Test Methods

There are eight methods of forced and direct entry that are defined within the standard: **picking**, **impressioning**, **forcing**, **drilling**, **sawing**, **prying**, **pulling**, and **driving**. These have been previously described in **Chapters 29-32**.

37_3.1.3.5.1 Picking

Picking tools are employed in an attempt to align the active components, including tumblers, levers, wheels, or pins, in order to open the lock.

37_3.1.3.5.2 Impressioning

Methods of impressioning, as defined in **Chapter 31**, are employed in an attempt to produce working keys.

37_3.1.3.5.3 Forcing

Rotary forces are applied with the test tools in three critical areas in an attempt to open the target lock:

- **In the key slot;**
- **On the exposed part of the cylinder;**

- **On the exposed portions of the lock assembly.**

37_3.1.3.5.4 Drilling

Drilling requires that a drill and one or more bits are utilized to attack the plug, exposed lock body, and other parts in an attempt to compromise critical components to effect an opening.

37_3.1.3.5.5 Sawing

A saw is employed in an effort to cut, compromise, remove, and open critical components, including the plug, body of the cylinder, and lock bolt.

37_3.1.3.5.6 Prying

Tools are utilized in an attempt to pry the bolt out of engagement with the strike opening within a door lock assembly.

37_3.1.3.5.7 Pulling

Techniques of pulling are directed at critical locking components including the plug, body, bolt, or other areas in order to compromise and open the device.

37_3.1.3.5.8 Driving

Driving is the opposite of pulling. Tools are utilized in an attempt to drive or force the plug, body of the lock, lock bolt, or other part to allow bypass of the mechanism.

37_3.2 UL 768 Standard for Combination Locks

UL 768 provides the testing protocol for combination locks used on security containers. Specifically, the standard applies to locks designed for attachment on doors of safes, chests, vaults and the like to provide a means of locking the boltwork against unauthorized opening. They are intended to test the ability of combination locks to resist unauthorized manipulation and derivation of the number sequence by sense of sight, touch, or hearing. The standard does not address forced opening.

Locks are classified by UL as **Group 1**, **Group 1R**, or **Group 2.** These are defined as follows:

- **Group 1: Those locks that have a high degree of resistance from expert or professional manipulation. The protection against expert manipulation includes advanced design features not found in conventional designs;**

- **Group 1R: Those locks that have a high degree of resistance to expert manipulation, including use of radiological means;**

- **Group 2: Those locks that have a moderate degree of resistance to unauthorized opening.**

37_3.2.1 Resistance to Manipulation

The essence of the standard relates to protection against surreptitious and covert manipulation. In order for a lock to be listed, it must meet the requirements outlined below. Numbers in parenthesis indicate the specific UL paragraph within the standard.

37_3.2.1.1 Group 1

- **A Group 1 lock shall resist unauthorized opening by expert or professional manipulation for a period of 20 man-hours (10.1);**
- **The time specified in paragraph (10.1) may include one man working 20 hours, two men working together 10 hours, or the like. Lock experts may be called upon to assist in these tests (10.2);**
- **Tests on Group 1 locks shall involve (1) expert manipulation techniques, including walking the tumblers, feeling the tumbler gates, sighting variations on the dial, or (2) any other techniques that may develop as a result of the examination (10.3);**
- **The protection against expert manipulation shall include advanced features not found in conventional designs (10.4);**
- **The combined weight of instruments or detection devices used in this test is not to exceed 50 pounds (22.7 kg) (10.5);**

- **A three-tumbler lock shall not open if the dial is turned more than one full dial graduation on either side of the proper graduation for each tumbler wheel. A four-tumbler lock shall not open if the dial is turned more than 1 1/4 dial graduations on either side of the proper graduation for each tumbler wheel (10.6);**
- **Punching of a Group 1 or Group 1R combination lock shall result in the lock bolt becoming immobilized by mechanical means (10.7);**
- **The immobilization by mechanical means is not required on an offset-spindle type of lock in which punching of the spindle does not defeat the locking action.**

37_3.2.1.2 Group 1R

- **A Group 1R combination lock shall comply with all of the requirements for Group 1 locks and in addition shall be secure against radiological attack for 20 hours with a radioactive source not exceeding the equivalent of 10 curies of cobalt-60 at a 30″ (762 mm) distance (10.8).**

37_3.2.1.3 Group 2

- **Testing of Group 2 locks shall consist of setting the tumblers to various combinations to determine that the lock will operate as intended but will not open with the dial turned beyond the tolerances specified in paragraph 10.10 (10.9);**
- **A three-number wheel lock shall not open if the dial is turned more than 1 1/4 dial graduations on either side of the proper graduation for each tumbler. A four-tumbler lock shall not open if the dial is turned more than 1 ½ dial graduations on either side of the proper graduation for each tumbler (10.10).**

37_3.2.2 General Construction and Performance Standards

The following requirements pertaining to construction, performance, strength and marking apply to combination locks that

are certified under UL 768.

37_3.2.2.1 Construction

- **A lock shall permit a choice of at least 1,000,000 combinations;**
- **The lever shall fit snugly on its post and shall be secured tightly. The fence shall be perpendicular to the plane of the tumblers;**
- **The clearance between the fence and the tumbler wheels shall be not less than .025″ (0.64 mm) when the bolt lever is raised by means of the driver cam, and not less than .015″ (0.38 mm) when the lever is raised by means other than the driver cam;**
- **Tumblers shall run true, and be at right angles to the tumbler post.**

37_3.2.2.2 Non-metallic Parts

- **Factors taken into consideration when judging the acceptability of non-metallic parts are (1) mechanical strength, (2) resistance to impact, (3) moisture absorptive properties, and (4) resistance to distortion of the material under conditions of normal or abnormal usage. Tests of polymeric materials are defined below, and appear in Section 13 of the standard.**

37_3.2.2.2.1 Strength

- **The mechanical strength and resistance to impact of parts made of polymeric material are to be considered as acceptable for the intended use on the basis of satisfactory performance in the Operation Test, Section 9, and Endurance Test, Section 11.**

37_3.2.2.2.2 Age-Stress Distortion

- **There shall be no warping to the extent that intended functioning will be impaired when representative samples constructed of polymeric material are aged for seven days in a circulating-air oven maintained at 90°C (194°F).**

37_3.2.2.2.3 Moisture Absorption

- **Polymeric materials shall function as intended after three representative samples, previously conditioned as described in paragraphs (13.2-13.4) are exposed for 10 days to warm moist air having a relative humidity of 98 percent at a temperature of 140° F (60° C).**

37_3.2.2.2.4 Corrosion Protection

- **All working parts of the lock mechanisms shall be constructed of brass, bronze, stainless steel, or equivalent corrosion-resistant materials, or shall have a protective finish that permits the lock mechanism to comply with the requirements of the Salt Spray Corrosion Test.**

37_3.2.3 Operation

- **The lock shall operate as intended on the combination to which it is set.**

37_3.2.4 Endurance Test

- **The lock shall operate for 10,000 complete cycles of running the combination at a speed not exceeding forty-eight revolutions per minute.**

37_3.2.5 Salt Spray Corrosion Test

- **A combination lock constructed of materials other than brass, bronze, stainless steel, or equivalent corrosion-resistant materials shall operate as intended, following a seventy-two hour exposure to salt spray (fog) as described in the Standard for Salt Spray (Fog) Testing, ASTM B11-73 (1979);**

- **During this test the locks are to be operated once during each twenty-four hour period;**

- **Following the exposure, the lock is to be allowed to dry for twenty-four hours in a room having an ambient temperature of 25°C (77° F) and then is to be tested for operation.**

37_3.2.6 Marking

UL requires specific marking on each listed lock in order to identify the manufacturer and security rating. Information must be visible regarding:

- **The manufacturer's or private labeler's name or identifying symbol;**
- **The model, style, or catalog identifier;**
- **The designation of Group 1, Group 1R, or Group 2;**
- **If a manufacturer produces combination locks at more than one factory, each lock shall have a distinctive marking, which may be in code to identify it as the product of a particular factory.**

37_3.2.7 Glossary of Terms Relating to Combination locks

In order to interpret UL 768, the following definitions apply:

- **Drive Cam: A component that engages the tumblers and moves the bolt during the ordinary opening or closing procedure;**

- **Drive Pin: A protrusion on or through a cam or tumbler that engages the adjacent tumbler;**

- **Fence: A part of the lever that fits into the tumbler gates, permitting the lever to engage the drive cam;**

- **Gate: The cutout in the periphery of the tumbler that is engaged by the fence on the lever assembly;**

- **Lever: A component that retracts the bolt;**

- **Tumbler Pack: An assembly of tumblers, flys,**

washers, springs, and rings;

- **Tumbler Post: A component, integral to the lock case or cover, on which the tumbler pack is assembled and about which the tumblers rotate;**
- **Tumbler Wheel: An assembly, usually in the form of a circular disc, having a gate and drive pin whose location may be set to selected positions to permit the user to change the combination.**

37_4.0 UL Fire Ratings

There is a great deal of misunderstanding as to the relationship between the burglary and fire resistance of a container; generally, the two do not go hand in hand. Ordinarily, a safe or vault is primarily designed for **one** rating, although there are exceptions such as the Chubb Planet. Fire-rated safes and vaults contain special doors and bodies that are rated in terms of hours of resistance to heat.

Two hundred years of testing has been carried out by safe manufacturers, notably Chubb, in developing fire-resistant materials and overall approaches to protecting valuables against the effects of high temperature. Safes are routinely subjected to heat and cold, explosion, and impact during an actual fire. These conditions are simulated during testing. General guidelines require a one-hour UL or SMNA rating for light fire conditions, a two-hour rating for moderate fire conditions, and a four- to six-hour SMNA rating for severe fire conditions.

Fire safes will have a minimum amount of metal as compared to a burglary safe: thus their lower security rating. Special insulation is used to draw heat away from the metal surfaces within these containers. The insulation is designed to retain the heat, rather than allow the metal to transmit it to the safe's contents. Older safes are inherently unreliable because the insulation becomes dry after a period and loses its properties.

37_4.1 Fire Testing Criteria

Safes that carry UL fire ratings must meet three primary tests: **endurance**, **impact**, and **explosion** hazard. The **fire endurance** test requires that a safe must withstand up to one-half hour of

incineration at up to 1550° F, or up to 1700° F for one hour, depending upon the rating. The product must maintain interior temperature below 350° F, thereby safeguarding documents from damage.

The **fire impact** test requires that when a safe is heated to 1550° F, then dropped nine meters and reheated to 1550° F for one-half hour, that the safe stays locked and internal temperatures never exceeding 350° F. The **explosion hazard** test requires that when the safe is subjected to 2000° F flash fire, it will not rupture or explode.

37_4.2 Specific Fire Ratings

CLASS C: One-hour resistance of fire reaching 1700° F, with internal temperature remaining less than 350° F. The safe is also tested for combined explosion and impact. One test requires that the units are preheated to 2000° F for thirty minutes, then hoisted thirty feet and dropped. After cooling, the safe is again heated to 1500° F.

CLASS B: Two-hour resistance to 1850° F with interior temperature not exceeding 350° F, with the same explosion and impact requirements for a Class **C** container.

CLASS A: Minimum four-hour resistance to 2000° F, prior to the interior temperature rising above 350° F. A **Class A** safe is also tested for explosion and impact.

37_4.3 UL Fire-Resistive Container Classifications

See **Chapter 33** for detailed information regarding the construction of fire safes and vaults. The following material takes into account the specifications in UL 72, Tests for Fire Resistance of Record Protection Equipment.

37_4.3.1 General Construction Requirements

The insulation used in record protection devices must be capable of retaining its heat- insulating properties equivalent to Portland cement, concrete, or gypsum concrete. All mechanical

components of record protection storage devices must be constructed so that normal and repeated operation can occur without damage to the insulating and fire-resistive qualities.

37_4.3.2 Specific Testing Protocols

The UL test protocols are similar to those developed by SMNA.

37_4.3.2.1 Explosion Hazard Test

A furnace is preheated to 2,000° F. An empty sample is closed, locked and placed into the furnace for thirty minutes (twenty minutes for units rated one-half hour) and if no explosion results, the unit is allowed to cool without opening the furnace doors. After cooling, the container is opened and dismantled. An examination is conducted to determine the heat-insulating properties of the sample. This evaluation includes:

- **Condition of interior finish;**
- **Security of interior equipment;**
- **Locks;**
- **Part fastenings;**
- **Any signs of undue transmission of heat or moisture.**

37_4.3.2.2 Fire Endurance Test

The contents are placed inside the container so that the material contacts the interior walls to allow heat transfer. The unit is then closed, locked, and exposed to uniformly distributed fire, the temperature of which is regulated and increased according to the standard time-temperature curve summarized below.

The application of flame and temperature is continued for the period required for the desired classification, and the container is allowed to cool without opening the furnace. The interior temperature is recorded throughout the test and during the subsequent cooling period until a definite decline is noted. The internal temperature of the container must never exceed 125° F, 150° F, or 350° F, depending upon rating.

After cooling has occurred, the container is opened, dismantled and its contents examined for usability. The locking mechanisms and part fastenings are evaluated for security and the interior scrutinized for any visible evidence of undue heat transmission.

This procedure must be repeated one year subsequent to the first test to insure compliance after aging of materials.

37_4.3.2.3 Relative Humidity Test

After preconditioning, the unit is heated for twelve hours to obtain an interior temperature of 70° ± 5° F and a relative humidity of 50 ± 5 percent. The unit must successfully maintain an interior relative humidify less than 80 percent of 85 percent during its respective Fire Endurance Test and during that part of the cooling period when the interior temperature is above 120° F. Units are also examined for any signs of moisture penetration into the interior.

37_4.3.2.4 Combined Explosion Hazard Impact Test

The container is heated to 2000° F for thirty minutes. If no explosion results, then the temperature is reduced to the standard time-temperature Curve and the fire continued for another fifteen or thirty minutes, depending upon rating. The test sample is then withdrawn. Within two minutes, the unit is dropped from thirty feet into a pile of brick on a heavy concrete base. The safe is examined, reheated and reexamined as per the requirements of the Fire and Impact Test.

37_4.3.3 UL Label Type Classifications

UL classifies containers based upon the time they will withstand exposure to high temperatures. The following table provides a summary of ratings and requirements.

Class 125 Insulated Record Containers/Fire-Resistant Safes

½ hour IT1, T1, F1, E1, FI4
1 hour IT1, H2, T1, F1, E1, FI4
2 hours IT1, H2, T2, F1, E1, FI3
3 hours IT1, H2, T3, F1, E1, FI2
4 hours IT1, H2, T4, F1, E1, FI1

Class 150 Insulated Record Containers/Fire-Resistant Safes

½ hour IT2, T1, F1, E1, FI4
1 hour IT2, H1, T1, F1, E1, FI4

2 hours IT2, H1, T2, F1, E1, FI3
3 hours IT2, H1, T3, F1, E1, FI2
4 hours IT2, H1, T4, F1, E1, FI1

Class 350 Insulated Containers/Fire-Resistant Safes

½ hour (old UL label E) IT3, T05, F1, FI5
1 hour (Insulated filing drawers) IT3, T1, F1, E1
1 hour (old UL label D Fire Resistant Safes) IT3, T1, F1
1 hour (old UL label C) IT3, T1, F1, E1, FI4
1 hour (old UL label D Insulated filing devices) IT3, T1, F1, FE1
2 hours (old UL label B) IT3, T2, F1, E1, FI3
4 hours (old UL label A) IT3, T4, F1, E1, FI2

37_4.3.3.1 UL Test Protocols

IT1 Interior temperature less than 125° F
IT2 Interior temperature less than 150° F
IT3 Interior temperature less than 350° F
H1 Interior relative humidity <85 percent (class 150)
H2 Interior relative humidity <80 percent (class 125)

T4 time-temperature curve four hours to 2000° F
T3 time-temperature curve three hours to 1925° F
T2 time-temperature Curve two hours to 1850° F
T1 time-temperature curve one hour to 1700° F
T05 time-temperature curve one-half hour to 1550° F

F1 Fire Endurance Test

FE1 Fire Endurance and Explosion Test (no explosion through 30 minutes of exposure to a 2000° F fire)

FE2 Fire Endurance and Explosion Test (no explosion through 20 minutes of exposure to 2000° F fire)

E1 Explosion Hazard Test

FI1 Fire and Impact Test (no explosion after 30 minutes of exposure to 2000° F, immediate 30-foot drop, standard reheating for 60 minutes to 1700 F.)

FI2 Fire and Impact Test (no explosion through 30 minutes of exposure to 2000º F, 30 minutes of standard exposure to 1700º F, an immediate 30-foot drop test, and a standard reheating for 60 minutes to 1700° F.)

FI3 Fire and Impact Test (no explosion through 30 minutes of exposure to a 2000º F, 15 minutes of standard exposure to 1638° F, an immediate 30-foot drop test, and a standard reheating for 45 minutes to 1638° F.)

FI4 Fire and Impact Test (no explosion through 30 minutes or exposure to a 2000º F, an immediate 30 foot drop test, and a standard reheating for 30 minutes to 1550° F.)

FI5 Fire and Impact Test (no explosion through 20 minutes of exposure to 2000° F).

Time-Temperature Curve

Minutes	Temperature °F
5	1000
30	1550
60	1700
120	1850
180	1925
240	2000

37_5.0 Safe Manufacturers National Association (SMNA)

The Safe Manufacturers National Association established specifications for fire, burglary, and robbery-resistive containers. SMNA is no longer in business, but containers carrying its ratings are still in use. For that reason, information regarding SMNA classifications is presented here.

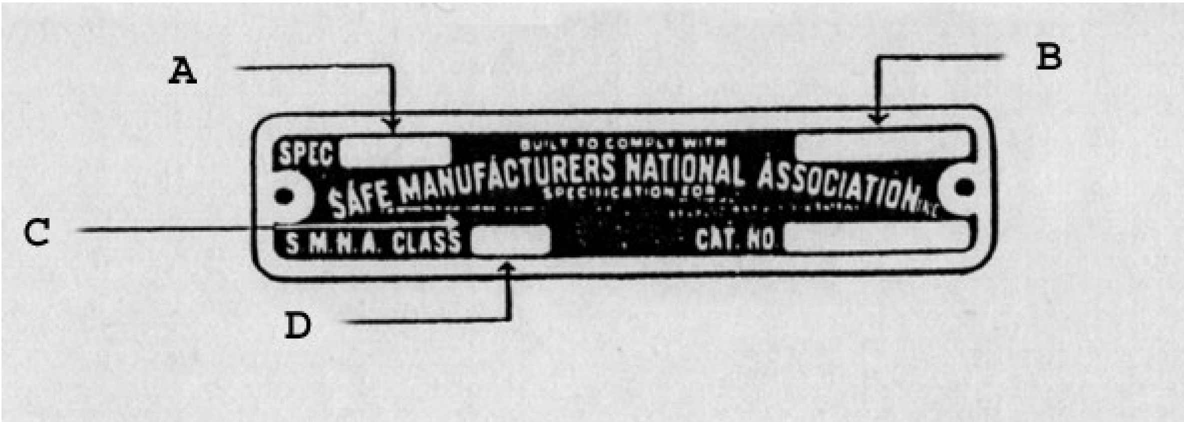

Figure LSS+3703 The SMNA label components: "A" is the specification, such as F1-D; "B" is the SMNA designation, such as "Y" or "W"; "C" is the type of label, such as fire-resistant safe, or fire-insulated vault door; "D" is the SMNA classification, such as Class "A" or "B."

All SMNA labels have a green, black or red background. A green background was used on most fire-insulated containers; all SMNA labels for money chests and burglary-resistive containers have a red or black background. Each label contains the following information:

- **"Safe Manufacturers National Association";**
- **SMNA specification;**
- **Type of label;**
- **SMNA classification;**
- **SMNA designation.**

The SMNA designation "W" or "Y" indicated the cost of a container. A "W" denoted a retail list price of $75 or less; containers that cost more were assigned the "Y." Labels used on fire-insulated **containers** defined one of the following SMNA classifications: **A, B, C, D, E,** or **150.** Fire-insulated **doors** had one of four classifications: **one hour, two-hour, four-hour,** or **six-hour.** Money chests and burglary or robbery-resistive products were classified by one of the following groups: **"U-1"** through **"U-10",** or **"U-12."**

Burglary and robbery classifications were based on test data or SMNA construction specifications that conformed to the National Bureau of Casualty and Surety Underwriters' requirements. Fire-resistive classifications for safes, chests and insulated record containers were based on tests conducted by Underwriters

Laboratories.

37_5.1 Burglary and Robbery-Resistant Containers

Specifications for SMNA-rated burglary and robbery-resistant containers are detailed as follows:

Group 3: Round door chests, body thickness 1″ minimum, door thickness 1 ½″ exclusive of boltwork and locking mechanism. Locking mechanism to be lug or bolt-type. If lug-type, bolts to be protected by drill-resistive inserts or pins, outside surface of body and door to be case- hardened or of equivalent drill resistance. Body to be made of one piece, SAE 1020 or equal steel casting, forging or rolled steel. Door to be made of one piece of equivalent material. Fit of door, equipped with combination lock, to be not more than .004″ clearance between door and jamb at any joint, with hinge removed.

Group 4: Round door chests, body thickness 1″ minimum, door thickness 1 ½″ exclusive of boltwork and locking mechanism, locking mechanism to be lug or bolt-type. If lug-type, bolts are to be protected by drill-resistive inserts or pins. Body to be of cast or welded construction or a combination of cast and welded construction. Cast bodies to be SAE 1020 or equal steel, welded bodies to be of commercial steel. Doors to be of steel equivalent in strength of that used for bodies, fit of door to be not more than .004″ clearance between door and jamb, with hinge removed. Door to be equipped with combination lock.

Group 5: Rectangular door chests. Body to be 1″ minimum, door to be 1½″ minimum exclusive of boltwork and locking mechanism. Body and door to be of commercial steel plates of laminated or welded construction, equipped with combination lock.

Group 6: Round or rectangular door chests. Body thickness ½″ minimum, door thickness 1″ minimum exclusive of boltwork and locking mechanism. Constructed of commercial steel, laminated or welded. Door equipped with a combination or key lock.

Group 9: Containers consisting of wall safes and similar products with body thickness not less and ¼″ and door thickness not less than ½″. Door equipped with a combination or key lock.

Group 10: Containers such as lockers, truck boxes, etc. Door equipped with a combination or a key lock.

Group 12: Any industry product in any class that is equipped with a deposit slot that is
accessible from the exterior of the container. The slot voids any fire or burglary
rating to which the product would otherwise be entitled. Note that the term “thickness”
applies to thickness of steel, which may be solid or laminated. SAE means Society of
Automotive Engineers.

37_5.2 Money Chests and Robbery-Resistive Products

UB 1: Burglary-resistive chest, Groups U-1-2-4-5-6-7, Y, Burglary-resistive Underwriters Laboratories Labeled chest, red. The fire resistant vault door is green.

BR 1: Burglary/Robbery-resistive container, Groups 3-4-5-6-9-10, Y, Burglary/Robbery-resistive container, black

M 1: Deposit chute container, Group 12, Y, deposit chute container, black.

37_5.3 SMNA Specifications for UL Labeled Chests

SMNA labeled Burglary-resistant chests carry the following UL classifications:

- **Group U-1: TXTL-60**
- **Group U-2: TRTL-60**
- **Group U-4: TRTL-30**
- **Group U-5: TL-30**
- **Group U-6: TL-15**
- **Group U-7: “KL”.**

37_5.4 Fire Tests: Endurance, Impact, and

Explosion

Three types of fire testing were done by SMNA: **endurance**, **impact**, and **explosion**.

37_5.4.1 Fire Endurance

The Fire Endurance Test measured the ability of a product to withstand heat and flame. A container was lightly loaded with papers, loosely distributed throughout, and allowed to touch the internal walls. The safe was then placed in a furnace and the temperature raised in accordance with the American Standard Time-temperature Curve, according to the product class being tested. There were five classifications:

- **Class A: to the 4 hour-2000° F point;**
- **Class B: to the 2 hour-1850° F point;**
- **Class C & D: to the 1 hour-1700° F point; and**
- **Class E: to the ½ hour-1550° F point.**

The interior of the test sample is measured on a regular basis until the maximum temperature is reached. So long as the inside of the safe does not reach 350°F, the papers can be handled normally without breaking and information on the pages can be easily read; the safe is said to have passed the test.

37_5.4.2 Impact Protocol

The impact protocol simulates conditions during a fire: the test consists of three parts. The product, heavily loaded with papers, was placed in a testing furnace and the temperature elevated, based upon classification of the container:

- **Class A: to the 1 hour, 1700° F point;**
- **Class B: to the 3/4 hour, 1640° F point; and**
- **Class C: to the ½ hour, 1550° F point.**

The sample, while still in a highly heated condition, was removed from the furnace, hoisted to a height of thirty feet and dropped, bottom downward, onto a bed of broken brick covering a thick concrete base. After allowing to cool to a normal temperature, the sample was subjected to the final phase of the procedure.

The container was again placed into the furnace, bottom upward, and the temperature raised to the required level for the particular class being tested. The furnace was shut down and the sample allowed to cool. The container was considered to have withstood the test if the papers inside were capable of ordinary handling without breaking, and were decipherable by normal means.

37_5.4.3 Explosion Hazard

The sudden heating of a container can generate hydrogen airstream mixtures that can cause rupture. The test was designed to determine if a product could withstand sudden heating that could impair its fire resistance. A safe was first lightly loaded with papers, loosely distributed. The container was placed in a preheated furnace, at 2000° F. The temperature was maintained for thirty minutes. If no explosive pressure developed, then the test was completed successfully.

37_5.5 Classifications and Labeling for Special Safes and Vaults

There are special insurance classifications and labeling for mercantile safes and bank safes. These are taken from the Insurance Services **Office Manual of Burglary Insurance**.

37_5.5.1 Mercantile Safes, Chest, or Cabinet

The following safe, chest and cabinet classifications are applicable to mercantile containers. Each must be equipped with at least one combination lock, except a safe or chest equipped with a key lock and bearing the label, "Underwriters Laboratories, Inc. Inspected Key locked safe **KL Burglary**."

B:	**Fire-Resistive**
Doors:	Steel less than 1" thick. Any iro safe, or chest having a through which money car deposited.

Walls:	Body of steel less than ½" thick, Any iron or steel safe having a slot through w can be deposited.
C: Burglar-Resistive	
Doors:	Steel at least 1" thick. Safe or chest the following label: "Underwriters' Laboratories, Inc. Inspected Key locke **Burglary.**"
Walls:	Body of steel at least ½" thick. Safe or chest bearing the following la "Underwriters Laboratories, Inc. Inspe Key locked Safe KL Burglary."
E: Burglar-Resistive	
Doors:	Steel at least 1 ½" thick.
Walls:	Body of steel at least 1" thick.
ER: Burglar-Resistive	
Doors and Walls:	Safe or chest bearing the following la
F: Burglar-Resistive	
Doors and Walls:	Safe or chest bearing one of the follo labels: **TL-30, TR-30, TX-60.**
G. Burglar-Resistive	
Doors:	One or more steel doors (one in front other) at least 1 ½" thick and aggrega least 3" thickness.
Walls:	Not applicable.
H. Burglar-Resistive	
Doors and Walls:	Safe or chest bearing one of the follo labels: **TX-60, TR-60, TRTL-30.**
I. Burglar-Resistive	
Doors and Walls:	Safe or chest bearing the following la **TRTL-15x6**
J. Burglar-Resistive	
Doors and Walls:	Safe or chest bearing the following la **TRTL-30x6.**
K. Burglar-Resistive	
Doors and Walls:	Safe or chest bearing one of the follo labels: **TRTL-60, TXTL-60.**

37_5.5.2 Bank Safe Classification: Safe, Chest or Security Locker

There are twelve classifications for bank safes: **A-K** and **BR.** The highest letter designation corresponds with the level of security. The specification defines the construction of walls and doors in terms of metal, thickness, and grade. Classifications **A**, **B**, **BR**, and **C** relate both to night depository receiving safes and traditional enclosures. It is interesting to note that there is no universal standard for ATM machines, although the internal safes **are** rated. The closest standard appears to be UL 291, level 1 for such devices.

Certain of the other classifications correlate to UL ratings. Thus:

Class	UL
BR	TL-15 Burglary (walls and door);
C	Equal to BR. No longer manufactured;
D	No longer manufactured;
E	No longer manufactured;
F	No longer manufactured;
G	Doors (lug type, hung) >1.5″ thick. If outside of a vault, then must be equipped with a time lock. May carry a rating of TL-30, TR-30, or TX-60;
H	Safe or chest with TX-60, TR-60, or TRTL-30 rating;
I	Safe or chest bearing a TRTL 15X6 label;
J	Safe or chest rated at TRTL-30x6 Burglary;
K	Safe or chest rated as TRTL-60 or TXTL-60.

37_5.5.2.1 Bank Safe Construction Requirements

Each door of each safe, chest, or security locker must be equipped with at least one combination lock, except a safe, chest or security locker equipped with a labeled Underwriters' Laboratories, Inc. approved key lock. The thickness of steel in doors is exclusive of boltwork and locking devices. If a safe has more than one combination-locked door (one in front of the other), the combined thickness of the steel doors, excluding any

door with less than 1" of steel, shall be used in applying the bank safe classifications.

Night depository: This unit consists of a head, chute and receiving safe in which deposits can be made from outside the bank. Deposits are made in a bag or envelope.

37_6.0 Padlock Testing and Standards: American Society for Testing and Materials (ASTM)

Extensive evaluation criteria have been developed for padlocks due to the popularity of these devices. The following ASTM standards relate to environmental, functional, operational and security requirements. The protocols encompass both surreptitious and forced-entry. Specially made padlocks that are used by the Department of Defense or other high-security locations are not included in these standards.

37_6.1 ASTM References

The following reference documents and standards are relevant for padlock evaluation:

- **ASTM F883**
- **B 117 Method of Salt Spray (fog) Testing**
- **G 53 Practice for Operating light and Water-Exposure Apparatus for Exposure of Nonmetallic Materials**
- **A 156.5 Standard for Auxiliary Locks and Associates Products.**

37_6.2 ASTM Terminology

The following terminology is utilized by ASTM in describing testing protocols relating to padlocks. These definitions are equally applicable to UL standards and descriptive materials in **Chapter 32.** Some definitions have been omitted in this discussion due to their inclusion elsewhere in this book.

Cam: The flat material fastened to or a part of the back of the cylinder plug that operates the locking and unlocking mechanism when activated by the plug.

Case: The housing for the locking assembly.

Clevis: A fastening device that joins a chain to a padlock.

Cylinder: The cylindrical subassembly of a lock containing a cylinder plug.

Cylinder Bitting: The arrangement of tumblers within a cylinder.

Cylinder Decoding: The procedure used to produce a key without having the source from which to copy.

Cylinder Picking: Operating a cylinder with tools in a non-destructive manner, rather than with the correct key.

Cylinder Plug: A portion of the cylinder that activates the lock when the correct key is inserted and operated.

Removable Cylinder: The subassembly of a cylinder containing the cylinder plug, tumbler mechanism, and keyway. It may also constitute the entire cylinder, extractable from the rest of the padlock.

Heel: The portion of a shackle permanently retained in the padlock case.

Keyway: The opening in the cylinder plug into which the key is inserted.

Padlock: A locking device made up of a case, shackle, and the shackle-retaining assembly. Components performing the same purpose of a shackle but differing in design are sometimes used instead of a shackle.

Plug retainer: The portion of the cylinder that prevents the cylinder plug from being withdrawn.

Rapping: A non-destructive procedure to open a lock by applying impact or shock.

Shackle: The component of a padlock entering the case and effecting the locking function.

Shroud: Material that is employed as added protection to a padlock in order to resist attack.

Toe: The portion of a shackle that is withdrawn from the padlock case, leaving a clear opening so that engagement in a hasp or other closure may be accomplished.

Tumbler: A moveable mechanical element that prevents operation of the cylinder plug except by activation of the correct key.

37_6.3 Classification and Grades of Padlocks

There are two classifications of padlocks: **key** and **combination** operated. Padlocks can be described within several grades of performance, listed in the order from lowest to highest:

- **Key is captive in cylinder when padlock is unlocked;**
- **Removable cylinder;**
- **Changeable combination;**
- **Combination-operated with key control;**
- **Corrosion resistant;**
- **Provided with non-ferrous shackle;**
- **Environmental resistant.**

37_6.4 Specific Tests and Protocols for Padlocks

There are several testing protocols to determine the ability to resist forced and covert entry attempts. These require the padlock to be subjected to different kinds of stresses to assess the ability of the mechanisms and materials to withstand attack.

37_6.4.1 Forcing Tests

There are six types of **forcible** tests that are performed upon padlocks:

37_6.4.1.1 Tensile Test

After being placed in a special fixture, force is applied to the padlock slowly along the vertical centerline of the lock, with a direct and equal tension to each leg of the shackle. Failure occurs if the padlock is opened.

37_6.4.1.2 Drop Test

With an impactor, the weight is dropped the required number of times on each face and side of the locked padlock case. Failure occurs if the padlock is opened.

37_6.4.1.3 Shock Test

Using the impactor, the weight is dropped the required number of times on the top of the locked padlock case. Failure occurs if the padlock is opened.

37_6.4.1.4 Cylinder Plug-Pulling Test

The keyway is drilled with a No. 20 (0.61”) diameter bit. A type AB No. 12 screw, at least 19 mm (0.75”) deep, is inserted. The required tension is applied axially between the case and the installed screw. Failure occurs if the cylinder plug or cylinder assembly completely separates from the case, or if the padlock can be opened by manipulation with a screwdriver at the conclusion of the test.

37_6.4.1.5 Cylinder Plug-Torque Test

The padlock is installed in a rigid fixture such as a vise, to support it firmly but not restrict free rotation of the plug in the cylinder. A bladed tool is inserted into the keyway so that a torque load can be applied to the plug. Failure occurs if the padlock opens.

37_6.4.1.6 Shackle Cutting Test

Shackles shall withstand cutting and severance when two shearing blades of American Iron and Steel Institute (AISI) S-2 material are positioned in a tensile loading device having a compression load capability and compressed with the required force. Failure occurs if the shackle is severed.

37_6.4.2 Surreptitious-Entry Tests

Five surreptitious-entry tests are performed on padlocks:

- **Picking and manipulation;**
- **Impressioning and decoding;**
- **Shackle shimming;**
- **Cylinder drilling and shimming;**

- **Rap tests.**

37_6.4.2.1 Picking or Manipulating Test

Cylinders and combination mechanisms within padlocks must resist picking or manual manipulation for the required time. In the case of pin tumbler locks, the plug must be loaded with one each of the longest and shortest pins that are furnished by the manufacturer. The remaining chambers must contain other sizes. Tools should not leave any visible marks that are detectable by the unaided eye.

37_6.4.2.2 Impressioning and Decoding Tests

A cylinder must resist successful impressioning and decoding.

37_6.4.2.3 Shackle Shimming Test

A shim inserted between the shackle and case in either or both shackle holes must be incapable of releasing the locking mechanism.

37_6.4.2.4 Drilling and Shimming Test

Cylinders must resist drilling with handheld tools, and shimming for a required period. Indicia of drilling must not be obvious to the unaided eye.

37_6.4.2.5 Rap Test

Rapping, as described in C**hapter 32**, requires the application of shock to the case. A padlock must resist rapping for a required time.

37_6.4.2.6 Cycle Tests

Cycle testing for cylinder locks provides that opening and closing sequences be executed the required number of times in each rotational orientation, not to exceed ten cycles per minute and without the addition of lubrication. Failure occurs if the test cannot be completed, if the padlock does not operate at the conclusion of the test, or if the key breaks.

Combination locks are cycle tested in slightly different fashion. Single-dial (multiple disc) padlocks are operated in alternate

directions for the required number of cycles at a rate not to exceed ten cycles per minute, with no more than a two seconds dwell. One cycle is equal to the number of revolutions necessary to upset all combination discs. At the conclusion of the test, the lock must open when the correct combination is dialed.

37_6.4.2.7 Corrosion and Environmental Tests

Locks must be resistant to corrosive elements, dry contaminants (such as silicon carbide grit), condensation, ultraviolet radiation, wet freezing environment, and be impervious to salt spray for the required number of hours.

37_7.0 Key or Combination Changes (Differs)

A standard (X1.7.1) has been promulgated relating to the number of "safe" key changes or differs that can be obtained from a cylinder. As has been demonstrated elsewhere in this text, the number of useable differs are limited and will vary according to the number of tumblers within a plug. Differs becomes important in a complex keying system and directly relate to security and the ability to pick or manipulate a lock. A limited number of differs can also promote the use of cross-keys within a master key system. See **Chapter 11**.

Certain locks employ special systems to increase the number of differs. Medeco is a prime example, utilizing the rotating tumbler. Unless such methods are employed, a simple six-pin master keyed system is limited to approximately four thousand safe key changes. This number can be further reduced if higher security is required. Obviously, with fewer pin positions, safe key changes are substantially reduced.

37_8.0 Americans with Disabilities Act (ADA)

The ADA requires that special hardware be employed in public accommodations in order to remove architectural barriers. All new facilities must comply with the requirements of the act. Older facilities must be modified when feasible. The relevant portions of Title III of the ADA provide:

- **"A public accommodation shall remove architectural barriers in existing facilities where such removal**

is readily achievable, i.e., easily accomplishable and able to be carried out without much difficulty or expense."

- **"Door Hardware: Handles, pulls, latches, locks, and other operable parts on accessible doors shall have a shape that is easy to grasp with one hand and does not require tight grasping, tight pinching or twisting of the wrist to operate. Such hardware shall be mounted within reach ranges. When sliding doors are in the fully open position, operating hardware shall be exposed and useable from both sides."**

37_9.0 United States Government Requirements for Security Devices

The General Services Administration (GSA), originally established in the 1950s, is the primary government agency responsible for the acquisition of security hardware for all federal agencies. Until the GSA was established, sensitive government information and assets were only protected against fire and burglary, but not sophisticated methods of attack. Pursuant to **DoD 5200.18**, the GSA "established and publishes minimum standards, specifications, and supply schedules for containers, vault doors, alarm systems, and associated security devices suitable for the storage and protection of classified information. Heads of DoD Components may establish additional controls to prevent unauthorized access."

The GSA publishes military and federal specifications that must be adhered to by all agencies within the United States government. This includes any private entity doing business with the government, if classified information is controlled by such entity. Specifications are written by the GSA, DoD, or the Interagency Committee for Security Equipment (IACE).

Before a manufacturer can be certified as compliant, its security hardware is subjected to rigorous testing by government laboratories. Containers and locks are examined at the **Army Intelligence Material Directorate**, pursuant to Federal Specification FP-L-2740. A comprehensive analysis is performed, relating to forced-entry, manipulation resistance, surreptitious and covert methods of entry, radiological tests, and general material and operational protocols. Compliant products will be

placed on the Qualified Products List (QPL).

37_9.1 Primary Manufacturers for GSA Security Hardware

There are two predominant manufacturers for Class V and VI containers: Hamilton and Mosler. Overly produces vault doors, and Schwab has also entered the GSA market. Other entrants have included Diebold, Herring-Hall-Marvin, Art Metal, and Hillside. The two major lock manufacturers are Mas-Hamilton and S&G.

37_9.2 General Requirements for GSA Containers

General requirements for marking, identification, opening and repair are summarized here. **Specifications** govern the manufacture and purchase of hardware; **regulations** control service and repair.

37_9.2.1 Marking and Identification

All GSA-approved containers must be identified by a specific label, denoting security classification. All containers will be marked on the outside of the front face of the container with a label reading "General Services Administration Approved Security Container" along with the name of the manufacturer. All containers will have a certification label affixed to the external side of the locking drawer describing the protection provided by the container.

EXAMPLE: **"This is a U.S. Government Security Container, Class 6 Cabinet, which, under the test defined in Federal Specification AAF-358-F, affords protection for:**

> **30 man-minutes against surreptitious entry**
> **20 man-hours against manipulation of the lock**
> **20 man-hours against radiological attack**
> **No forced-entry requirement."**

All containers will also bear an identification label on the external side of the locking drawer showing the model and serial number, year of manufacture and government contract number under which manufactured. GSA-approved security products include file cabinets, map and plan files, weapons cabinets, modular vaults, vault doors, and locks.

37_9.2.2 Opening in Case of Lockout

DoD 5200.1R controls service and repair of all GSA-approved containers. Other regulations may further define personnel and procedures. This order states that "neutralization of lockouts or repair of any damage that affects the integrity of a security container approved for storage of classified information shall be accomplished only by authorized persons who are cleared or continuously escorted while so engaged."

The **Industrial Security Manual for Safeguarding Classified Information**, DoD 5220.22-M, specifies how 5200.1R is to be implemented for defense contractors. They must be "specifically trained in approved methods of maintenance, neutralization of lockout, and repair of perforations."

37_9.2.3 Requirements Regarding Entry and Repair of Containers

Opening and repair is tightly regulated with respect to methods, procedures, and personnel so that the security of the device is not compromised. There are very specific requirements regarding the entry and repair of GSA containers. These include:

- **Means must be utilized that allow complete repair of containers;**
- **The container must retain its integrity, color, and condition (restored to original condition);**
- **There must be no evidence that entry has been made. If that is impossible, then a security officer must be notified so that the label may be officially removed, and the container labeled as unsuitable for storage of classified material;**
- **Old specification containers, produced prior to 10/1/1990 may be opened by drilling under the dial, although such practice is not recommended for newer containers (those built after 1990);**
- **A record of service must be maintained whenever work is performed on a container.**

37_9.3 Classification of Containers

The primary function of a GSA container is to protect against specific types of attack, mainly covert and surreptitious entry;

most commercial products do not have such requirements. The specifications can be changed to reflect increased threats because of improved penetration techniques.

Depending upon the required security, containers are classified according to the necessary level of protection. There are currently eight classes (I-VIII). Class I-IV, and Class VII containers are no longer manufactured, although they are still in use. Class V and Class VI equipment is approved for storage of classified information including top secret.

Federal Specification AA-F-358G (March 7, 1989) is applicable for non-insulated filing cabinets and security containers. It defines the construction, materials, paint, color, face hardware, internal locking components, testing, inspection, and the locks that are utilized to secure the containers.

Class I: Insulated (one-hour fire)	10 minutes forced-entry 30 minutes surreptitious
Class II: Insulated (one-hour fire)	5 minutes forced-entry 20 minutes surreptitious
Class III: Not insulated	No forced-entry requirement 20 minutes surreptitious
Class IV: Not insulated	5 minutes forced-entry 20 minutes surreptitious
Class V: Not insulated	10 minutes forced-entry 30 minutes covert entry 20 hours surreptitious
Class VI: Not insulated	No forced-entry requirement 30 minutes covert 20 hours surreptitious
Old Class VII: Not insulated	No forced-entry requirement 60 minutes surreptitious
New Class VII: 30 minutes covert	20 hours surreptitious
Class VIII: Insulated (one-hour fire)	15 minutes forced-entry 120 minutes surreptitious

37_9.3.1 Covert and Surreptitious Entry

In March 1989, AA-F-358G was rewritten to encompass and define covert entry as "a means of entry that will leave evidence not obvious to the user, but which could be detected by a qualified person." Surreptitious entry is now defined as "entry that is made in such a manner that there is no evidence apparent even to the expert that the entry was made." The rewritten specification also includes the new lock specification, FF-L-2740.

All containers are required to provide 20 man-hours protection against lock manipulation and radiological attack. Containers that were built in classes that are now defined as obsolete may continue to be utilized, if presently in service.

37_9.4 Federal Specification for Combination locks

The ANSI/UL 768 specification is utilized for combination locks. The federal requirement (FF-L-2740, October 12, 1989) covers all devices that are designed to be mounted on safes, security files, vault doors and similar items. It defines the type, styles, models, classes and sizes, as well as manipulation, radiographic and thermal resistance.

The government continually tests all qualified locks to determine whether entry protection can be improved. If it is determined that a lock fails to provide adequate protection, it will be removed from the QPL.

37_9.4.1 General Provisions Regarding Locks

- **The UL label shall not, in itself, constitute GSA approval of the lock;**
- **All containers must be equipped with a combination lock capable of resisting manipulation and radiological attack for 20 man-hours (UL Group 1R);**
- **Dial and dial ring design shall prevent casual observation of the combination during dialing;**
- **Only the knob of the dial shall be available to grasp for dialing; all other moveable surfaces shall be shielded from touch;**
- **Each lock shall be supplied with a dust cover to protect the dial and dial ring.**

37_9.4.2 Special Provisions Affecting Security of Locks

- **Bolt Lookout: The lock shall have a mechanical relock device that will block the bolt in the locked position if the lock cover plate is moved more than .10″ (2.54 mm) at any point from its normal operating position;**

- **Case and Bolt Strength: A force of 600 pounds is applied to the bolt. Any fracture or bending of the bolt or case shall be a failure;**

- **Combinations: The lock combination shall be input by dialing. The combination for opening the lock shall not exceed four numbers. Each number shall be within the range of 0 and 99, inclusive. The lock shall have as a minimum 1,000,000 operational combinations. These shall be number sequences which may be set on the lock after excluding those settings which are prohibited by the manufacturer due to the lock design. Operational combinations include those settings which are not recommended but which may be used, such as 20-40-60;**

- **Combination Redial: Once the lock bolt has been extended to the locked position, it shall not be possible to reopen the lock without completely redialing the lock combination. For purposes of this requirement, the locked position means the bolt has been fully extended;**

- **Covert Entry: The lock shall resist covert entry for a period of 30 man-minutes. For the purpose of the covert entry test, access to the lock shall be limited to the dial and spindle. The lock will be presumed to be adequately protected against viewing or physical manipulation of the lock or lock case and against punching. The lock shall resist covert opening for the period specified in (3.6.2);**

- **Dissimilar Metals: Dissimilar metals, as defined in MIL-STD-889, shall be plated or compatible to prevent operationally destructive corrosion;**

- **Emanation Analysis: The mechanism shall not emit any sounds or other signals which may be used to surreptitiously open the lock within a period of 20 man-hours;**

- **Entry: For the purpose of this specification, entry means retracting the bolt;**

- **Lock Bolt: The lock bolt's cross section shall be not less than .312″ x 1.00″ (7.93 x 25.4 mm) with a minimum projection from the case of .437″ (11.1 mm) in the locked position and flush to .062″ (1.575 mm) in the unlocked position, and shall have not less than .312″ (7.92 mm) throw;**

- **Manipulation: The lock shall resist opening through manipulation for a period of 20 man-hours;**

- **Material Deterioration and Control: The lock shall be fabricated from compatible materials, inherently corrosion and deterioration resistant or treated to provide protection against corrosion;**

- **Normal Use: For the purpose of this specification, normal use means dialing the combination, retracting the bolt, and extending the bolt;**

- **Operation Test: The lock shall be subjected to 10,000 cycles of operation without replacement of any component. One cycle shall consist of dialing the combination at a speed not exceeding 48 revolutions per minute, retracting the bolt, throwing the bolt and scrambling the combination. • Following the cycling, the lock shall be subjected to fifty combination changes, including three open and close operational verifications after each change. The lock shall then be checked to verify that the dialing tolerance is still within the**

acceptable range specified by UL 768. The lock shall operate smoothly and the dial torque shall be in the range specified in section (3.4.10). Any failure of the lock during the test shall be cause for rejection;

- **Radiological Analysis: The lock shall resist opening through radiological analysis for a period of 20 man-hours;**

- **Surreptitious Entry: Locks shall be tested for resistance to surreptitious entry. Attempts shall be made to unlock through manipulation, radiological analysis and emanations analysis and automatic dialing devices. Manipulation and analysis may include the use of computer enhancement techniques for signals or emanations. The lock shall resist opening for the times specified in section (3.6.1);**

- **Temperature: The lock shall operate in a temperature range of -10°F to 158° F (-23.3° C to 70° C). At temperatures exceeding 158° F (70° C), a thermal relock shall cause the lock to be dead bolted to prevent entry;**

- **Wear Test: The lock in the locked condition shall have the dial turned at 600 RPM for a period of not less than eight hours- four hours in a clockwise and four hours in a counterclockwise direction. At the end of eight hours, it shall not be possible to open the lock through surreptitious or covert techniques.**

37_9.4.3 FF-L-2740 Combination Locks

The full text of Federal Specification FF-L-2740 is cited below.

FF-L-2740 Federal Specification for Combination Locks

37_10.0 European Standards

There are equivalent entities in Europe that perform similar functions to Underwriters Laboratories. For example, the German Association of Good Insurers (Verband der sachversicherer e.V. (VdS)) has provided certification and testing services for many years in that country. In Japan, the Japanese Industrial Standards are relied upon by all manufacturers for containers utilized in that country.

In 1997, after more than five years of negotiations between participants, a new European standard for safe and vault door burglary resistance testing and classification was issued. Unlike its American counterpart, the CEN standards have no limitations on the types of tools, amount of fuel that can be used for torches, the size of holes, or other factors that are specified in equivalent UL attack protocols. The following European standards have been drafted. At the time of publication, **CEN 1143-1** has been ratified.

- **CEN 1300 Secure storage units: Classification for high-security locks according to their resistance to unauthorized opening.**

- **CEN 1143 Secure storage units: Requirements, classification and methods to test for resistance to burglary. Part 1: Safes, strong room doors and strong rooms.**

- **CEN 1047-2 Secure storage units: Classification and methods of test for resistance to fire. Part 2: Data rooms and data containers.**

37_10.1 Calculation of Resistance Value of Container

Unlike UL standards, CEN has adopted a Resistance Value system to assess and calculate the vulnerability of a particular security device to attack. A resistance value of a container is calculated with the equation: **VR = (sum t)(c) + sum BV**, where

VR = Resistance Value in Resistance Units (**RU**);
Sum t = total of all operating attack times in minutes;
c = highest tool coefficient of tools used for attack, in RU per minute;
Sum BV = sum of the basic values for all attack tools used

in RU.

The certification and basic values that correspond to each tool are tabulated in the standard. Once the VR is calculated, a reference table is consulted to ascertain the corresponding resistance classification. The value can range from 0-X (expressed in Roman numerals). When a container is evaluated, the team leader at the testing facility is allowed to assess the best method of attack and select optimum tools to accomplish entry with the least amount of effort and time. The resistance grade is based upon the level of success that is achieved by the entry team. The European system is far more complicated than is utilized in the United States, but may provide a more realistic approach to assessing the security of a lock, safe, or vault. The following standard has now been adopted by the CEN for locks, safes, and vaults:

37_10.2 CEN 1300 Secure Storage Units:

Classification for high-security locks according to their resistance to unauthorized opening.

This standard defines the requirements and specifications for classifying high-security locks that are used on products for the secure storage of cash, valuables and data media. The protocol addresses tests that can be carried out upon the lock, or through actions that can be influenced by or through externally accessible elements or hardware that is necessary for the operation of the lock.

Tests on optional features such as time-lock functions, facilities for integration with an alarm system, and remote control capability are not included in the Standard, notwithstanding that such functionality can influence the primary security of a lock. The performance of a device is measured by several evaluation criteria, and classification is made after testing and a comparison of the results with the specified grade requirements.

37_10.2.1 Duration of Certification of Devices

Once certified, a device is listed for five years. After that period, the lock should be reexamined based upon the last certification test. Changes in methods of entry will dictate whether the testing protocol or requirements may be modified.

37_10.2.2 Definitions

Certain definitions have been adopted in the course of drafting this standard. Those relevant to our discussion are included here.

Atmospheric, Electrical, Electromagnetic, and Physical Environmental Resistance: A lock must be able to withstand a specified range of conditions and continue to meet the security operation and reliability criteria.

Biometric: The code is operated by means of human characteristics (fingerprint, voice, etc.).

Blocking Feature: That physical part of the lock that prevents movement of the boltwork.

Code: Identification information which can be input into a lock and which, if correct, enables its security status to be changed.

Code Spying and Copying: An attack which involves identification of the correct code without having direct access to the lock.

Coding Means: Means by which the code is internally retained.

Destructive Burglary: Physical attack that damages the lock in a manner that is irreversible and cannot be hidden.

Electronic Lock: A lock that is secured partly or fully with electrical or electronic elements.

Fail-Secure: The failure of the lock system or any of its principal components must leave the lock in a secure state.

High-security Lock (HSL): An independent assembly, normally fitted to doors of secure storage units, into which a coded input can be entered for comparison with a memorized code. A correct match allows a blocking function to be released or changed.

Locking Device: That part of the lock which enables or prevents the moving of the blocking feature.

Manipulation: Any method of attack made directly against an in situ lock and aimed at removing the blocking function without causing obvious damage. This includes the case wherein a lock continues to function normally after manipulation, although its

security could be permanently degraded.

Material: The code is defined by the physical features or properties (mechanical, magnetic, electrical) of a token.

Mechanical Lock: Lock secured by mechanical elements only.

Monitoring: Spying or unauthorized recognizing of the code input by any method, including the use of instruments, and observation by human means.

Reliability: The ability to function correctly and achieve specified security criteria after a large number of duty cycles.

Token: An object whose physical form or properties define the input code, such as a key.

Useable Codes: The smallest number of code or key trials by which an expert having full knowledge of any imposed code constraints, plus details of the manufacturer's tolerances and clearances, can be certain of opening the lock.

37_10.2.3 Security Criteria

Based upon the above definitions, the standard defines criteria to assess the security of a lock in terms of manipulation resistance, destructive burglary resistance, spying resistance, as well as monitoring, atmospheric, electrical, electromagnetic, and physical environmental resistance.

37_10.2.3.1 Manipulation Levels

Four levels of security are specified that are based upon manipulation resistance: 1, 2, 3, 4, with 4 being the most secure. The resistance value that correlates to security is based upon the capability to manipulate the lock to an open condition and is measured according to the tests specified in the standard in section (9.2). The value is expressed as **resistance units** (RU) for the tools used and the time in minutes taken to open the lock.

The number of manipulation trials that can be conducted within a specified time frame are also defined based upon the security level, coding means, and technology. The maximum number of trials per hour varies from 10-300. In certain cases, there is no limit.

Manipulation Resistance Level	Accepted for Lock Class	Minimum Units Required
1	A	35
2	A,B	75
3	A,B,C	200
4	A,B,C,D	620

37_10.2.3.1.1 Security against Manipulation

All locks must provide security against manipulation. The techniques to be thwarted and commensurate level of vulnerability will obviously vary with each security level. Resistance is dependent upon many factors, including the inherent design of the locking mechanism and upon the trustworthiness of the operating staff. All security measures incorporated within the lock are to be assessed and integrated into the test protocol.

37_10.2.3.1.2 Manipulation Tests

Manipulation tests are conducted by experts during a predetermined period of time, and after investigation of the lock, and a certain number of the specified open-close cycles. Initially, three experts will conduct separate investigations and preliminary tests of each lock to be approved. The actual timed manipulation tests are carried out by one expert that is selected by the test laboratory. The experts may utilize instruments or tools that are defined in the tool table (noted elsewhere in this section). The code or key is not made available to the expert prior to the test.

37_10.2.4 Destructive Burglary Resistance

There are three primary requirements for each lock relating to destructive resistance criteria:

- **Without the use of the correct code or key, the maximum force which should be exerted against any external feature or through the keyhole must not be capable of opening the lock;**
- **For destructive tests in combination with manipulation, the same resistance value (RV) shall be required as for the manipulation levels noted elsewhere in this chapter. The resistance value is**

based upon the times during which destructive tools are used and shall be calculated at 5 RU/minute.

- **The tools that may be used for destructive attacks shall conform to category A of the Standard "Secure Storage Units: Methods of test and classification for resistance to burglary" specified in EN1143-1.**

37_10.2.5 Spying Resistance

This portion of the specification contemplates **observation** and **monitoring.**

37_10.2.5.1 Observation

- **The observation of the use of a code or key will not permit complete or partial reconstruction of the information, even with knowledge of the structure of the input device;**
- **Any input information into an electronic lock shall be unrecognizable thirty seconds after the last input;**
- **The angle from which identification can be optically observed for security classes C, D shall not be more than 30° about the centerline (total 60° included angle) in the horizontal plane.**

37_10.2.5.2 Monitoring

- **Monitoring is any process that allows the derivation of information from which a code or key can be deduced. The capability must be limited to instruments not closer than 5.0 meters to the input device for all locks of Class C, D. Monitoring may occur acoustically or by the use of radiation interception;**

- **For electronic locks higher than Class B, any cable by which the code identification is transmitted shall not be accessible without leaving damage obvious to the operator.**

37_10.2.6 Atmospheric Resistance Tests

This portion of the standard describes corrosion and temperature requirements.

37_10.2.6.1 Corrosion Test

Corrosion tests shall conform to ISO 6988:1985. The lock must be tested for three cycles with no diminishment in security.

37_10.2.6.2 Temperature

For all classes of locks (**A**,**B**,**C**,**D**), storage temperatures of -10^{o} to $+70^{o}$ are required. The lock must operate within a temperature range of 0^{o} to 50^{o}, and <70% relative humidity.

37_10.2.7 Electrical and Electromagnetic Resistance

This portion of the standard relates to operating voltages, discharge of static electricity, EMI, electromagnetic emission, and resistance to fast transients.

37_10.2.7.1 Operating Voltages

For all electronic locks that are powered from mains, proper operation must be assured with a variance of ±15% and the frequency within ±20% of the nominal value.

37_10.2.7.2 Discharge of Static Electricity

Testing is in accordance with **IEC 801-2** and ranges from 10-50 kV, with an energy level of 7.5 - 187 Jewels. In all cases, the lock must:

- **Continue to function correctly;**
- **Security shall not be affected;**
- **Security shall not be reduced even if the lock is so damaged that it ceases to operate.**

37_10.2.7.3 Electromagnetic Interference

Tests shall be in accordance with **IEC 801-3.** Tests measure frequencies from 27 Khz-1 GHz for all security classifications. The EMI requirements vary from 3-50 V/m. In all cases, the lock

must continue to function correctly and the security and functionality shall not be affected. Security must not be reduced, even if the lock is so damaged that it ceases to operate.

37_10.2.7.4 Electromagnetic Emission

All electronic locks shall conform to **EN 50081** and **EN 50022.**

37_10.2.7.5 Fast Transient

Locks are evaluated that are connected to mains power in accordance with **IEC 801-4.** Peak voltages range from 1-4 kV, with 5ns rise times. In all cases, the lock must continue to function correctly, and the security and functionality shall not be affected. Security must not be reduced, even if the lock is so damaged that it ceases to operate.

37_10.2.8 Physical Environmental Resistance

This portion of the standard addresses vibration and shock values and relates to acceleration, frequency range, and octave levels per minute. Shock resistance relates to drop testing from a height of one meter, acceleration of 50 g, and five shocks in each axis.

37_10.2.9 Reliability Testing

Reliability testing requires that the lock shall function properly and consistently and maintain security based upon the use of the right code during 10,000 cycles of locking and unlocking. Electronic locks are evaluated in combination with temperature tests. Code-changeable locks must be reprogrammed at least 100 times, carried out periodically during cycle testing. Locks cannot deviate ±1% of the total setting range.

37_10.2.10 Design Requirements

General design requirements are defined for all locks and apply to the actuation of bolts, protection of security-relevant components, and the inability to derive code information from supplementary devices fitted to the lock. Specific requirements that relate to mechanical locks include:

- **The code shall not have more than 40% of the coding**

elements (levers or tumblers) with the same depth (or height). Not more than two adjacent elements shall have the same code designation. There shall be at least 60% of the lift height difference between the highest and lowest code element;

- **There shall be no number or code on either the key or lock that identifies a permutation for the specific mechanism;**

In high-security (level **D**) locks, the following additional requirements shall be met:

- **Means must be provided by which the locking status is made obvious to the user, such as preventing removal of the key except in the locked state;**
- **Locks shall have a feature to insure that the code is scrambled after locking;**
- **The mechanism shall contain a device that signals successful scrambling to the operator.**

Electronic locks must meet a number of additional requirements. Those relevant to security are noted here:

- **For locks of level B, C, D with parallel codes, a record of the codes used for the last ten openings shall be stored; the record shall be secure for at least one year in the case of a power failure;**
- **The internal electronic circuitry or processor system shall not be capable of being communicated with to read the program during closed-door condition even on the cabling between input device and lock electronics, except for code identification and changing;**
- **For locks of level B, C and D, the input device shall not be capable of being forcibly removed without leaving such marks or damage as is obvious to the operator.**

37_10.2.10.1 Security Requirements

There are a number of specific design requirements that are based upon the type of mechanism being certified. These relate to useable codes and type of coding means, fail-secure, parallel

locks, and code changes.

37_10.2.10.1.1 Useable Codes

There should be a minimum number of useable different codes, and a sufficiently large number of permutations must be provided. This is to insure that the opening code is not discovered by expertly planned trials and a very small probability of the code being found by accident. The number of useable codes is dependent upon the security classification. Thus:

Class	Minimum number of Useable Codes
A	25,000
B	100,000
C	1,000,000
D	3,000,000

37_10.2.10.1.2 Fail-Secure

There are three requirements:

- **The entry code shall be retained as the only valid opening code until deliberately reset;**
- **A power failure in closed lock configuration shall not, for an unlimited time, affect the security or locking condition;**
- **A system that operates from commercial power only shall be relockable during a failure of the mains supply.**

37_10.2.10.1.3 Parallel Locks

If parallel locking systems are utilized for increased reliability from lockout, then all of the above requirements must be met for each security class.

37_10.2.10.1.4 Code Changes

There are two primary requirements:

- **A code cannot be altered without first entering the correct code to access the lock;**
- **In Class C and D locks that require internal access**

for code alteration (with the door open), the system must be designed to insure that the code can be changed only by the person who has knowledge of the current code.

37_10.2.11 Tool Categories

Three separate tool categories have been defined with respect to the assessment and computation of resistance units: **common hand tools**, **lock opening tools**, and **special tools**.

37_10.2.11.1 Common Hand Tools

Common hand tools can be purchased by any person from retail hardware stores. The tools are sufficiently small to be inconspicuously carried. No special skills are required for their effective use, and they do not need commercial power. Their use will not generate enough noise to attract attention. Examples of common hand tools include:

- **Screwdriver;**
- **Pliers;**
- **Tongs;**
- **Tweezers;**
- **Files;**
- **Punches;**
- **Hammers;**
- **Pocket torches;**
- **Measuring items;**
- **Magnifying glasses.**

37_10.2.11.2 Lock-Opening Tools

Lock opening tools are those that can be purchased only from specialty tool supply companies and available only to bona fide locksmiths. In order to utilize the tools effectively, special training and skills are required, together with a detailed knowledge of the internal mechanism of specific locks. Several specialized lock-picking, decoding and impressioning tools are identified in the Standard. These include:

- **Picking tools;**

- **Lock spares;**
- **Blank keys;**
- **Tryout keys;**
- **Sound amplifier and filter;**
- **Optical or fiber optic probes;**
- **Robot dialers;**
- **Electromagnetic radiation receivers.**

37_10.2.11.3 Special Tools

The category of special tools describes any lock-opening device that in its complete or entire form cannot be purchased and is specially designed, manufactured or modified for the intended use. Their design and manufacture requires considerable skill and a detailed knowledge of locks and lock-opening techniques. It is possible that these tools will be highly specific and effective against one type of lock only.

Detailed information regarding tools and their resistance units for optional tests such as chemical, x-ray, explosion and others are agreed to between the vendor and testing facility.

37_10.3 EN 1143-1:1997 Secure storage units - Requirements, classification and methods of test for resistance to burglary - Part 1: Safes, strong room doors and strong rooms.

37_10.3.1 Introduction

This European standard sets forth the criteria for testing, classifying, and determining the burglary resistance of free-standing safes, built-in safes (floor and wall), strong room doors and strong rooms (with or without a door). It is intended that the test protocols may also be utilized to aid in the design of security systems to provide certain levels of penetration resistance. It must be recognized that attack times may take longer under actual field conditions as compared to tests conducted in a laboratory environment. This is due to the competence of the criminal, conditions at the crime scene, and the availability of tools and mains power.

37_10.3.2 Definitions

A number of specific definitions have been adopted for this particular standard. The following nomenclature applies:

Accessories: Installations and devices that are contained within the structure or which pass through the structure of the strong room or strong room door(s) to provide for ventilation or for deposit of cash and valuables. Such accessories may be open or closed.

Boltwork: The complete mechanism that is utilized to activate and deactivate one or more bolts that effect locking of a container.

Built-in Safe: A safe whose protection against burglary is partly dependent upon materials incorporated into or attached to it during installation. A floor and wall safe are special types of built-in safes.

Freestanding Safe: A self-contained enclosure whose protection against burglary depends only upon the materials and construction of its primary manufacture and not upon materials added or attached during installation, such as floors, walls, or other barriers.

Lock: A device that is able to recognize a coded input and which performs a blocking function on the boltwork or the door.

Operating Time: This definition refers to the time during which a tool is used in an attempt to create a change in the test specimen.

Relocking Device: A system that is comprised of blocking and detecting elements which will prevent the boltwork from being withdrawn upon one or move events associated with a forced-entry attempt. A relocker can be **active** and comprise part of the locking mechanism, or **passive** and independent.

Resistance Grade: The classification designation to denote the burglary resistance of a container.

Resistance Unit (RU): This is a measure of burglary resistance that results from one minute's use of a tool carrying the coefficient of 1 and the basic value 0. It is the basis for producing a numerical evaluation of burglary resistance within

this standard. Factored into the value is the difficulty in transporting the container, use of forcible-entry tools at the site, and the requisite knowledge and experience for the efficient use of such tools.

Safe: A storage unit that is designed to protect its contents against burglary when closed and locked. It has at least one internal side of one meter in length.

Strong room: A storage unit that protects against burglary when closed and locked. Internal measurements will exceed one meter per side in all directions. Strong rooms may be case in-situ, constructed from prefabricated elements, or a combination of such practices.

Strong room Door: This component consists of a door, lock(s), boltwork, and frame. The door provides primary access to a strong room.

Tool Coefficient: A specified number, expressed in resistance units per minute, that is allocated to a group of tools to represent factors such as noise, smoke, fumes, sparks, flames, and other by-products that increase the likelihood of detection.

37_10.3.3 Classification Scheme

Safes, strong rooms, and doors are classified for a resistance grade, based upon specific criteria. An **EX** optional post-detonation designation may also be provided for containers that incorporate protection against explosion.

For EX designation, safes, strong room doors and strong rooms (with or without door) shall meet the post-detonation resistance value according to specified values, and shall have any cable openings so constructed that explosives (e.g. fuses or charges) cannot be introduced through such holes.

37_10.3.4 General Requirements

The standard specifies certain general requirements that must be met by all enclosures:

- **There can be no holes through the protection material other than for locks, cables or anchoring;**
- **Cable openings cannot exceed 100 mm^2. If they exist,**

they must be obstructed or plugged by the manufacturer through means that cannot be removed externally without leaving traces;

- **A free-standing safe with a mass less than 1,000 kg shall have at least one hole by which it can be anchored, and the anchoring assembly for each hole must be capable of sustaining the force specified elsewhere in the standard;**
- **Post-detonation resistance values are within a range of 6-68 for safes and 4-250 for strong rooms, depending upon the design of the enclosure.**

37_10.3.4.1 Requirements for Classification of Safes into Resistance Grades

Minimum requirements are specified for the classification of safes and strong rooms into resistance grades based upon several criteria:

- **Locks that are fitted;**
- **Level of access that is attained;**
- **Weight and mass of the enclosure;**
- **Tool attack testing criteria set forth in the standard;**
- **Use of explosives.**

37_10.3.4.2 Documentation Provided by Manufacturer

Extensive documentation regarding the enclosure must be provided to the testing laboratory relating to all technical issues, including:

- **Description of enclosure;**
- **Drawings and specifications with data regarding size, weight, dimensions, tolerances, and horizontal and vertical cross-sections;**
- **Manufacture;**
- **Installation and mounting data;**
- **Encasement material;**
- **Mechanical designs;**
- **Quantity, placement, and features of locks,**

boltwork, and relockers;

- **Specific data regarding bolts to include the quantity, pitch and position of door bolts, their dimensions (e.g., cross-section), throw and engagements, and their type (e.g., moving or fixed);**
- **Location and design parameters of local barrier materials;**
- **Elements relevant to physical security, including method of joinder, anchoring, and fastening of components, joints and connections, mounting of frames;**
- **Marking, position, and dimensions of any holes that pass through the barrier material, together with a detailed representation of specially protected areas;**
- **Optional security measures, such as time-delay locking systems;**
- **Listing of all compatible locks that may be fitted to the enclosure;**
- **Information regarding any materials or devices that are intended to generate gas, smoke, soot, or markers in the event of physical attack primarily by torch or high temperature or which could generate harmful substances during testing;**
- **Statements of the nature and position of any cables and/or facilities for penetration detection systems, for the mounting of electromechanical securing devices, and alarm devices;**
- **Full instructions for installation, including data regarding:**
  - **The method of anchoring free-standing safes with a mass less than 1,000 kg**
  - **Full details and specifications regarding the method of encasing built-in safes and the materials that must be utilized for doing so;**
  - **The method and techniques for the construction of monolithic cast in situ strong room, including full details regarding building materials, reinforcement, joinder, and the methods for assembling prefabricated strong room elements.**

37_10.3.5 Tool Attack Test

37_10.3.5.1 Introduction

The test serves to establish values for the complete access of a container and the partial-access minimum resistance values of a safe.

A testing team examines a test specimen together with the technical documentation, and devises a program of attack. The testing team attacks the test specimen. The time taken to gain partial or complete access, assessed by inserting a test block, is recorded and used to calculate a resistance value.

The tools and program of attack used during testing shall be those most likely, in the opinion of the testing team, to result in the lowest resistance values. Exploratory tests may be made.

37_10.3.5.2 Testing Team

The test team is comprised of a leader, timekeeper, and operatives to carry out the necessary attacks on the specimen. Tests are conducted according to the current state-of-the-art, and in compliance with **EN 45001**, to insure consistency of result.

37_10.3.5.3 Definition of Attack Tools

Any tool used for the testing shall be given a coefficient and basic value according to tables that are defined within the standard. Categories for the different types of attack tools are delineated.

37_10.3.5.4 Test Protocols

Test protocols are specified for:

- **Free-standing safes;**
- **Doors;**
- **Strong rooms.**

These define the required extent of entry that constitutes sufficient access to make a determination that the container or enclosure has been compromised.

37_10.3.5.4.1 Free-Standing Safe

The tests shall comprise at least one tool attack test for:

- **Partial access against the area of the body, wall, or the door of the test specimen;**
- **Complete access against the body or the door;**
- **Additional tool attack tests are required against wall, top, base or door if the test specimen has areas or zones of a different construction and for which the resistance value can be reasonably expected to be lower (e.g. in the area of preexisting holes).**

37_10.3.5.4.2 Built-in Safes

The test shall comprise at least one tool attack test for:

- **Partial access against the door or lid (including the frame and encasement, if appropriate);**
- **Complete access against the door and/or against the body to remove the built-in safe from its encasement;**
- **Additional tool attack tests are required if the test specimen has areas or zones of a different construction and for which the resistance value can be reasonably expected to be lower (e.g. in the area of preexisting holes).**

37_10.3.5.4.3 Strong room

The test shall comprise at least one tool attack test for complete access against the strong room wall and one tool attack test against the strong room door for complete access.

37_10.3.5.4.4 Strong room without Door

The test shall comprise at least one tool attack test for complete access. Additional tool attack tests for the complete access are required against walls, ceiling or base if the construction of the strong room has areas or zones of different construction and for which the resistance value can reasonably be expected to be lower (e.g., in the area of preexisting holes).

37_10.3.5.4.5 Strong room Door

The test shall comprise at least one tool attack test for complete access on the door (including frame and adjoining wall sections if necessary). Additional tool attack tests for complete access are required if the test specimen has areas or zones of different construction and for which the resistance value can reasonably be expected to be lower (e.g. in the area of preexisting holes).

37_10.3.5.4.6 Holes

Any holes (other than those through the base of a safe and which are provided for anchoring) which are present in the test specimen may be exploited in the testing.

37_10.3.6 Tool Categories that are acceptable for Testing

Specific Categories of Containers or enclosures:

- **Safes shall only be tested with tools of categories A, B. C and D;**
- **Strong rooms and strong room doors can be tested with tools of categories A, B. C, D and S.**

37_10.3.6.1 Special limitations for Tools

During any tool attack test, the following tools shall not be used simultaneously:

- **Two electric-powered tools (A.7, A.8, A.9 and A.10);**
- **Two thermal tools (A.11);**
- **Two hand-hammering tools (A.5);**
- **An electric-powered tool and a thermal tool;**
- **Hand-hammering tool and an electric-powered d tool;**
- **Hand-hammering tool and a thermal tool;**
- **Two specially made electric-powered tools (A.6);**
- **For hand-hammering tools used with both hands, the number of blows is limited to 250 per tool attack test;**
- **In any single tool attack test, only two operatives**

and the testing team leader are allowed to work on the test specimen. Only two persons are allowed to work on the test specimen at one time;

- **Dust cleaners and compressed air may be used for cleaning the test specimen;**
- **Testing shall only be done in areas or against features that have not been weakened by earlier tests.**

37_10.3.6.2 Procedure for Testing

A detailed protocol is established within the Standard to document the procedures employed during all phases of the test. All tools must be prepared for immediate use, once the test begins. Specific timing requirements and values are defined, and assignment of values are given to different aspects of the test, based upon the category and usage of tools. For example, tools of category "A" are allocated 1/60 minute per blow when the tool impacts directly against the test specimen. In this manner, precise timing of an attack can be ascertained.

37_10.3.6.3 Calculation of Resistance Values

For each tool attack test, the resistance values $\mathbf{V_R}$ is derived from the following formula and represents the resistance value in resistance units (**RU**) for that tool attack test:

$$\mathbf{V_R = (\Sigma \tau \times C) + \Sigma BV}$$

where:

Σt is the sum of all operating times in minutes

C is the highest tool coefficient of the used attack tools

ΣBV is the sum of the basic values for all attack tools used

37_10.3.6.4 Explosive Testing

The test is for determining the resistance against attacks with explosives. In practice, an explosive charge is detonated. A tool attack test is then made to measure the remaining resistance value. Upon completion of the tests, a calculation is made, based upon analysis of many factors contained within a comprehensive

formula, to determine the resistance value of the container or enclosure.

37_10.3.6.4.1 Explosives

The charge shall be of pentaerythritt trinitrate (PETN) with the following properties:

- **Density (1 500 ±50) kg/m3;**
- **Specific energy (5000 ±500) J/g;**
- **Detonation velocity (7000 ± 500) m/s.**

37_10.3.6.4.2 Determination of Explosive Charge Mass

The mass of the explosives charge is based upon the resistance grade and container and is defined within the standard.

37_10.3.6.4.3 Methods and Conditions for Explosive Attack

Specific protocols are set forth within this Standard for the methods to be employed in the utilization of explosives. This depends upon the type and design of the container or enclosure to be attacked.

37_10.3.6.4.3.1 Safes

The explosive charge is positioned in a compact shape at the geometric center of the storage volume of the safe. The door is closed and locked; the charge is then detonated. After detonation, the tool attack shall be continued until the complete access or the required post-detonation resistance value has been reached.

37_10.3.6.4.3.2 Strong room Doors and Strong rooms

Preparatory tool attacks may be undertaken and shall follow the tool attack test to create holes into which the explosive charge can be located. The charge is placed, stemmed, and detonated. After detonation, the tool attacks shall be continued until the complete access or the required post-detonation resistance value has been achieved.

37_10.3.6.5 Marking of Product

Any product that has been assigned a resistance grade within a classification must be marked. The marking shall be indelible and shall appear on a securely fixed metal plate on the inside face of the door, in the locking chamber, or on the face of the prefabricated elements for strong rooms. The marking shall comprise:

- **Manufacturer name or identification code;**
- **Standard designation and resistance grade;**
- **EX designation (if applicable);**
- **Year of manufacture;**
- **Type, model number and description or size of the product (optional);**
- **Serial number.**

37_10.3.6.6 Identification and Description of Attack Tools

The standard provides coefficient basic values for each tool and category that is allowed to be utilized in attack tests. In addition, the intended primary use of a tool is described. Each classification of tool is given a coefficient and resistance unit rating. If tools are utilized for different purposes, then the highest RU is assigned. The assignment of a basic value RU is dependent upon many factors, including the weight of the tool and its length.

37_10.3.6.6.1 Categories of Tools

Fourteen categories of tools, accessories, and supplementary implements are defined within the standard for use in forcible entry. The identification number has been included for reference. In Sections **A.1-A.6** tools are specified as **Manual use without External Power**. In Sections **A.7-A.10: External power supplies are required** (A.7, A.8, A.10 can be used with cutting and/or cooling fluids.

The classification of tools described within CEN 1143 should be considered as supplementary to the discussion in **Chapter 32**, wherein the different methods of application of energy for

forced-entry are examined.

(A.1) Manual Tools

These are handheld tools that are used for non-destructive assembling and disassembling of detachable elements, e.g., to detach screws, pins or bolts, spring clips. Tools included:

- **Screwdrivers;**
- **Fork/ring wrenches.**

(A.2) Hand Gripping Tools

These implements are employed for the gripping (lever transmission) of tools and materials, e.g., fixing/holding of chisel. Tools included:

- **Universal pliers;**
- **Wrenches;**
- **Chisel holder;**
- **Forge tongs.**

(A.3) Hand Levering Tools

These transmit physical force by a lever, e.g. pry-up a door, deform or fracture weak components. Tools included:

- **Screwdriver;**
- **Tire levers;**
- **Hand levers;**
- **Crowba**

rs.

(A.4) Hand Sawing, Milling, Cutting, and Drilling

These tools are used for manual grinding, cutting and detaching of various materials without additional electric means of propulsion, e.g., sawing steel sheets. Tools included:

- **Hand drill;**
- **Saw;**
- **File;**
- **Side cutter;**
- **Bolt cropper;**
- **Plate shears;**
- **Steel cutters.**

(A.5) Hand-Hammering Tools

These tools are used to break various materials and to propel different accessories such as chisels, drift punches and wedges. Tools included:

- **Hammers;**
- **Hand axes;**
- **Pickaxs.**

(A.6) Specially-made Tools

These are tools which are usually not commercially available but

are conceived or provided especially for certain purposes at the test. If appropriate, sources of electricity not exceeding the working voltage (max. 240 V) may be used for attacks dealt to electromechanical security devices.

(A.7) Electric Powered Tools, without Impact

These tools are used to drill or cut (without impacting option) and their working energy is supplied by a source of electricity. Tools included:

- **Drilling machines.**

(A.8) Electric-Powered Rotary Tools with Impact Option

These are electric drilling machines that can be used with or without impacting options. Tools included:

- **Hammer drills;**
- **Jackhammers;**
- **Concrete breakers.**

(A.9) Electric-Powered Impacting Machine Tools without Rotation

Tools that are used for hammering, breaking up or deforming materials are described within this category. Included tools:

- **Building hammers.**

(A.10) Electric Powered Grinding/Slitting Machine Tools

These tools are used for cutting or abrasion. Tools included:

- **Electric disc cutters;**
- **Diamond core drills.**

(A.11) Thermal Cutting/melting Tools

These thermal tools receive the necessary energy either by an exothermic chemical reaction (heating/cutting gas, solid material/cutting gas) or by arc cutting. Tools included:

- **Gas cutting and welding oxygen lance;**
- **Electric cutting and welding.**

(A.12 Accessories for Tools listed in A.1-A.11

These tools include drills, saw blades, abrasive discs, nozzles, and electrodes. They are consumable and/or replaceable and used together with the tools shown in Sections **A.1-A.11**. Accessories include:

- **HSS drill bits;**
- **Carbide-tipped drills;**
- **Saw blades;**
- **Chisels;**
- **Electrodes for lance;**
- **Wedges;**
- **Punches;**
- **Discs;**
- **Diamond core drills;**
- **Diamond discs.**

(A.13) Miscellaneous Tools

This group includes tools, special procedures and devices that must be taken into account. Their use is timed. Materials include:

- **Battery lamps;**
- **Cooling/cutting agents;**
- **Chemical;**
- **Hydraulic**

- **equipment;**
- **Fiber optics;**
- **Electronic devices;**
- **Hooks;**
- **Fishing devices.**

(A.14) Non-tools

These are implements to enhance testing work. Their use is not timed but represented only by a basic value. Materials include:

- **Torches;**
- **Fiber optics;**
- **Electronic devices.**

37_11.0 Japanese Industrial Standards

The JIS (Japanese Industrial Standard) was established in 1921 as the result of legislation enacted by the Japanese government. JIS performs equivalent functions to Underwriters Laboratories; it sets minimum testing standards for all products utilized in the private and government sectors.

37_12.0 Statutes, Precedent, and Legal Issues

There are a number of federal statutes relating to locks and keys with respect to duplication and distribution through channels of interstate commerce. The General Services Administration and Department of Defense have also promulgated federal regulations regarding the classification, acquisition, testing, maintenance, installation, and repair of security containers, locks and keys. These were summarized earlier in this chapter. Some states have also enacted legislation regarding licensure of locksmiths and the possession of burglary tools designed for covert or forced-entry by unauthorized persons.

There has been increasing concern by locksmiths and some litigation involving the reverse engineering, analyses, detection

and disclosure of defects in locks and security containers. Certain manufacturers have attempted to prevent the disclosure of defects and have filed civil lawsuits in an effort to insure that defendants do not make public such findings. Issues involving reverse engineering, free speech, and trade secrets have been argued by both locksmiths and manufacturers. There has also been increased awareness of potential liability issues on the part of locksmiths and security experts, partly as the result of media coverage of the compromise of master key systems. A comprehensive summary of liabiliity issues is provided as a guide to all locksmiths to reduce their potential exposure to litigation.

37_12.1 Federal Statutes

The United States criminal code, Title 18, and the Postal Code, Title 39, contain relevant statutes relating to locks and keys. The actual postal regulations are cited below, from **Publication 52**, issued in July, 1999.

47 Motor Vehicle Master Keys and Locksmithing Devices

471 Definitions

471.1 Motor Vehicle Master Keys

A key is any of the following:

a. Any key other than the key (or an exact duplicate) furnished with the
motor vehicle by the manufacturer.
b. The key (or an exact duplicate) furnished with a replacement lock.
c. Any key or manipulation device designed to operate two or more motor
vehicle ignition, door, or trunk locks of different combinations, including
any pattern, impression, or mold from which a master key or manipulation device can be made (18 U.S.C. 1716 and 39 U.S.C.3002).
July 1999

471.2 Locksmithing Devices

A device is any of the following:
a. A device or tool (other than a key) designed to manipulate the

tumblers
in a lock into the unlocked position through the keyway of such lock.
b. A device or tool (other than a key or a device or tool under 471.2a)
designed for bypassing a lock or similar security device, or for opening
it by a method normally not used by consumers to open such locks or
security devices.
c. A device or tool designed for making an impression of a key or similar
security device in order to duplicate such key or device.

472 Mailability. The following conditions apply:

a. Motor vehicle master keys, as defined in 471.1, are nonmailable unless sent to any of the following categories of addressees:
(1) Lock manufacturers.
(2) Professional locksmiths.
(3) Motor vehicle manufacturers or dealers.
(4) Federal, state, or local government agencies.

b. Locksmithing devices, as defined in 471.2, are nonmailable except when sent to any of the following categories of addressees:
(1) Lock manufacturers or distributors.
(2) Bona fide locksmiths.
(3) Bona fide repossessors.
(4) Motor vehicle manufacturers or dealers.
(5) Bona fide automotive repair shops or businesses.

Note: This statute appears to prohibits the sending, through interstate commerce, of locksmithing devices to any law enforcement agency.

473 Packaging and Marking

No marking of any kind that indicates the nature of the contents may be placed on the outer wrapper or packaging of any mailpiece containing motor vehicle master keys or locksmithing devices. Mailable matter must be properly and securely packaged within the general requirements in DMM C010.

474 Nonmailable Matter Found in the Mails

All nonmailable motor vehicle master keys and locksmithing devices discovered in the mailstream must be reported in accordance with POM 139.117.

§ 18 USC 1386 Keys and keyways used in security application by the Department of Defense.

(a)(1) Whoever steals, purloins, embezzles, or obtains by false pretense any lock or key to any lock, knowing that such lock or key has been adopted by any part of the Department of Defense, including all Department of Defense agencies, military departments, and agencies thereof, for use in protecting conventional arms, ammunition or explosives, special weapons, and classified information or classified equipment shall be punished as provided in subsection (b].

(2) Whoever—

(A) knowingly and unlawfully makes, forges, or counterfeits any key, knowing that such key has been adopted by any part of the Department of Defense, including all Department of Defense agencies, military departments, and agencies thereof, for use in protecting conventional arms, ammunition or explosives, special weapons, and classified information or classified equipment; or

(B) knowing that any lock or key has been adopted by any part of the Department of Defense, including all Department of Defense agencies, military departments, and agencies thereof, for use in protecting conventional arms, ammunition or explosives, special weapons, and classified information or classified equipment, possesses any such lock or key with the intent to unlawfully or improperly use, see, or otherwise dispose of such lock or key or cause the same to be unlawfully or improperly used, sold, or otherwise disposed of,

Shall be punished as provided in subsection (b).

(3) Whoever, being engaged as a contractor or otherwise in the manufacture of any lock or key knowing that such lock or key has been adopted by any part of the Department of Defense, including all Department of Defense agencies, military departments, and agencies thereof, for use in protecting conventional arms, ammunition or explosives, special weapons, and classified information or classified equipment, delivers any such finished or unfinished lock or any such key to any person not duly

authorized by the Secretary of Defense or his designated representative to receive the same, unless the person receiving it is the contractor for furnishing the same or engaged in the manufacture thereof in the manner authorized by the contract or the agent of such manufacturer shall be punished as provided in subsection (b).

(b) Whoever commits an offense under subsection (a) shall he fined under this title or imprisoned not more than 10 years, or both.

(c) As used in this section, the term "key" means any key, key blank, or keyway adopted by any part of the Department of Defense, including all Department of Defense agencies, military departments, and agencies thereof, for use in protecting conventional arms, ammunition or explosives, special weapons, and classified information or classified equipment.

18 USC §1704 Keys or locks stolen or reproduced.

Whoever steals, purloins, embezzles, or obtains by false pretense any key suited to any lock adopted by the Post Office Department or the Postal Service and in use on any of the mails or bags thereof, or any key to any lockbox, lock drawer, or other authorized receptacle for the deposit or delivery of mail matter; or

Whoever knowingly and unlawfully makes, forges, or counterfeits any such key, or possesses any such mail lock or key with the intent unlawfully or improperly to use, sell, or otherwise dispose of the same, or to cause the same to be unlawfully or improperly used, sold, or otherwise disposed of; or

Whoever, being engaged as a contractor or otherwise in the manufacture of any such mail lock or key, delivers any finished or unfinished lock or the interior part thereof, or key, used or designed for use by the department, to any person not duly authorized under the hand of the Postmaster General and the seal of the Post Office Department or the Postal Service, to receive the same, unless the person receiving it is the contractor for furnishing the same or engaged in the manufacture thereof in the manner authorized by the contract, or the agent of such manufacturer—

Shall be fined not more than $500 or imprisoned not more than ten years, or both.

18 USC §1716a Nonmailable locksmithing devices and motor vehicle master keys

(a) Whoever knowingly deposits for mailing or delivery, or knowingly causes to be delivered by mail according to the direction thereon, or at any place to which it is directed to be delivered by the person to whom it is addressed, any matter declared to be nonmailable by section 3002 of title 39, shall be fined under this title or imprisoned not more than one year, or both.

(b) Whoever knowingly deposits for mailing or delivery, causes to be delivered by mail, or causes to be delivered by any interstate mailing or delivery other than by the United States Postal Service, any matter declared to be nonmailable by section 3002a of title 39, shall be fined under this title, imprisoned not more than one year, or both.

Note: This statute applies to any interstate common carrier, such as Federal Express, UPS, or DHL. The federal criminal statute prohibits the mailing of items that are deemed non-mailable by the U.S. Postal Service.

§ 39 USC 3002 Non-mailable motor vehicle master keys, found in **39 CFR 111.1.**

§ **39 USC 3002a Non-mailability of locksmithing devices.**

(a) Any locksmithing device ***is*** non-mailable mail, and shall not be carried or delivered by mail, and shall be disposed of as the Postal Service directs, unless such device is mailed to:

(1) a lock manufacturer or distributor;
(2) a bona fide locksmith;
(3) a bona fide repossessor;
(4) a motor vehicle manufacturer or dealer.
(5) Bona fide automotive repair shops or businesses.

(b) For the purpose of this section, “locksmithing device" means--

(1) a device or tool (other than a key) designed to manipulate the tumblers in a lock into the unlocked position through the keyway of such lock;

(2) a device or tool (other than a key or a device or tool under paragraph (1) designed for the unauthorized opening or bypassing of a lock or similar security device; and

(3) a device or tool designed for making an impression of a key or similar security device to duplicate such key or device.

37_12.2 Case Law and Legal Precedent

37_12.2.1 Discovery and Disclosure of Proprietary Information about a Lock: Trade Secrets and Reverse Engineering

Can a locksmith or government agent disassemble a lock to determine potential design defects that allow bypass? Several manufacturers, including Chicago Lock and ElSafe (Norway), have attempted to prevent such practice and the disclosure of information obtained as the result of analyses and reverse engineering. The landmark case of **Chicago Lock Company v. Panberg(436)**, 676 F.2d. 400, 1982, was argued before the United States Court of Appeals for the Ninth Circuit in 1982 and involved the decoding of Chicago tubular locks and reprinting of key code lists by the Defendant in a trade publication.

In that case, the locksmith defendants compiled a list of key code-serial number correlation to create a book which could be sold to other locksmiths so that those locksmiths could make duplicate keys without having to pick the locks. To create the book, the defendants obtained the serial number-key code correlation from a 'comparatively small' number of locksmiths, who themselves had reverse-engineered the locks of their customers. Chicago alleged that the defendants' actions constituted a misappropriation of the manufacturer's trade secrets.

Chicago Lock brought suit against locksmiths and publishers of a specialized trade journal to enjoin unauthorized dissemination of key codes for one line of locks. The lower court held that the acquisition of the codes were trade secrets that were improperly obtained, and enjoined publication. The Court of Appeals reversed and found for the defendants.

Two critical questions were raised by this case: **Does a locksmith and lock owner owe a duty to the lock manufacturer not to disclose confidential or proprietary information about the lock?**

What does the trade secret doctrine provide with regard to reverse engineering and the method by which information is obtained about a lock?

A locksmith who obtains information by examining or working on a lock or safe is held not to have obtained it through improper means. The court stated "It is well recognized that a trade secret does not offer protection against discovery by fair and honest means such as independent invention, accidental disclosure or by so-called reverse engineering, that is, starting with the known product and working backward to divine the process." (at page 404).

The court further held that "the concept of 'improper means'…connotes the existence of a duty to the trade secret owner not to disclose the trade secret…."

"We find untenable the basis upon which the District Court concluded that the individual locksmith owes a duty of nondisclosure to the Company. The court predicated this implied duty upon a "chain" of duties: first, that the locksmiths are in such a fiduciary relationship with their customers as to give rise to a duty not to disclose their customer's key codes without permission, and second, that the lock owners are in turn under an 'implied obligation [to the company] to maintain inviolate' the serial number-key code correlation for their own locks."

"The Court's former conclusion is sound enough: in their fiduciary relationship with lock owners, individual locksmiths are reposed with a confidence and trust by their customers, of which disclosure of the customers' key codes would certainly be a breach. The duty, however, could give rise only to an action by 'injured' lock owners against the individual locksmiths, not by the Company against the locksmiths or against the Defendant."

"The court's latter conclusion that lock owners owe a duty to the Company, is contrary to law and to the Company's own admissions. A lock purchaser's own reverse engineering of his own lock, and subsequent publication of the serial number-key code correlation, is an example of independent invention and reverse engineering expressly allowed by trade secret doctrine."

The Chicago case is a well-recognized and respected authority. It was cited with approval by the United States Supreme Court in the landmark case of **Bonito Boats, Inc. v. Thunder Craft Boats, Inc.**, 489 U.S. 141, 160 (1989), and in M.F. Jaeger, Trade Secrets Law,

§**5.04[3][b] (1996).**

37_12.2.2 First Amendment Protection of Commercial Speech

Dissemination of information about a lock or safe constitutes commercial speech, which is protected by the First Amendment. The Supreme Court has recognized that "the free flow of commercial information is 'indispensable to the proper allocation of resources in a free enterprise system because it informs the numerous private decisions that drive the system." **Rubin v. Coors Brewing Co(437).**, 131 L. Ed. 2d. 532, 538 (1995), and **Virginia State Board of Pharmacy v. Virginia Citizens Consumer Council, Inc.**, 425 U.S. 744, 761 (1976).

A locksmith may disclose any defect that he discovers, so long as his statements are true. Truth is an absolute defense to libel and business defamation. A locksmith may have liability for failing to disclose a known defect or security risk in a product that he sells, recommends, or installs.

See **www.security.org** regarding information about the ElSafe lawsuit in Hawaii and the pleadings that were filed in that case in an attempt to prohibit a locksmith from making certain disclosures about defective products.

37_12.3 Issues of Liability for Locksmiths and Security Experts

Increased security concerns after 9/11 and the post Iraq war terrorism threat have lead to a heightened awareness of potential liability upon the part of locksmiths and security experts for negligent acts in the recommendation and installation of security hardware within the commercial and government sectors. Increasingly, locksmiths are taking on the role of, or representing themselves as security experts with respect to consulting with, recommending, designing, installing and maintaining security systems and related hardware. The complexity of the industry and the wide array of available components have required that the locksmith obtain special training and education for specific disciplines. The integration of electronics, microprocessors, emerging and mature access control technologies, and advances in mechanical locking systems have made the job of the security professional all the more demanding. A successful

locksmith in this environment cannot continue to do business as a general practitioner and yet hold himself out as a security expert without specialization and the requisite training and equipment.

Media attention with regard to vulnerability of commercial and public buildings, including the compromise of master key systems, has caught the attention of both security professionals and the legal community. Locksmiths, security consultants, and security management must understand their possible exposure to litigation and subsequent damages for their failure to act properly, or negligent actions that result in harm to people or property. Every locksmith and security consultant has a fiduciary duty to their clients with regard to certain issues outlined in this section. A breach of that duty can lead to serious consequences and can result in jury awards for actual and in some cases punitive damages, as well as potential criminal liability for certain acts. Damage to reputation and the ability to continue in business is also of paramount concern.

Some locksmiths impliedly or directly represent that they have the expertise to provide consulting services to their clients with regard to issues of security, master keying, alarm systems, or forensic investigations when in fact they do not. Unless they have the appropriate education (and continuing education), training, experience, and professional certifications from ALOA, ASIS, AFTE or other organizations, then the making of such representations can result in the potential for significant liability and resultant damages.

Whenever you meet with a client or prospective client, you must be certain not to overstate your knowledge or capabilities, either directly, or by implication. Recommendation of certain locks, safes, and security hardware implies that you have the requisite knowledge about the products and the environment and threat levels into which they will be installed or located. This is especially true in the arena of high security locks. You must be able to knowingly discuss potential security issues or vulnerabilities with regard to such hardware and systems. You have a duty to point out any known vulnerabilities that could make such installation unsuitable for the client. Remember, your opinion is being relied upon as that of an expert. Most often, the customer is not expected to have the necessary expertise to make independent evaluations as to suitability of the product for its intended purpose: you are. If you tell a customer that a lock will provide sufficient security for his application and it does

not, then you may be held liable if there was a known defect in its design, or it was installed improperly.

The critical issue is an understanding by the client of the risks associated with a specific component within a security system. They cannot be expected to make an intelligent assessment with regard to the risks if they do not fully understand them. Much of the controversy stemming from the New York Times article on master keying dealt with the issue of whether locksmiths were aware of the ability to decode master key system through the use of a change key. There is no question that locksmiths that routinely deal with master key systems were clearly aware of the potential to compromise the security of virtually any conventional master key system. The legal issue, however, is whether clients of the locksmith were aware of such risks. In many cases, they were not. The potential exposure for locksmiths is the failure to adequately discuss the security risks or any master key system with their customers, so that the customer can make the decision as to whether to implement a master key system, and how extensive that system should be.

The following summary provides an overview of liability issues, but may not be considered as exhaustive, given the inventiveness of plaintiff's attorneys, and the penchant of some juries for outlandish verdicts. These actions (or failure to act) could subject you and/or your business to significant liability.

Employee Guidelines and Procedures:

- Failure to establish operating procedure and guidelines for the protection of information and property of clients;
- Failure to properly vet employees with regard to background and experience, which leads to theft of property or compromise of customer data;
- Cutting of keys stamped DO NOT DUPLICATE or other indication that they should not be copied without specific permission of person in authority;
- Cutting of keys on restricted blanks without the proper authority;
- Cutting keys by code without full information about the customer or locks and customer's authority to have a code-cut key produced;

Failure to Maintain Adequate Security for Business Location of Locksmith:

- No alarm system to protect the premises;
- Insufficient level of data security: protection against fire, theft, employee compromise;
- Failure to protect mobile information in vans and other service vehicles and on laptop computers and PDAs;
- Allow network or Internet access to computer-stored customer records or databases containing such records;
- Failure to protect restricted key blanks;

Records:

- Failure to maintain confidential records in a secure manner;
- Failure to protect the following critical records:
    - TMK Register
    - End user register;
    - Progression and bitting list;
    - Authorization and inventory cards;
    - Parity records and registers;

- Violation of duty to maintain certain records as confidential;
- Use of analog cellular telephone or radio channels to discuss proprietary or confidential information regarding a client, and which is intercepted;
- Transmission by e-mail or facsimile of confidential information in a non-encrypted format, or to the incorrect recipient;
- Failure to maintain sufficient computer security where client records are stored;
- Loss or theft of a laptop containing confidential information and the failure to protect that laptop computer from compromise by a third party;
- Compromise of confidential information on a voice mail system regarding a client;
- Failure to maintain an adequate and timely backup of client data;
- Failure to properly and securely erase discarded hard drives that contain client information. This can be a problem when computers are thrown away, given away, or traded;
- Failure to provide for adequate physical security of records to protect against theft or destruction;
- Failure to establish and follow a records retention and destruction policy that meets the needs of customers and complies

with any statutory requirements;

- Failure to protect customer information within files against disclosure or compromise. This may be especially important for clients that secure medical records. A federal statute that became effective on April 14, 2003, known as the Health Insurance Portability and • Accountability Act (HIPAA) has stringent security requirements that could logically be extended to a locksmith in the event that the requisite security is not implemented;
- Failure to advise clients of a breach in security that could affect the security of his employees, facility, or property.

Compromise of Customer Confidential Information:

- Failure to protect, or disclosure of code lists, TMK registers, bitting lists, etc;
- Cut and distribute restricted keys to unauthorized individuals, or failure to follow established rules and guidelines with regard to the distribution of such keys;
- Failure to take proper measures to protect computer information from hacking;

Improper Installation, Maintenance, Repair, or System Design:

- Improper installation of hardware that is the proximate cause of a loss;
- Failure to properly maintain, program, or set codes, combinations, or time locks that result in a lockout condition;
- Failure to make proper repairs to safes and vaults after forced entry or drilling. Such failure may make the container more vulnerable to subsequent attack, reduce or eliminate insurance coverage, nullify UL classifications or ratings, cause subsequent malfunction or lockout, and also subject you to liability for destruction of the container;
- Defective repairs that reduce tolerances or reduce resistance to covert entry. This may include filing of pin tumblers or plugs, or adding unnecessary master pins;
- Improperly change or modify UL or other rating labels;
- Failure to change factory original combination or password upon installation;
- Failure to adhere to manufacturers recommended installation procedures;
- Use of old or worn pins or springs;

- Failure to utilize pins and springs in all chambers within a lock;
- Set combination in the forbidden zone which results in a mechanical malfunction;
- Violating MACS rules that results in mechanical malfunction;
- Erase audit trail within electronic memory, either intentionally or by mistake and which causes a loss;
- Failure to utilize balanced drivers, thereby allowing the lock to be covertly opened through "combing";
- Designing change keys, master keys, or TMKs that do not follow industry guidelines and that contribute to system bypass or circumvention;

Failure to Consider Inherent Dangers

- Opening a safe that contain explosive residue, tear gas, or drugs where harm is caused;
- Improper handling of heavy container that falls and damages other property or results in injury to persons;

- Failure to report property found in locked containers, such as explosives, drugs, child pornography or other contraband;

Damage to Property

- Property damaged within a container that is opened by force;
- Relockers triggered due to lack of experience; causing additional damage during the opening process;

Violation of Fiduciary Duty

- Disclosure of confidential information to law enforcement or others without authorization or court order;
- Non-disclosure of known security defects or potential for bypass in locks and hardware that is sold to, or utilized by a customer;
- Failure to be current with regard to literature and security advisories regarding products that are sold and represented as secure;
- Failure to maintain control of customer locks;
- Failure to maintain control of customer keys and key blanks;
- Use of customer information or key data for unauthorized

purposes;

- Theft from customer location by employees of locksmith, as a result of access to confidential information regarding the premises;
- Sale of restricted blanks to unauthorized individuals or entities;
- Unauthorized creation or milling of blanks to create restricted blanks that are utilized by customers of the locksmith or other locksmiths. There are two potential issues: violation of copyright or patent protection, and compromise of customer security.
- General breach of fiduciary duty owed to customer;

Documentation of Work Performed

- Failure to properly document installation, upgrade, or maintenance;

Performance of Work to Recognized Industry Standard:

- Failure to properly or adequately assess the security requirements of a customer location;
- Misrepresent the security of hardware or a system that is installed or implemented for a customer. There are two issues: making a representation regarding security that is not actually provided, and charging for something that was not received;
- Failure to utilize restricted blanks, if needed or sold as such;
- Improper pinning of Interchangeable core locks that allow for a change key or TMK to act as control key;
- Create key interchange between interchangeable core systems that creates an unknown or unauthorized control key and which leads to a loss;

Master Key Systems:

- Work performance that calls into question the training and competence of the locksmith;
- Improper system design that creates key interchange that results in a loss;
- Use of non-standard master key systems that result in loss of security;
- Improper system design that results in unintended cross-keying

and subsequent loss;

- Poor documentation that makes it difficult to expand, maintain, or evaluate a system;
- Repeat the TMK or system in the same geographic area for different customers;
- Mistakes made in defining the KBA that results in key interchange, cross-keying, or other errors;
- Use of master pins that are not required and which reduce the security of a lock, resulting in ease of picking or other covert means of entry;
- Release of master keys to the wrong individual, contrary to established guidelines;
- Cutting or duplicating sectional keys on the wrong blank that allows access to keyways for which the user does not have authority;
- Pinning certain cylinders that should not be on the master key system;
- Failure to follow the .023" rule that results in mechanical malfunction and inability to access critical areas;
- Failure to advise property owners in major housing or apartment construction projects that locks have been master keyed for construction personnel, and that such keying will remain after the project is completed;
- Utilizing pre-written master key systems that are published and are available to the general public;
- Utilization of the same master key programs for more than one customer;
- Use of the same bitting lists, keyways, and master key system architecture for multiple clients;
- Failure to warn and document such warning to customer regarding the risks associated with the use of master key systems;
- Failure to adequately warn customers of cross-keying issues and the reduced security that results from intentional cross-keying;
- Master keying all or several customer locations for the convenience of the locksmith without disclosing such fact to each client;
- Failure to conduct comprehensive site survey and keying conference with the client prior to performance of work;

Failure to Exercise Due Diligence and Follow Standard Procedures:

- Effecting entry into locked location for third party after failing to obtain sufficient identification which results in

theft, other loss, or burglary;

- Owner claims disappearance of goods from container or other area that was opened by locksmith, but to which there was no witness to document contents during the opening;

General Liability Issues:

- Represent to customer that locksmith has expertise in certain specialties that he does not have;
- Acting as an expert in forensics or security when you do not have the requisite expertise;
- Failure to maintain liability insurance;
- Failure to comply with licensing laws for specific jurisdiction;

CHAPTER THIRTY-EIGHT: SECURITY

Security: Analysis and Reduction of Risk

LSS202: Ross Anderson on security engineering

PART A: Burglary and Related Attacks

Burglary

The concept of security encompasses more than just locks, safes, and vaults. Rather, the elusive and imprecise term describes many factors that must all complement each other to achieve the desired result. Security can be likened to a formula, comprised of hardware, software, organizational measures and procedures, awareness, vigilance, monitoring, and commitment. No one component should ever be relied upon as an alternative option, sole measure, or solution.

The final three chapters of this book will provide a summary of

the primary components of what is referred to as "security." Many in-depth treatments have been written about the subject that examines in detail each aspect of the concept. There is no necessity to duplicate such works here. Rather, the materials that follow will provide a summary of issues that must be considered in the evaluation of any security program. The emphasis will be on loss prevention, concentrating on the analysis and reduction of risks for robbery and burglary associated with certain types of businesses. **Chapter 39** focuses on physical security measures. It provides a comprehensive catalog of generic security hardware, and the vulnerabilities of such devices to attack. An in-depth treatment of alarm systems is presented in the final chapter.

Throughout the book, we have concentrated on the development, operating theory, design, use, and bypass of locks and safes. It is therefore appropriate to focus on issues related to security hardware that augments, supports, or is reliant upon locks, safes, and vaults to insure physical integrity and protection. Our discussion will survey each physical security component that must be examined by those responsible for decision making. Construction practices, materials, subsystems such as alarms and ventilation, the location and placement of secure areas and containers, and the vulnerability of such components will be detailed.

Insurance companies throughout the world have become increasingly concerned about the problem of burglary and resultant losses, and for good reason. Claims have escalated, based upon trends in property crimes. Insurers have taken a proactive stance, concentrating on the analysis of crime and its prevention as relates to loss. In the end, it should not be the responsibility of the insurance company to cover losses, if they could have been prevented through adequate security measures.

Munich Reinsurance Company in Munich, Germany is one of the premier companies that are aggressively attempting to make it more difficult for the burglar or robber to achieve success. They provided invaluable assistance during the research phase of this book. Their extensive expertise and experience in loss prevention and analysis and testing of security hardware is known throughout the world. Many of the graphics in these last three chapters were provided by them and for which the author is most grateful. Additional information about the company is available at **munichre**.

38_1.0 Physical Security Measures and Procedures

38_1.1 Introduction: Security Engineering

LSS202: Ross Anderson on security engineering

The real mission of this book is to deal with the larger concept of "security engineering." That is, locks, safes, physical security issues and alarm systems are all components for providing defense in depth of an installation or facility and are all equally critical components. According to **Ross Anderson(438)**, security engineering deals with the interrelationship of security components and systems to protect against both expected and unexpected dangers. In our context, it relates to both forced and covert entry through a myriad of means that are described throughout this text. The concept takes into account those individuals who act with malicious intent, mischance, or error.

Throughout this text, we are concerned with procedures, hardware, software and methodology that are required and geared to implement security and to provide the means to determine that level of security that meets the perceived threats for which the system has been designed.

Security can involve many disciplines, including locks, safes, computer networks, access control, physics, chemistry, knowledge of methods of attack, psychology of the intruder, organizational methods, legal requirements, business processes and organizational requirements, and quality assurance standards. The failure to adequately engineer the security for a facility has broad ramifications, both to life and property. Failures can result in loss of critical assets, loss of information, loss of protection of critical materials, danger to the environment, loss of life, damage to economic infrastructure, loss of privacy, facilitate crime, present danger to a business model. There are potentially many other more subtle effects.

The purpose of security engineering is to protect against known risks and to prevent unknown or unperceived risks from occurring. Every system has its own security requirements. It is incumbent upon planners to insure that they are protecting against the right things and in the right way. Often, this is not the case.

Where do we start in the security engineering analysis? What is the threat. Where does it come from? Where would it be directed? Once the threat is identified, what is the defense? What irregularities in the process would result in a breach of security? Where would the attack come from? Outside or within? Are there loopholes in the current system? What procedures are in place to assure that a breach in security does not occur, and if it does, that it will be detected immediately?

What is the threat? This is perhaps the most difficult to evaluate because every business, every installation, every operation has its own set of unique dangers. The author has been involved in criminal and civil investigations for the past thirty years. There are as many types of threats to security as there are employees and different kinds of facilities. For example, look at banks. Probably the greatest threat within a bank is an dishonest employee, not the robber or the burglar. It is clearly internal theft. The robber presents a different kind of threat to the bank, but not as persistent.

Likewise, in commercial business such as restaurants, bars, hospitals, retail outlets, medical clinics, transportation and communications facilities, there are different kinds of threats. Virtually anywhere there is an item of value or an asset or tangible property, intellectual property, or something that someone needs, there is always one or more threats. Perhaps the most difficult part of the security engineer's job is to correctly analyze the threat, from where it comes from, and how to adequately deal with it through the implementation of tactical security measures and procedures. Three simple examples of threat analysis for different environments can illustrate the point that each has unique and varied security issues:

Banks:

Bookkeeping systems
Dual signature responsibility requirements
Authentication of transactions
Personal identification
Wire transfer procedures and encryption
Physical security of cash and document handling
Safes and strong rooms
Alarm systems
Monitoring systems
Cryptography for critical transfer of information, such as ATM networks and wire transfer network

Computer network security

Hospitals:

Safety procedures for staff, patients, visitors
Patient records and privacy
Theft prevention
Patient privacy
Protection of medical records
Electronic authentication and encryption tools to assure the integrity of records and data
Federal access requirements regarding patient records
Protection of critical materials, such as narcotics
Data backup procedures
Power failures
Communications failures
Computer networks
Fire control and prevention
Criminal activity
Kidnapping

Homes:

Physical security against burglary, robbery, and home invasion
Internet access
Wireless systems security
Alarm systems: burglary and fire
Environmental monitoring systems
Transponder systems that are used in vehicles
Cellular security
Cordless telephones
Babysitter monitoring
Satellite television
Copyright controls for copyrighted media (CD, DVD)
Prepayment meters for utilities

The primary goal of Locks, safes, and security is to provide the information necessary to understand different types of physical security systems involving locks and safes and allied hardware in order to evaluate and design the requisite level of protection into any facility and to correctly assess vulnerabilities.

Certain physical procedures can be implemented to improve security and reduce the risk of loss. Their extent and comprehensiveness must be based upon an analysis of the property to be protected and the facility that must afford primary

security. Fundamental issues to consider will include:

- **The specific property to be protected;**
- **Exposure to loss;**
- **Value (both material and sentimental);**
- **Ability of goods to be resold or fenced;**
- **Ease of transport of the property from the premises;**
- **Quantity of property available for theft;**

With respect to the premises and implementation of security measures, consider the following:

- **Existence of electronic security systems for burglary, fire, and other forms of electronic monitoring;**
- **Occupants of the premises and their ability to provide watch;**
- **Security staff;**
- **Construction of facilities and burglary resistance or rating;**
- **Access and openings to facilities;**
- **Methods of access;**
- **Methods of escape;**
- **Methods of transport of goods.**

38_1.2 Risk Survey

A risk analysis should be considered as a starting point for the development and implementation of a security program. The following survey presents the primary issues to be evaluated in order to reduce the potential for loss through burglary and robbery. It is intended for both simple and complex businesses.

The assessment of risk must encompass both **physical hazards** and **moral risk.** This means that a thorough investigation must be made and knowledge acquired with regard to the following issues:

- **Premises to be protected;**
- **Neighborhood;**
- **Police information, trends, and statistics on crime in the area;**
- **Loss prevention techniques;**

- **Security guidelines, regulations, and standards.**

The survey addresses four primary levels of risk:

- **Simple as well as highly exposed businesses;**
- **Safes and strong rooms;**
- **Robbery on the premises;**
- **Robbery of cash or valuables in transit.**

The purpose of a risk survey is to develop detailed, accurate, and comprehensive information so that decisions can be made as to how to reduce risks of loss. The implementation of physical hardware and organizational procedures resulting from such surveys must always meet the following criteria for reasonableness:

- **Proposed measures must correspond to the actual risk;**
- **All factors must be considered that can either increase or reduce such risk;**
- **Proposed action must be economical and reasonable: they must maximize their effect at a minimum expense;**
- **The security measures must be comprehensive in scope and affect all aspects of the problem or potential risk;**
- **Partial solutions cannot be an acceptable alternative.**

38_1.2.1 Nature of Risk: General Issues

The nature of the risk takes into account those issues that may be considered by burglars or robbers to determine the desirability for them to target a specific business, location, or goods. Relevant criteria include:

- **Security awareness of owner and employees;**
- **Does the business appear to be well organized;**
- **Previous burglaries, robberies, losses, or attempts. Burglars often return to the scene if it is an easy target. If there were**

previous attacks, the following information should be evaluated:

- **Date of loss;**
- **Extent of loss;**
- **Method of entry;**
- **Added security measures that were implemented to correct for earlier risks;**
- **Many false alarms. This may indicate that a criminal is attempting to undermine the reliability of monitoring systems;**
- **Type and nature of business;**
- **Type and value of goods or commodities;**
- **Exposure of business;**
- **Are high-value items concentrated in small areas;**
- **What is the size of individual items of value;**
- **Can the goods be disassociated, taken apart, or reconstructed so as to make identification impossible;**
- **Can the goods be sold in divergent geographic areas to make tracing difficult or impossible;**
- **Is there anything unique about the goods;**
- **Is there a large amount of cash and/or goods available for theft;**
- **Can the establishment be easily cased;**
- **Can target goods be "preselected" for theft;**
- **Ability to sell, fence, or use such goods;**
- **Demand for such goods;**
- **Location of storage of goods within the building;**
- **Design of storage areas;**
- **Type of containers, if valuables are stored within enclosures;**
- **Use of safes, vaults, and strong rooms;**
- **Weight of safes;**
- **Security rating of safes and vaults;**
- **Local incidence of burglaries and robberies;**
- **Difficulty in transport of goods from the premises and to hidden distribution locations by burglars;**
- **Local vehicle and pedestrian traffic;**
- **Illumination and visibility of premises;**

- **Perimeter protection;**
- **Enclosure of premises;**
- **Access and transport routes to and from the premises;**
- **Perceived risk of detection within the premises;**
- **Adjacent rooms belonging to or used by other persons such as lessees and subtenants;**
- **Whether adjacent rooms, cellars, attics, basements, garages, or other areas are secured;**
- **What use is made of adjacent rooms, and can burglars enter the premises through such rooms;**
- **What is the construction of the walls of adjacent areas;**
- **Would it be possible to cut through adjacent barriers without notice;**
- **Reliability and rating of physical security hardware, including doors, door frames, locks, hinges, and bolts;**
- **Maintenance staff and work schedules;**
- **Emergency power supplies and generators;**
- **Protection against sabotage;**
- **Electronic surveillance;**
- **Blind spots in monitoring systems;**
- **Design of interior rooms containing high-value items, and whether they are protected by an outer shell that is alarmed;**
- **Alarm systems: silent or local;**
- **Holdup systems that are in place;**
- **Central station direct wire or dial-up alarm;**
- **Personal wireless panic alarms;**
- **Employment of security company or patrol;**
- **Secure internal wiring;**
- **Secure underground telephone cabling;**
- **Burglary insurance;**
- **Financial condition of the company;**
- **Competitive position of company;**
- **Likelihood that a theft would be disclosed to authorities;**
- **What is the interaction between staff and potential**

robbers or burglars;

- Is there a physical division or barrier between the merchandise and the would-be criminal;
- What is the layout of areas where high-value items are kept;
- Can potential criminals be closely observed while they are in the premises;
- Would customers recognize that a robbery was in progress;
- Visibility of safes from outside of premises;
- Would personnel be in a position to sound an alarm in time to summon assistance;
- Are current records of inventories maintained, including valuation and description of goods;
- Special identifying marks on goods;
- Can stolen goods be easily traced;
- Types of safes and vaults on the premises:
  Design, manufacturer, model, and classification;
    - Size and weight;
    - Value of goods stored within such containers;
    - Type of locking system;
    - Type of alarm system;
  - Persons who have keys or combination.
- Storage of tools in close proximity to targets;
- Information regarding frequent visitors to premises;
- Information regarding guard dogs on the premises.

38_1.2.1.1 Management Attitudes Towards Security Measures, and Insurance

- Management procedures with regard to reporting losses;
- Reliance upon insurance as the primary means of loss prevention;
- Age and condition of the premises;
- Commercial risks: how long has the business been in existence and its financial condition;
- Staff input regarding security and risks;
- Working hours;
- Overall cleanliness of the facility;

- **Previous experience with loss, and result (increased security measures implemented).**

38_1.2.2 Issues Relating to Burglary

38_1.2.2.1 Building Construction, Location, and Access

- **Adjacent buildings;**
- **Age of building;**
- **Type of construction: exterior walls made of masonry, reinforced concrete, wood, glass, metal;**
- **Wall thickness: exterior and interior;**
- **Type of building;**
- **Character of building: shops, office, dwellings, mixed usage;**
- **Number of stories, basement, attic;**
- **Use of areas adjacent to premises;**
- **Adjacent buildings or rooms;**
- **Unoccupied rooms adjacent to premises;**
- **Connection between adjacent buildings;**
- **On which floors are the target premises operating;**
- **Access between stories: stairs, elevators, escalators, and whether they are open or enclosed;**
- **Fire escape;**
- **Elevators;**
- **Ventilation or air conditioning ducts;**
- **Dome lights or skylights;**
- **Glass roof;**
- **Balconies;**
- **Trellises, sills, or cornices;**
- **Façade elements that can be used for climbing;**
- **Cellars, and connection to other areas.**

38_1.2.2.2 Geographic and Demographic Information

It is axiomatic that the risk of burglary is inversely

proportional to the risk of discovery during the crime. Thus, geographic and demographic information is important to any survey.

- **Nature of area: isolated, rural, urban, metropolitan;**
- **Geographic location: commercial, industrial, residential;**
- **Geographic proximity: within city limits, outside city limits;**
- **Geographic characteristics near premises: parks, forests, open areas, lakes;**
- **Potential response time of law enforcement;**
- **Is the neighborhood of such a nature that burglars can easily conceal themselves without detection or disturbance;**
- **Can burglars easily case the target;**
- **Are there unoccupied buildings, industrial plants, parks, or other places for cover;**
- **Will crowds allow escape without attention;**
- **Type of business: manufacturer, wholesale, retail;**
- **Relationship between business and valuables stored within the premises;**
- **Total space occupied by the business;**
- **Traffic: normal, heavy, continuous, isolated;**
- **Distance from closest police station;**
- **Distance from nearest occupied dwelling;**
- **Public access: major artery, street, side street, motorway;**
- **Neighborhood: residential, commercial, restaurants, shopping, unoccupied buildings, abandoned buildings;**
- **Economic quality of neighborhood;**
- **Sound levels: is the premises near installations or facilities that continuously or sporadically produce noise that can provide a cover for burglars;**
- **Anonymity of residents, making it easier for strangers to enter the premises and move about without being detected.**

38_1.2.2.3 Lighting

- **Night lighting;**
- **Interior lighting: rooms, windows, display cases;**
- **Exterior lighting: grounds, building;**
- **Type of illumination, brilliance, and sufficiency;**
- **Dark or shadow areas;**
- **Protection of lights against vandalism or damage;**
- **Can lighting be switched off by burglars;**
- **Are photoelectric cells utilized to sense lack of illumination.**

38_1.2.2.4 Security Devices and Hardware

38_1.2.2.4.1 Doors

- **Inspection of all doors, including infrequently used entrances such as emergency exits and cellars;**
- **Materials used for door leaves and frames;**
- **Type and quality of the door leaf:**
  - **Weight;**
  - **Resistance to displacement;**
  - **Sound patterns when tapped, indicating construction;**
  - **Removal of mortise lock to view interior construction;**
- **Mounting of door frame:**
  - **Weak points in door frames made of laminated wood or plastic;**
  - **How are they affixed to surrounding elements;**
- **Single leaf, double leaf;**
- **Wood panel, glass panel;**
- **Thickness;**
- **Hinge type;**
- **Hinge bolts;**
- **General condition of doors;**
- **Cracks or a loosening of the door frame from the surrounding construction;**
- **Gaps between the door leaf and frame;**
- **Gaps between the door leaf and floor.**

38_1.2.2.4.2 Locks

- **Type of mechanism: warded, lever, wafer, pin tumbler, combination, electronic;**
- **Security rating;**
- **Mortise Cylinder:**
    - **Rim Cylinder;**
    - **Deadlocking;**
  - **Strike plates;**
- **Proper mounting of security hardware, including striking plates and hinge bolts;**
- **Use of proper mounting screws and their thickness;**
- **Secure and proper mounting of locks, strike plates and hinges on the door**

leaf or frame;
- **Security rating of locks;**
- **Do all locks function properly;**
- **Key control procedures;**
- **Inventory of keys;**
- **Can keys remain in the possession of unauthorized persons;**
- **When was the last time the locks were changed.**

38_1.2.2.4.3 Windows

- **Type of window: fixed glazing, bottom-hinged, sliding sash, center-hung sash, swinging, casement, swinging bottom-hinged;**
- **Glass: Fixed glazing, ordinary glass, insulating glass, wired glass, toughened safety glass, laminated glass, polycarbonate;**
- **Thickness of glass and description of layers (materials and thickness);**
- **Glass mounting: screws, clamps, no mounting (putty or rubber restraining rims), lockable mountings, permanent;**
- **Aluminum, plastic, steel reinforcement;**
- **Grill: distance from bars, roller grating, roller shutters, reinforced;**
- **Grill materials: wood, plastic, steel, aluminum;**

- **Frames: wood, steel;**
- **Glass bricks: thickness, size, reinforcement;**
- **Skylights and dome lights should be considered as windows.**

38_1.2.2.4.3.1 Display Windows and Showcases

- **Type of glass;**
- **Mountings.**

38_1.2.2.4.4 Alarm System

- **Type, make, model;**
- **System inspected and tested regularly;**
- **Date of installation;**
- **Installer;**
- **Maintenance contract;**
- **UL approved;**
- **Insurance approved;**
- **Method of reporting: direct wire, dial-up, local, RF, packet, satellite, network;**
- **If local alarm:**
    - **Number of sounders or lights;**
    - **Location;**
    - **DB level output;**
  - **Visibility (lights);**
- **Number of telephone circuits;**
- **Emergency power: duty cycle;**
- **Type of control panel;**
- **Audit trail;**
- **What is protected by the alarm system:**
    - **Individual objects, rooms, areas, perimeter, safes and vaults;**
- **Individual authorization codes for each employee.**

38_1.2.2.4.5 Electronic Surveillance

- **Openings: doors, windows, skylights, air shafts**
- **Potential access points: walls, floors, ceilings**
- **Alarm trips and traps:**
  - **Magnetic contacts, glass-breakage detectors, alarm glass, films, trip wires, bolt-contacts, seismic, video, capacitance, volumetric monitoring (with microwave, infrared, ultrasonic), radio, photographic (film, video, time lapse);**
  - **Holdup alarms;**
  - **Other surveillance devices.**

38_1.2.2.4.5.1 How is Alarm System Activated:

- **Switch lock;**
- **Control panel or keypad;**
- **ID card reader;**
- **Is alarm active at all times;**
- **24-hour trips;**
- **Guard company for protection after business hours.**

38_1.2.2.4.6 Equipment Storage

Do not store equipment in places that can be accessed and used by burglars. Such items would include:

- **Vehicles;**
- **Forklift trucks;**
- **Ladders;**
- **Power plants;**
- **Welders;**
- **Hydraulic equipment;**
- **Tools;**
- **Drills;**
- **Dumpsters that could be used for hiding equipment should be locked.**

If outside storage is required, then all items must be secured with chains, locks, blocking devices or alarms.

38_2.0 The Psychology of Burglars and the Risks of Burglary

Through exhaustive analysis of thousands of burglaries by law enforcement agencies and insurance companies, a psychological profile of both the acts of burglary and the burglar can be accurately provided. The following summary attempts to offer the required link between the mind of the "typical" burglar, actions that may be expected during the commission of the crime, and the physical measures that may prevent or deter the criminal conduct.

38_2.1 Preliminary Considerations

The value of goods is only one factor and may not be particularly relevant in assessing whether they will be stolen. Considerations that might be more important include:

- **Access;**
- **Quantity of goods that are subject to theft;**
- **Value of goods;**
- **Danger inherent in their taking;**
- **Ease in removal;**
- **Storage requirements after the theft;**
- **Investment by the criminal in tools, equipment, and other expenses that must be made to facilitate the crime.**

38_2.2 Risk Assessment Considerations

The following assessments will usually be made by a burglar with respect to the theft of goods.

38_2.2.1 Access to Crime Scene

Access is of critical importance to most burglars because no **physical property crime** (other than one that involves the manipulation of an order or delivery process) can be committed without actually getting to the goods to be stolen. The following issues may be considered during the evaluation of the feasibility of burglary.

- **Do conditions appear favorable for the commission of the crime;**
- **Ease with which the target area can be cased or observed;**
- **Potential to compromise one or more staff members, with or without their knowledge;**
- **Ingress and egress to a crime scene;**
- **Method of entry and difficulty;**
- **Chances of interruption;**
- **Likelihood of being caught;**
- **Possible delays that may be encountered during commission of the crime;**
- **Impediments to access;**
- **Tools required to complete the crime;**
- **Tools required for access;**
- **Apparent security systems or security hardware in place;**
- **Likelihood of observation during commission of crime, evidenced by the presence of employees, alarm systems, watchmen, or lighting;**
- **Local alarm devices that provide optical or acoustic indication of intrusion;**
- **Perimeter protection;**
- **Alarms or electronic monitoring of objects of attack;**
- **Will apparent security measures complicate ingress or egress;**
- **Factors of uncertainty that may be encountered;**
- **Are there outer perimeter walls, roofs, skylights and areas within the building that are specially protected by electronic monitoring;**
- **What is the likelihood that there are unknown obstacles to entry of a target facility;**
- **How sophisticated or reliable are known electronic monitoring systems, and how difficult will they be to overcome;**
- **How many different alarm or monitoring systems must be bypassed;**
- **What is the likelihood that criminals can work**

undisturbed throughout the course of the burglary;
- **Is there a place of concealment for the burglar if intrusion is detected;**
- **Is the escape route protected or concealed;**
- **Are there any obstructions in the egress route, with respect to the type of property being removed;**
- **Difficulty of removal of goods from the premises;**
- **Are perimeter protection systems in place;**
- **Are protective devices recognizable from the outside;**
- **Will protective devices prevent damage to display windows;**
- **Will protective devices make the theft of goods more difficult;**
- **Are high-value goods concentrated in small places;**
- **Will a display window have to be entirely shattered to retrieve goods;**
- **Are goods that are visible behind a display window difficult to reach from the outside;**
- **Does it appear that "dummy goods" are shown in displays.**

38_2.2.1.1 Specific Construction Considerations Regarding Ingress

- **Roof and skylight construction;**
- **Ease of penetration;**
- **Rigid roof, made of reinforced concrete, gas concrete, or foamed concrete elements. Roofs may also be made of tile, clay, or concrete bricks placed between girders of steel;**
- **Non-rigid roofs, made of wooden or steel framing, covered with materials only partially secured, such as shingles or tiles;**
- **Windows and frames: construction and material;**
- **Building construction;**
- **Access through other than doors, such as ventilation shafts, dome lights, skylights;**
- **Access to setscrews that retain cylinder locks;**
- **Open ceiling access between offices or areas;**

- **Access to balcony;**
- **Electronic access, such as RF transmitter;**
- **Electronic bypass of access control;**
- **Strike plate access and replacement to bypass secondary bolt mechanisms;**
- **Which rooms are most vulnerable in terms of lightweight walls, numerous openings, or weak doors;**
- **Have access routes, including cellars, fire escapes, lifts, ventilation shafts, air conditioning ducts, skylights and dome lights been alarmed;**
- **Is it possible for burglars to move throughout a building without impediment;**
- **Is there a concentration of valuables in a small area, making their collection easier for burglars.**

38_2.2.1.2 Time

- **Elapsed time required for ingress to the target property;**
- **Time required for collection of goods;**
- **Egress or escape time that is computed from the moment the burglar has left the crime scene;**
- **Speed of ingress and egress;**
- **Estimate of overall time required to complete the theft;**
- **How much time will be needed to overcome each known obstacle;**
- **What is the probable response time of security staff or law enforcement in the event of detection;**
- **What is the fastest method of entry that will provide access to the target area of property;**
- **What is the time required to gather or collect the target property and remove it from the location;**
- **What are the weight and volume of the property to be stolen and the correlation of that information to collection and egress times.**

38_3.0 Organizational Procedures and Actions to Reduce Risks

Actions and measures taken by an organization can dramatically reduce the potential for loss from burglary. Such measures include:

- **Effective use of technical security systems;**
- **Background clearance of all staff through personal interview of references;**
- **Maintenance of internal security with regard to the value of goods and details of security systems;**
- **Competence of staff to supervise security systems and measures;**
- **Staff responsibilities with regard to security measures;**
- **Locking or securing of access points to facility:**
    - **Doors;**
    - **Windows;**
  - **Ventilation covers;**
- **Lighting turned on;**
- **Keys kept in secure area;**
- **Alarm documentation;**
- **Physical check of internal facilities such as washrooms, for hidden intruders;**
- **Physical checks of areas where objects of value are stored;**
- **Cash registers emptied;**
- **Safes and strong rooms;**
- **Alarm system turned on, and trips routinely checked for proper operation.**

38_3.1 Watchmen and Security Patrols

Watchmen can reduce the risk of loss but are expensive to maintain. For that reason, they are only utilized in large facilities or in instances where high-value items must be protected. In many installations, watchmen or security patrols are a necessary component of overall system security. Their principal value lies in the detection of open doors or windows, failure to properly set alarm devices, or in discovering breaches of security. At least two watchmen should be available to insure that one can act as a backup. Many tasks should be provided to break the monotony and routine of the job.

38_3.1.1 Watch Patrols

The watch patrol should be planned for maximum effectiveness, but not follow any fixed routine. It is important that all high-risk locations, such as safes and cash areas, be checked frequently. Obligatory reporting of status will improve security. Failure to report on a timely basis must trigger immediate investigative action. The effectiveness of watch patrols can be enhanced through the following hardware and security measures:

- **Comprehensive two-way communications system;**
- **Interagency communications capability for immediate assistance;**
- **Internal call boxes conveniently placed;**
- **All security staff must be able to communicate by radio and/or telephone;**
- **One watchman should always be located within a secure area;**
- **Varying the routine at least once per week, so that no meaningful intelligence can be gathered during casing;**
- **Use of time clocks that must be activated at periodic intervals;**
- **Use of alarm systems;**
- **Closed-circuit video and audio, including infrared cameras;**
- **Use of night vision equipment, where applicable;**
- **Capabilities to summon help or trigger an alarm from any point in the facility. This will include the ability to signal an emergency status from two-way radios or personal alerting devices;**
- **Use of guard dogs, where appropriate.**

38_3.2 Key Control

Key control has been discussed elsewhere in this text. The security of a lock or safe is dependent upon how the keys or combination is maintained. Therefore, it is vitally important that effective controls be put in place to insure that unauthorized persons can never obtain unauthorized access. The following procedures can help to assure effective key control:

- **Duplicate keys and the combinations to critical areas, computer rooms, alarm panels, electrical panels, and telephone switching facilities should not be kept on the premises;**
- **A record of key codes, safe and vault combinations, passwords, encryption algorithms, master keying schemes and other critical information should be maintained in a safe-depository or specially designated and closely controlled vault located on the premises. The keys or combination to this vault should be varied from time to time, or after there has been a change in staff or a security compromise;**
- **Only supervisory staff should have access to and responsibility for master keys and locks that protect key depositories;**
- **Keys for emergency exits must be protected to insure that they are not removed without permission or knowledge;**
- **Keys should not be capable of being copied when stored in elevator or emergency exit containers. Usually, these key-cabinets have a glass front and will allow an unrestricted view of the keys contained therein;**
- **Combination locks with dual control or time locks may be required for high-security areas.**

38_3.3 Background Investigation of Staff

Staff that has access to any secure area must be vetted. This includes maintenance and cleaning personnel. Background investigations must not simply be routine but should seek to determine any problems relating to honesty and integrity that have surfaced on prior occasions. Previous employers should be personally contacted, preferably through direct interviews. Polygraph may also be utilized to verify background.

38_3.4 Lighting

Illumination and visibility of the object and area to be secured is an inexpensive measure to reduce exposure to risk. The following issues should be considered with regard to lighting:

- **Leave lights on at all times;**
- **Visibility (from other offices or the street) of property or rooms that contain property;**
- **Do not use blocking screens that obstruct views into storefronts;**
- **Open curtains at night to allow full view of interior;**
- **Provide lighting to those areas most vulnerable to entry attempts;**
- **Illuminate all exterior areas of a building that provide access for entry;**
- **Provide Lexan or other shatter-resistant covers for all outside lighting;**
- **Use building materials that promote visibility, such as glass bricks;**
- **Mount all lighting so that it is out of reach;**
- **Utilize automatic control for turning lights on and off;**
- **Install interior and external floodlights that are triggered by alarm, unless a silent system is employed;**
- **Utilize flashing strobes or brilliant halogen floods to startle intruders if the primary goal is to protect display windows from damage;**
- **Provide for the remote control of outside power sources to prevent their use by burglars:**
    - **Be certain that the system cannot be manipulated in order to cause short circuits, thereby defeating illumination;**
    - **Use of power tools for break-in.**

38_3.5 Tools Used in the Commission of a Crime

Burglars should be forced to utilize specialized tools to gain entry. The process must be made as difficult as possible for the criminal.

38_3.6 Vehicles

All vehicles should be kept within alarmed buildings. Keys should never be accessible to intruders.

38_3.7 Storage of Goods with High Risk of Theft

The choice of a storage location for high-risk goods should not be based solely on economics or convenience. Issues of security must always be considered, including the following:

- **Assessment of the likelihood of theft for each type or classification of property;**
- **What objects or items are subject to the most significant threat;**
- **What is the acceptable threshold of risk for which no extraordinary measures will be taken to protect goods or property;**
- **Can high-risk items be concentrated or stored in just a few protected areas that can be adequately secured;**
- **Which rooms, areas, or buildings afford the highest security, based upon construction and monitoring capabilities described elsewhere in this chapter;**
- **Which areas can best be protected by electronic alarms;**
- **Can access routes be properly and adequately protected by alarms;**
- **Which areas can afford the best capability of observation and monitoring from the exterior. It is often wise to place valuable goods, as well as safes, in an area that can be watched by security staff or passers-by;**
- **Can the removal of goods be made more complicated and difficult during the course of a burglary;**
- **Can goods be affixed to walls, floors, or display surfaces to make their removal more difficult. This is especially critical in the case of storefront display windows that are subject to smash-and-grab attacks.**

38_3.8 Perimeter Protection

The necessity of perimeter protection must be evaluated on a case-by-case basis. Some systems provide almost no measure of security; others are quite effective. However, the risk of

burglary may be dramatically increased if no safeguards are implemented. As a rule, any perimeter security program must be backed up by other systems. The result to be accomplished by any program must be defined. Essentially, perimeter protection envisages achievement of two distinct goals: **physical deterrent** to entry through barriers and **early detection.**

In assessing the need to implement a security protection program, a number of arguments can be made in favor of such measures. Proponents usually urge that:

- **A system can complicate intrusion with physical barriers and time delays;**
- **Systems will allow for a faster detection time and subsequent response;**
- **Movement of stolen property becomes more difficult;**
- **Casing of the premises takes on more risk.**

38_3.8.1 Physical Barriers to Entry

Measures may be adopted to protect the boundaries of the premises. Barriers can be constructed to act as a deterrent to penetration. They can protect both the outer perimeter and buildings located on the property by making it more difficult to enter, but also increasing the chances of being observed or heard.

38_3.8.2 Perimeter Boundaries

Perimeter boundaries encompass walls, fences, gates, and access route restrictions.

38_3.8.2.1 Walls and Solid Wooden Fences

- **Makes entry more difficult;**
- **Makes movement of stolen goods more complicated;**
- **Provides cover for the intruder.**

38_3.8.2.2 Iron-Barred Gates

- **Allows unobstructed view of the premises and intruders;**
- **Must be designed to be secure;**

- **Hinges should be incapable of removal or disassembly;**
- **Additional locking bars enhance security.**

38_3.8.2.3 Netting Wire or Chain-Link Fences

- **Must be topped with barbed wire or razor wire to prevent climbing;**
- **Must be in good repair.**

38_3.8.2.4 Access Route Restrictions

- **Hydraulic barriers sunk into the ground to protect driveways.**

38_3.8.2.5 Enhancements to Perimeter Barriers

- **Lighting and automatic control;**
- **Alarms;**
- **Watchmen;**
- **Video systems;**
- **Audio systems.**

38_3.9 Planning for Protection of Buildings

Security is often a low priority in construction planning. Current building methods favor lightweight materials with many openings. Construction plans are usually developed with the priorities of finance, function, esthetics, and environmental, with little attention paid to crime prevention and reduction of risk. Such policies can be extremely costly to remedy after the fact.

Risks of penetration are increased in the following areas:

- **Back doors;**
- **Dome lights;**
- **Doors below floor level;**
- **Ground floor windows;**
- **Locations within a building with poor visibility or lighting;**

- **Roofs;**
- **Skylights;**
- **Walls to adjacent buildings or rooms containing high-value goods;**
- **Windows on upper levels, if they can be accessed with ladders, gutters, or fences.**

Enhanced protection should be implemented in many different areas that encompass doors, special entrances, ventilation openings, walls, windows, and access routes.

38_3.9.1 Doors

Doors present a high-security risk for many reasons:

- **They are a target location for break-in;**
- **Entry will not attract as much attention as windows or other areas;**
- **Forced-entry of a lock is less noticeable than of a window or door;**
- **It is usually simpler to remove booty through a door;**
- **Attacks upon doors usually take one of three forms. See Chapter 32 for a description of specialized tools used for this purpose.**

Forced-entry methods include:

- **Forced removal or alteration of locks, bolts, or hinges;**
- **Force applied to the door or its frame;**
- **Smashing doors open;**
- **Shattering glass inserts;**
- **Removing the lock from its housing;**
- **Bypassing the lock.**

38_3.9.1.1 Security Measures for Protecting Doors and Adjacent Areas

The following measures may be implemented to increase security for doors and nearby areas:

- **Added protection to doors that provide access to adjacent areas;**
- **Doors should be bolted from the inside;**
- **Double-doors should not be used for exit;**
- **Enhancement of any rear door that has a higher risk of attack;**
- **Exit doors should be readily observable from the street or by security staff;**
- **Exit doors should be well illuminated;**
- **Heavy strike plate;**
- **High-quality locks and strong bolts;**
- **Metal screws properly anchored for locks and bolts;**
- **Properly protected hinges and which are mounted on the inside;**
- **Hinges restricted from inside opening;**
- **Number and dimensions of hinges;**
- **Location of hinge mounting pins;**
- **Can hinges be pried loose with relative ease;**
- **How are hinge bolts mounted to door leaf and frame;**
- **Use of locking chains, bolts, and devices that prevent the key from being pushed out of the keyhole.**

38_3.9.2 Non-functional Entrances and Openings, including Windows, Doors, Cellar Shafts or Skylights

- **Permanently secure with brick, cinder-block, or cement.**

38_3.9.3 Ventilation Openings

Air conditioning and air-intake systems can pose a special threat because even as small an opening as 30 x 30 cm is large enough for one person to fit through. Heavy perforated plates of at least 5 mm, with holes less than 8 mm or protective bars must be utilized.

38_3.9.4 Walls

Walls and ceilings should be constructed of high-grade reinforced concrete at least 20 cm thick or a comparable material.

38_3.9.5 Windows

Many recommendations can be made to architects and building contractors regarding issues of security relating to windows. These include:

- **Minimize the number of ground floor windows;**
- **Keep accessibility to the premises through windows to a minimum;**
- **High windows should be utilized in storage areas and adjacent buildings, making them difficult to reach from the outside;**
- **Use of bars and horizontal metal strips can prevent anyone from fitting through open spaces;**
- **Glass bricks and honeycombed concrete should be used at vulnerable points.**

38_3.9.6 Other Openings in a Building

Many openings other than windows and doors can present an opportunity for entry. These include:

- **Skylights;**
- **Light wells;**
- **Basement windows;**
- **Steel-atticed windows;**
- **Ventilation openings;**
- **Dome lights;**
- **Lift shafts;**
- **Coal chutes;**
- **Goods lift shafts;**
- **Other areas.**

Any orifice that is larger than 5” square and can be reached from

the ground or other areas should be protected. Protective hardware to safeguard potential secondary access points include:

- **Iron grates;**
- **Bars fixed in cement within the walls;**
- **Glass bricks placed in reinforced concrete;**
- **Steel-latticed windows, with a padlock for the inside lever;**
- **Bolts and bars, especially for double doors used in coal chutes;**
- **Steel meshing fastened securely to walls and inaccessible from the outside;**
- **Screw fasteners or anchors.**

38_3.9.7 Secondary Protection

Physical protection of an asset and of locations that can provide access to property must be secured both directly and indirectly. Measures and techniques can be varied, and have many options.

38_3.9.7.1 Access Routes

If access to valuable property or other targets of burglars is limited to one route such as a corridor, stairs, tunnel, or a door, then they can be protected by alarm trips. It is essential that reliable devices be installed and secreted, especially if perimeter alarm traps would have been defeated.

Electronic protection of doors and alternate primary routes will prevent access to other parts of a building. A variety of sensors may be employed, including magnetic trips, pressure sensitive floor mats, microwave, passive infrared, ultrasonic, and proximity detectors.

38_3.9.7.2 Other Protective Measures

Secondary protective measures of special areas and equipment used in jewelry stores and related businesses are essential. These include:

- **All display items should be fastened or connected to the display windows;**
- **Items of value should not be displayed as a single piece;**

- **Jewelry should be permanently affixed or anchored, using locks or other devices;**
- **Distribute valuable items throughout display windows so that they are not concentrated, making it more difficult to steal all goods at once;**
- **Showcases and night displays should not contain any valuables, or the merchandise should be obvious dummies representing valuable goods;**
- **Limit the size of the display window surface, making it more difficult to break, extract, or gather items;**
- **Place permanent partitions within a display window to limit access to goods;**
- **Armed guards may be utilized for areas that cannot be adequately protected by other means;**
- **Utilize watchmen services to check all access points to the building on a non-scheduled, regular basis.**

38_4.0 Burglary Risks for Specific Businesses

There are higher risks of burglary for specific types of business activities. These risks are based upon many criteria, the most obvious of which is **value of target goods.**

The following high-risk businesses are most susceptible to burglary. These include banks, jewelry establishments and gas stations/convenience stores. In the materials that follow, protective measures applicable to each will be explored.

38_4.1 Banks

A bank is a logical target of professional burglars, so long as the thieves possess the requisite experience and tools. For that reason, extraordinary security measures are adopted. Certain specific areas present the greatest risk of attack. These include strong rooms, ATMs, and night depositories. Appropriate precautions must be taken to insure that these areas are secure.

38_4.2 Businesses Dealing in Precious Metals, Gems, and Jewelry

These classes of businesses are always a target of burglars for obvious reasons. Smash-and-grab burglaries, as well as the more traditional covert entries, are now common throughout the world. The reduction of risks associated with property crimes involving high-value gems and metals require consideration of many issues and procedures. These must not only include analysis of physical security measures but also of an overall program of protection. Special attention must be given to the following issues:

- **Construction of perimeter barriers must offer a high resistance to forced-entry;**
- **Display windows constitute perhaps the greatest threat. Special glass, bars, grating, or other devices must be employed. Wired glass should be placed in front of other physical barriers to signal an alarm at the earliest possible time;**
- **All windows should be mounted from the inside, so that all frames are protected;**
- **Massive bars that are securely anchored in exterior walls provide significant protection to windows;**
- **Recessed entrances with a rolling grill can provide protection to interior windows;**
- **Burglar-resistant doors, leaves, and frames should be utilized. Steel sheets at least 2 mm thick can be used for reinforcement. Any supplemental protection should be secured from tampering. If there are glass panels within perimeter doors, they should be electronically monitored and properly mounted;**
- **Only entry and exit doors should have locks that can be activated from the outside. All others should be bolted from the inside with iron crossbars. Brackets and strikes must be securely anchored to walls;**
- **Alarm systems must provide an indication when any door, window or other opening is not secured;**
- **High-security cylinder locks must be utilized in mortise configurations, with extending dead bolts;**
- **Hinges must be properly secured, sufficiently heavy, and preferably not accessible from the outside. Bypass through removal of hinge pins must not be possible.**

38_4.3 Safes and Strong rooms

The security ratings for bank safes, vaults, and strong rooms are equally applicable to businesses dealings in precious metals and gems. Ratings based on the value of stored goods should not be exceeded by more than fifty percent. Special alarm systems for security containers should be fully integrated into the master system. These are more fully discussed in **Chapter 40.**

Unfortunately, there are inherent conflicts between robbery and burglary protection as involves safes and vaults. On the one hand, prevention of robbery demands that the repository not be visible to the customer. However, good burglary prevention requires that the same container is visible from the street. A possible solution: use a video camera and place a monitor in the window. A motion analyzer should trigger an alarm for any movement within the area of the safe.

PART B: Taking by Force

Robbery

38_5.0 Protection against Robbery and Holdup

Worldwide, the incidence of robbery is on the increase as protective measures against burglary become more effective. The prime motivation for robbery is currency, other negotiable instruments, or small, high-value items such as jewelry. Statistics indicate that robbers will take risks based on the nature and value of their targets. They will resort to violence to obtain their loot or to insure escape.

One of the difficulties in robbery prevention is the conflicting goals of security and the safety of innocent victims. As the risk of apprehension through protective measures and procedures increases, so does the danger to human life.

38_5.1 The Psychology of Robbers and the Risks of Robbery

Just as in our earlier discussion of burglary, we must begin by an analysis of those factors that we know are considered by

robbers in planning their crimes. An insight into the issues that criminals consider important, as a deterrent and benefit, will provide the starting point for any viable security program.

The critical threshold question for any security planner becomes "how do we prevent a robbery from occurring?" In our discussion of the psychology of burglars, a number of issues were raised for consideration. Many of those same issues are relevant in the context of a robbery. However, additional considerations for the robber and security manager pertain specifically to the taking of property by force.

38_5.2 Primary Considerations and Questions by Robbers

The following issues should be examined from the perspective of the robber:

- **The robber need not have any level of sophistication, intelligence, or cleverness, unlike his burglar counterpart;**
- **Robbery provides the amateur criminal the possibility of instant wealth;**
- **Targets of robbery are accessible to everyone;**
- **Targets are often not protected;**
- **Hidden cameras are to be feared by the robber and, for this reason, can be extremely effective;**
- **Many robbers are photographed on video or film that results in later apprehension;**
- **Planning and preparation of the robbery is often straightforward and non-problematical;**
- **Menacing behavior, display of weapons, and speed are often sufficient to intimidate victims of a robbery into compliance and submission;**
- **The relationship of risk to reward is generally favorable;**
- **No fence or receiver is generally required;**
- **Protective measures that are not apparent prior to a robbery may be of secondary importance as a deterrent;**
- **Non-obvious protective measures may cause unpredictable reactions by the robber that can**

create hazards to life;

- **Is access to exposed objects restricted or too risky;**
- **Is the physical removal of the targets of a robbery difficult and thereby risky;**
- **Has the target object been removed from the premises, thereby eliminating the desirability and profit motive of the crime;**
- **Are target goods stored in secure areas or containers that will make robbery more difficult or risky;**
- **Are time locks or other devices employed that will limit the ability of employees to comply with demands;**
- **Are alarm systems reliable and active;**
- **Will identification systems make apprehension more likely;**
- **What is the potential for taking hostages to obtain a desired result;**
- **Will employees likely do what they are told by robbers;**
- **Is the value of target goods limited and thus the risk/reward ratio diminished;**
- **Is there less incentive to commit a robbery due to the likelihood of a small haul (and a concomitant lower risk of loss by the business);**
- **Does the business characteristically have large amounts of cash on hand;**
- **Is most of the cash deposited or transported by armored courier prior to closing;**
- **Is cash transported to or from the facility;**
- **Are any breaches in security possible and observable during cash or valuable transport that can later be exploited;**
- **What specific security measures are taken during the loading and unloading of cash or valuables;**
- **Is a routine established for the transport of valuables;**
- **Are there multiple cash drops throughout the day, reducing the likelihood of a large haul;**
- **Are there certain periods where the risk of robbery**

is increased, such as pay days;

- **Are high-risk events, such as cash receipt and deposits, well known or secret;**
- **Is cash or valuables kept in a safe or strong room;**
- **Is access to a safe or strong room complicated or made difficult through the use of electric controlled doors, delayed action time locks, or guards;**
- **If access to large amounts of cash is complicated, will resulting delays be hazardous;**
- **Are floor safes utilized for immediate deposit through a slit. This practice is especially prevalent and effective in gas stations and convenience stores;**
- **Are keys to safes kept on the premises, allowing compromise by robbers;**
- **Are sinkable cash desks, locked showcases, or remote-controlled containers utilized for storing valuables, that can cause delays in access;**
- **What is the ease, speed, and unobtrusiveness of access to target goods;**
- **Is there a clear escape route that is not complicated, or one that is fraught with uncertainty;**
- **Is the target location close to the perimeter of the building;**
- **How many barriers exist between the outside of the building and the target;**
- **How many people have direct access to the target goods;**
- **Do barriers separate target goods from the robber. These include bullet-resistant glass, intermediate doors, or revolving doors. Are such devices equipped with security equipment;**
- **Is there bullet-resistant glass on all ground floor windows;**
- **Are safety desks employed that after an alarm has been triggered will cause an armored wall to rise. These barriers, consisting of bulletproof opaque elements, can block access from the customer area within one second;**

- **Are internal cash rooms connected to tellers by pneumatic tubes or posts, thereby removing access to valuables to the interior of the building;**
- **Can unauthorized personnel be immediately recognized;**
- **Is the main security emphasis placed upon an alarm system with an inadequate response time;**
- **Are holdup alarms in place, and are they silent or local;**
- **How many unknown security factors appear to complicate a robbery;**
- **Are holdup trips placed at strategic locations that would not provide an indication to the robber of activation;**
- **Is there automatic locking of cash desks, sinkable showcases, exploding bait money with dye, or other alarm-triggered devices;**
- **What is the chance of identification and apprehension resulting from the use and placement of video or still cameras;**
- **Are there dead-spots in photographic coverage within the premises;**
- **What is the quality of photographs or video;**
- **Is real motion or time-lapse video in use;**
- **Are photographs rapidly available in case of robbery;**
- **Are cameras operating all the time, or only upon command;**
- **Can height, weight, and movement be determined from photographs based upon the placement of cameras, even if robbers wear masks;**
- **Are cameras housed in protective enclosures;**
- **Are video recorders placed in secure areas, so that the tape cannot be easily accessed by robbers;**
- **If observed by criminals, do guard staff appear alert to the threat of robbery;**
- **Is it possible to kidnap key personnel or their families, and gain immediate access to cash or other valuables;**
- **Robbers consider the construction and security of entrances, including emergency exits, personnel**

entrances, and secondary points. They prefer such points of entry and exit. Emergency exits are usually easy to circumvent, and thus they are likely targets for unnoticed ingress and egress. The robber can often gain an element of surprise and leave in the same manner; their escape is often hidden and cannot be readily noticed from the outside;

- **The method in which valuables are protected will influence the desirability of the target. If goods are not accessible to customers, they will not be as enticing;**
- **What is the value of the goods on hand and the breakdown as to type of commodity;**
- **Method of access into the premises;**
- **Location of windows;**
- **Construction of doors;**
- **How are goods protected;**
- **Description of work areas;**
- **Can work areas be entered by unauthorized persons;**
- **Number of employees;**
- **What is the least number of employees on the premises during the workday;**
- **Opening and closing procedures for the business;**
- **Robbers often prefer closing time because there are normally few customers present and there is the most amount of money on hand;**
- **Do employees wait outside to observe the exit of other employees, thus to be in a position to sound an alarm in case of robbery;**
- **Is there freedom of movement of customers while on premises;**
- **Is the customer ever left alone with valuable goods;**
- **Are cash control desks always occupied;**
- **Do cashiers always remain in contact with other employees;**
- **Have cash-handling personnel received special training;**
- **Where is cash stored on a temporary basis;**
- **Procedure for the transport of cash and other valuables within the premises and location of**

personnel;
    - **Where are they stationed;**
    - **What equipment do they utilize;**
  - **Do guards remain in a bullet-resistant enclosure;**
- **Does the amount of money vary by time of day, day of week or season, making certain times more advantageous for robbery;**
- **Is it possible to detain a robber until assistance arrives;**
- **Do access locks prevent unauthorized entry, using bullet-resistant glass and electromechanical locking devices;**
- **Can holdup alarms be easily activated;**
- **Are day-tills utilized with time locks;**
- **Is the cash-handling room separated from customer areas. In this regard, two methods have been found to deter robberies. A separate room, into which the customer can see but that is protected with bullet-resistant glass and special access door is effective. A separate cash room located within a strong room, isolated from the customers, and connected through a remote conveyance system, provides the best security. Robbers know that such an arrangement can allow the activation of an alarm and can limit the amount of cash that can be taken;**
- **Is the amount of cash on hand limited, thus requiring the customer to call in advance for large withdrawals;**
- **Robbers target locations where money or high-value goods are transported during business hours;**
- **Are armed guards present at the premises. This may reduce the risk of robbery but also increase the risk to patrons in the event that an attack does occur due to the likelihood of use of firearms.**

38_5.3 Organizational Security Measures

Four organizational measures will help to insure the security of cash or shipment of valuables: **secrecy, staff selection, transport logistics**, and **technical aids.**

38_5.3.1 Secrecy

Robbery of high-value targets is always facilitated by knowledge. Therefore, secrecy is essential with regard to details of transport, including:

- **Method of transport;**
- **Amount of goods or value;**
- **Time of transport;**
- **Route.**

Employees can become willing or unwitting accomplices, hostages, or subjects of blackmail through the acquisition of this knowledge. Therefore, information as to value, routes, or time should not be provided to anyone until necessary.

38_5.3.2 Staff

Positive vetting should be required of all employees charged with the transport and protection of high-value items. Vetting should include the following areas of background investigation:

- **Age;**
- **Sex;**
- **Employment history;**
- **Criminal record;**
- **Civil record;**
- **Credit history;**
- **Physical suitability;**
- **Mental suitability;**
- **Previous law enforcement experience;**
- **Weapons experience;**
- **Previous training and experience;**
- **Previous responsibility.**

38_5.3.3 Transport Logistics

Transport logistics relate to issues involved in the conveyance of valuable goods from one point to another. The time, means of transport, methods of loading and unloading, and routes all have significant impact upon security. Issues to consider include:

- **Amount of exposure of valuables in transit;**

- **Amount of valuables in any one transport;**
- **Security measures that would be recognizable to a robber;**
- **Establishment of a routine that is predictable or observable;**
- **Variation of times, routes, vehicles, and personnel;**
- **Detours or delays;**
- **Distractions of staff;**
- **Number of employees accompanying the transport;**
- **Protective equipment carried by staff;**
- **Amount of valuables guarded by only one employee;**
- **Number of transports in relation to the amount of valuables;**
- **Turnover of employees;**
- **Ability to utilize alarm systems while in transit;**
- **Two-way communications;**
- **Response time for assistance in case of robbery;**
- **Use of second vehicle;**
- **Building construction for location of loading and unloading valuables;**
- **Security within cash or valuables transfer area;**
- **Traffic patterns at time of loading and unloading valuables;**
- **Use of weapons;**
- **Visibility of weapons for deterrent value;**
- **Use of hands for carrying valuables, and inability to utilize weapons because both hands are busy;**
- **Use of professional couriers.**

38_5.3.3.1 Armored Car Services

Professional courier services are preferred as a means of secure transport. The many advantages of using qualified companies are well known. However, vendors must be closely screened with regard to issues of personnel, liquidity, security, internal security measures against espionage and sabotage, and sophistication and maintenance of equipment. So long as qualified and responsible services are utilized, the security and efficiency of transport may be enhanced. Benefits of employing third-party contractors for high-value transport include:

- **Increased security;**
- **Professional staff training;**
- **Proper equipment;**
- **Reduction in cost of transport;**
- **Simplified administrative procedures;**
- **Lower insurance costs;**
- **Lower risk of loss;**
- **Simplified administration;**
- **Reduction in liability;**
- **Elimination of human resource issues;**
- **Reduction in scheduling conflicts;**
- **No moral responsibility for injury to bystanders if a robbery occurs;**
- **No legal issues relating to weapons training and handling;**

38_5.3.4 Technical Aids

Certain technical aids can act as a deterrent, making robbery more risky or impossible. Such aids include:

- **Method of storing cash: safe or vault;**
- **Construction of safe or vault;**
- **Use of time-delay locks or time locks (discussed in Chapter 33);**
- **Design of transport vehicle and incorporated physical security measures;**
- **Use of armored cars.**

38_6.0 Robbery Risks for Specific Businesses

As with burglary, there are higher risks of robbery in certain classifications of businesses. Such assessments are based upon many criteria, perhaps the most important of which is the value of target goods. The same high-risk businesses that were identified in the previous discussion about burglary are most susceptible to losses through robbery.

A risk survey for different types of businesses is presented for assistance in analyzing potential for losses primarily due to

robbery. Many of the same considerations apply to burglary. The survey is intended to provide those charged with the responsibility of protecting persons and property with a comprehensive checklist. Many of these issues correlate with our earlier discussion of physical security measures.

38_6.1 Nature of Risk: Specific Issues for Banks

Bank robberies present extreme risk of violence to staff, customers, and third parties. Security is based upon an approach that encompasses many techniques, with the ultimate goal of protecting human life. Measures that are adopted will in large part be based upon the organization of each bank and associated costs of implementation.

Any security measure must attempt to prevent the possibility of hostage-taking and unpredictable reactions on the part of the robbers. Thus, the practice of blocking exit doors, for example, is extremely dangerous. There are two basic methods to deter robbers and lessen the likelihood of an armed robbery: **increase the risk**, and **reduce the reward**.

38_6.1.1 Increasing the Risk of Bank Robbery

There are several risk factors considered by the robber:

- **Difficulties or complexities;**
- **Delays in execution;**
- **Increased risk of apprehension;**
- **Armed guards, both within the bank and outside;**
- **Bullet-resistant barriers;**
- **Remote video monitoring;**
- **Activation of silent alarms in an unobtrusive manner;**
- **Escape routes;**
- **Direct-wire alarm system to police;**
- **Reliability of alarm system;**
- **Protection of staff, using bullet-resistant barriers;**
- **Use of safety counters that create an instant separation between staff and customers upon activation. Raised panels can form an opaque barrier that can isolate robbers;**

- **Removal of direct contact with the cashier;**
- **Staff training in robbery prevention;**
- **Video or time-lapse cameras;**
- **Bait money, marked notes, recorded serial numbers;**
- **Cash bundles containing exploding dye or smoke, triggered upon leaving the bank, that makes use of the money impossible;**
- **Sophisticated holdup alarms with silent hostage notification;**
- **Time locks, notice of which is prominently displayed;**
- **Use of remote service centers and video terminals to handle customer transactions.**

38_6.1.2 Reducing the Reward

If cash or other valuables cannot be obtained by the robber, then there is no reason to commit the crime. Any physical security precaution or procedure that reduces the availability or access to valuables will have a tendency to thwart robbery attempts and ultimately reduce losses. The following procedures can be implemented to reduce the haul from a robbery:

- **The amount of cash at any teller cage can be reduced;**
- **Delayed cash withdrawal;**
- **Storing cash in a container with a time lock;**
- **Centralized cash storage with pneumatic tube transport. The cash-storage area must be totally inaccessible to robbers.**

38_6.1.3 Reducing the Overall Risk

The following steps may be taken to reduce the risk and attendant losses from robbery:

- **Surveillance, using film and video;**
- **Protection of cash on premises;**
- **Reduction of cash on premises;**
- **Use of special storage vaults with armored slots that do not require opening of the safe;**
- **Use of time locks;**

- **Varying of means of transport to bank;**
- **Varying of times of transport;**
- **Precautionary steps when entering or leaving premises with high-value items;**
- **Avoidance of use of entrances which are not visible or protected;**
- **Policy of not allowing persons to enter business prior to or after normal hours;**
- **Daily counts of cash and goods should be done only after the premises is locked.**

38_6.1.4 Organizational Procedures

- **Controlled access and authorization hierarchy;**
- **Key control and security;**
- **Personnel policies regarding remaining in secure areas and guarding assets;**
- **Periodic testing of security systems.**

38_6.2 Nature of Risk: Specific Issues for Businesses Dealing in Precious Metals, Gems, and Jewelry

Businesses dealing in jewelry, gemstones, and precious metals are especially vulnerable to robbery and burglary. They are a prime target due to the nature of the goods they sell, their portability, and ability to be easily fenced. Jewelers and gem dealers are high-risk businesses because they are not able or not willing to implement comprehensive security measures to prevent crimes against property. They, or their insurers, simply accept the added risk. Measures to reduce the potential for robbery must be adopted that will be effective, yet not obtrusive. The following issues are particularly relevant in evaluating and formulating an overall security program:

- **Staff training regarding robbery techniques and response procedures;**
- **Holdup alarms strategically placed within the store and at the entrance if manned by a staff member. Silent alarms should be disguised and readily available to staff. Regulations may require that there is a visible change in the status of the alarm**

when activated;

- **At least one staff member should be isolated from the main customer area. This individual should have an unobstructed view of the store and be able to activate an alarm without interruption;**
- **Do not leave customers alone once they enter the store;**
- **Observe all visitors to the store for suspicious movement or actions;**
- **Remote-controlled entry door locks that will admit only one person at a time;**
- **Bullet-resistant panels on front doors, windows, and showcases;**
- **Unobstructed view of the interior from the outside;**
- **Position staff members throughout the active area of the store in order that each can be observed by another employee, and it is impossible for a robber to capture all employees at one time, thereby preventing an alarm;**
- **Maintain valuable items in a protected area at all times;**
- **Keep less valuable items in controlled areas such as locked showcases, cabinets, or drawers that require keys or entry codes;**
- **Design showcases so that only one drawer at a time can be accessed;**
- **If high-value items cannot be kept in secure containers, then they should be displayed in a dispersed manner so that it is impossible for a robber to gather such items quickly;**
- **Remove high-value items from showcases during business hours only when showing to a prospective customer;**
- **Do not change display stock during normal hours;**
- **Show a customer only one item at a time;**
- **Utilize safes or vaults with storage areas that can be individually secured. Many small compartments should be available. A central locking device should block all but one compartment from access at any time;**
- **Keys for safes, vaults, and strong rooms should be**

located in secure areas that cannot be seen by customers. All key containers should be protected by time lock, and such fact should be visible to all customers;

- **Consider implementing a separate, secure sales area for special customers and high-value items. This room should have a separate security and access system as well as its own vault;**
- **Secure inside access to goods that are stored within display windows. Utilize locked wood, glass, or metal partitions.**

38_6.3 Nature of Risk: Specific Issues for Gas Stations

Gas stations and particularly 24-hour truck stops have always experienced a high risk of robbery, regardless of the location. Their vulnerability is comparable in many respects to banks and jewelry stores. The risk is based upon the following factors:

- **The type of service station: self-service or full service. In the latter, there is a higher risk;**
- **Early and late night operation;**
- **Large amounts of cash;**
- **Easy to case and observe;**
- **They do not attract much attention, even with loud noises;**
- **Rapid ingress and egress from the location;**
- **Small staff;**
- **Poor or inadequate security measures.**

The most common holdup techniques will usually involve one or more of the following scenarios:

- **Taking money directly from the attendant while outside at the service area;**
- **Taking money inside the station;**
- **Taking money from the owner, manager, or employee after business hours as they are leaving the premises.**

38_6.3.1 Reducing the Risk of Robbery

Certain steps can be taken to reduce the potential risk of robbery to gas station employees. These include:

- **Never handle cash in an unprotected area, i.e. outside the office;**
- **Cash should never be visible from the outside;**
- **Outside tills must be automatically locked and alarmed for tampering;**
- **Insure proper lighting of all areas, both inside and out;**
- **Protect all lighting fixtures from breakage;**
- **Provide an unobstructed view of all areas, both inside and out, by staff;**
- **Be certain that customers can look into all areas of the station;**
- **Telephones must be available to staff in a protected area;**
- **Provide separate telephone facilities for customers;**
- **Install local and silent-alarm systems with direct connection to the police for immediate response;**
- **Cash drops must be made throughout the day;**
- **Deposits must be made during business hours;**
- **Utilize safes with deposit slits;**
- **All safes must be encased in concrete;**
- **Keep all extra cash in the safe;**
- **No keys for the safe should be kept on the premises;**
- **Time-delay locks must be installed on all safes;**
- **Post a notice that safes cannot be opened by staff;**
- **Insure that shift-change procedures do not allow large amounts of cash to remain unprotected;**
- **All tills should be automatic locking;**
- **Separating walls of bullet-resistant glass should be provided between the cash desk and merchandise areas, thereby blocking access by customers to the cashier;**
- **Doors to the cashier area must automatically close and lock. A key must be required for entry;**
- **High-security locks should be used on all doors leading to cash-handling areas;**

- **Use sliding, rotating, or payment trays for cash transport between the cashier and customer.**

38_6.4 Nature of Risk: Specific Issues for Safes and Strong rooms

The following issues must be analyzed to determine potential risk of loss with respect to valuables stored in safes, vaults, and strong rooms:

- **Value and type of goods stored:**
  - **Cash;**
  - **Precious metals;**
  - **Gems;**
  - **Type of documents.**
- **Classification and type of container:**
  - **Make, model, serial number, year of production;**
  - **Security devices that have been installed;**
  - **Inspection and certification by testing institute;**
  - **Has the certification label been attached to the safe by other than the manufacturer or in an unauthorized manner.**
- **Mounting of repository:**
  - **Embedded in wall;**
  - **Thickness of wall;**
  - **Description of walls, ceiling, and floor material, thickness, structure);**
  - **Method of anchoring to wall;**
  - **Embedded in concrete;**
  - **Dimensions, height, weight;**
  - **If a safe, is it on casters;**
- **Dimensions of strong room;**
- **Type of alarm system and sensors;**
- **Use of time lock;**
- **Location of repository within the premises;**
- **Number of issued keys that can provide access to strong room or vault;**

- **Number of persons required to activate locking system;**
- **How many persons know the combination;**
- **Persons authorized to operate the locking system;**
- **Procedure for opening and securing the repository;**
- **Measures to protect against holdup;**
- **Can the repository be seen from the outside;**
- **Is there illumination on the entry to the safe or vault;**
- **What is the likelihood that noise will be heard from the outside in the event of a break-in;**
- **Have all prior attempts at burglary or robbery been evaluated for weaknesses in security.**

38_6.5 Nature of Risk: Specific Issues for Cash in Transit

There are certain specific risks associated with transporting cash and other high-value items. Factors that must be considered in determining appropriate security measures include:

- **Number of intermediate pickup points;**
- **Is the transport direct from the pickup to delivery point;**
- **Are there several transports at a regular interval from the same pickup to the same delivery point;**
- **Times of transport;**
- **If night transport, what is the lighting at the destination;**
- **What is the time required for each transport;**
- **What is the length of the transport route;**
- **Description of the transport route;**
- **Can streets with little traffic be controlled by robbers;**
- **Longer routes on high-traffic streets provide more security than secluded streets;**
- **Procedures in the event of roadblocks, accidents, or breakdown of transport vehicle;**
- **Coverage of two-way radio systems used by transport personnel;**

- **Intermediate storage of high-value goods while in transit;**
- **Is the location of pickup and delivery points varied;**
- **What goods are transported:**
  - **Value of goods for each transport;**
- **Highest value of goods transported;**
- **Description of transport destination:**
  - **Location of building;**
  - **Distance from nearest police station;**
  - **Description of the area: rural, residential, commercial, industrial, isolated;**
    - **Traffic patterns at transport destination:**
      - **Isolated and little traffic;**
      - **Normal traffic;**
  - **Continuous and heavy traffic.**
- **Are company employees or commercial carrier utilized for transport:**
  - **How many employees on the transport;**
  - **Experience and training;**
  - **Age;**
  - **Are employees security vetted.**

Transport personnel are often involved in thefts, either directly or as informants. Careful selection, vetting, and supervision is imperative. Periodic background investigations should be conducted that include credit history analysis. Changes in circumstances, behavior, and temperament of employees should be carefully monitored.

Rotation of transport personnel at short notice can reduce the risk of robbery and holdup. High-value transports should not be carried out by a single employee. If an escort is provided, a safe distance should be maintained from the transport to prevent interception by robbers. Issues for consideration include:

- **Is transport in a vehicle or on foot:**
  - **If a vehicle is utilized for transport, is it specially equipped;**
  - **Protection against robbery and burglary;**
  - **Equipment, weapons, and security measures for**

transport personnel;
  - **Escorts from police, military, or private guards;**
  - **Radio communications;**
- **Type of container used for transport:**
  - **Clothing, wallet, money belt, money bag, safe;**
  - **Simple transport container, such as a bag;**
  - **Cash-carrying case;**
  - **Repository.**

Non-secured methods of transport, such as in unprotected enclosures, are not recommended. The thought that inconspicuous transports are somehow more secure is inaccurate. Robbers will usually follow the transport from pickup point and wait for the most opportune moment. Issues to evaluate include:

- **Departure procedures from pickup point;**
- **Delivery procedures;**
- **Loading and unloading procedures. The risks associated with loading and unloading of high-value items can be reduced through organizational, technical and construction measures;**
  - **Organizational: additional specially trained and equipped security staff;**
  - **Technical: security containers;**
  - **Construction: entry and exit points that cannot be observed or penetrated by unauthorized persons;**
- **Limitation on the value of goods transported in any one shipment;**
- **Change in procedures to eliminate casing;**
- **Changes in passwords, codes, routes, and schedules.**

38_7.0 Master Key Systems

Master keying systems generally reduces security unless hybrid locks are utilized. See **Chapters 11** and **17** for a full discussion of locks and keying techniques. Almost all conventional master key systems can be compromised through a process of extrapolation, described in **chapter 31**. Issues to consider in evaluating the security of any keying system will include:

- **Levels of master keying, actual and required;**
- **Group master keying levels;**
- **Who should and should not have access to each specific area;**
- **Cross-keying potential;**
- **Use of restricted or different keyways;**
- **Time of day restrictions;**
- **Delay upon entry;**
- **Lockout capability;**
- **One-way entry restrictions;**
- **Audit functions;**
- **Number of keys in the system.**

Security can be enhanced by implementation of the following procedures:

- **Maintain a complete listing of all locks that are master keyed and the location where installed;**
- **Maintain a complete register of key issuance;**
- **Minimize the number of master keys released in the system;**
- **Do not allow unauthorized persons to have keys in their custody, use, or view;**
- **Maintain all spare master keys in a locked, controlled access cabinet;**
- **Conduct routine key audits of master keys;**
- **Do not let unauthorized persons make copies of keys;**
- **Know your locksmith or person/organization responsible for changing, repairing, or rekeying locks;**
- **Establish a procedure for providing access to maintenance personnel and other outside workers. Do not loan keys to such individuals without a proper policy of identification and background checks;**
- **Removable-core or construction locks should be employed in new facilities so that keys may be changed prior to utilization of the building;**
- **Select locks employing restricted keyways.**

CHAPTER THIRTY-NINE:

Security: Physical Protective Measures

Master Exhibit Summary

Hinges and forensic evidence. Courtesy Don Shiles.

Case example: removal of sliding glass door. Courtesy of Don Shiles.

LSS202: Ross Anderson on biometrics

39_1.0 Introduction

This chapter presents detailed information about physical security devices and technologies, encompassing hardware and structural components. An examination of the proper application of security hardware, together with common methods of bypass and forced-entry, is intended to complement the information presented in **Chapter 38.** Organizational measures, where relevant, are suggested with respect to the implementation and use of security devices.

Physical security measures can be organized within two primary classifications: external access protection, and internal protection of specific assets or areas. Within each primary category, the principal devices, technologies, materials, and construction techniques have been described. Alarm systems are treated as a separate topic in **Chapter 40. Munich** Reinsurance Company, Munich, provided much of the information and graphics for this chapter. Appreciation is expressed to them for their assistance.

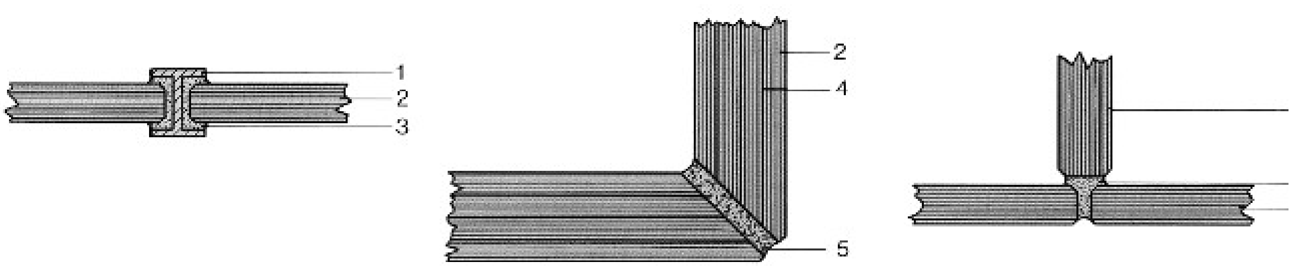
PART C: Perimeter Protection

External Access Protection

The following discussion shall examine the components that are

involved in the external or perimeter protection of property. Included in the materials shall be the hardware, barriers, safeguards, and procedures that prevent an intruder from gaining access to a building or other secure area.

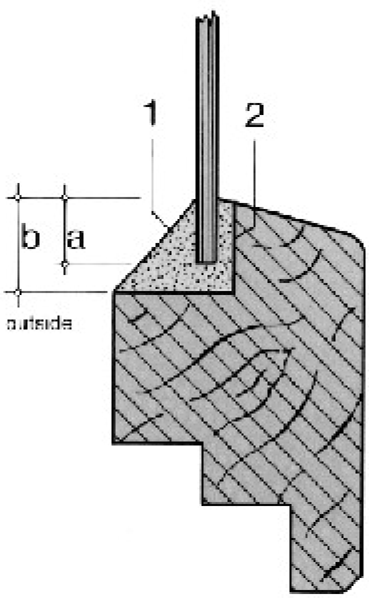
39_2.1 Glass



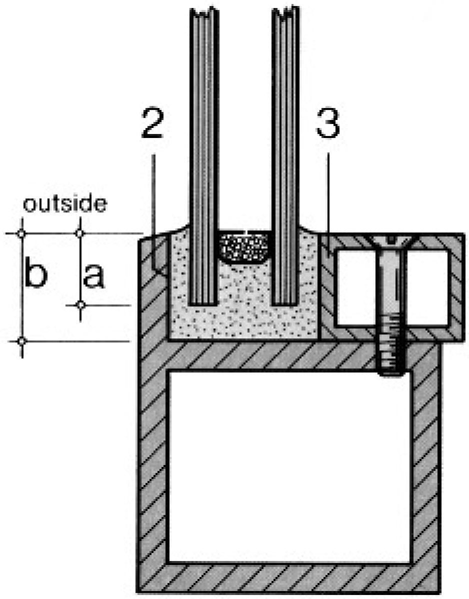
Glass is used extensively in commercial locations. It provides an attractive method of entry, due to its characteristics of brittleness and ease of destruction. Although the shattering of glass can generate noise and create a risk of injury, it is still a favored target for burglars. There are many different types of glass, depending upon the intended use. Characteristics that differentiate each primary category include:

- **Thickness;**
- **Tensile strength;**
- **Thermal transfer specifications;**
- **Noise conductivity;**
- **Mounting.**

39_2.1.1 Ordinary Glass

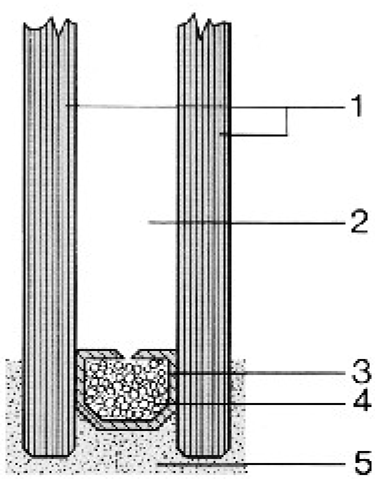


Ordinary glass should not be used in any location where burglars may effect entry by smashing it. Regardless of thickness, it will provide no security. Standard glass should always be protected with alarms and mounted bars to reduce the risk of smash-and-grab attacks.



39_2.1.1.1 Installation of Ordinary Glass

The following guidelines apply to the installation of high-quality glass panes and construction of window frames and joints:



- **Compliance with installation instructions from the manufacturer;**
- **Glass installed with unprotected elastic sealant can be easily removed once the putty has been destroyed. Glass should always be mounted from the inside;**
- **Rebate grooves and mountings must be designed to resist external attack;**
- **Glass rebate depths must take into account the elasticity of glazing when plastic is utilized to maintain the position of panes;**
- **Joints must be protected from attack. Elastic sealant should only be used with such protection.**

39_2.1.2 Insulating Glass

Two or more panes of standard glass, separated by a gap of dry air or gas, are utilized where thermal transfer and sound absorption is desired. Contrary to popular opinion, a vacuum does not exist between the panes.

39_2.1.2.1 Two-Ply Insulating Glass

Insulating glass is comprised of panes separated by air gaps, spacers, dehydrating agents, and elastic sealant.
Burglary-resistance ratings are based upon the specifications for

individual panes: if ordinary glass is utilized, it has no special properties.

39_2.1.3 Wired Glass

Ordinary glass may have netting, braiding, or a wire lattice embedded during production for protection against fire and injury. The glass has no special burglary resisting properties and can easily be shattered. The purpose of the wire is to maintain a bond between glass fragments once the pane is broken.

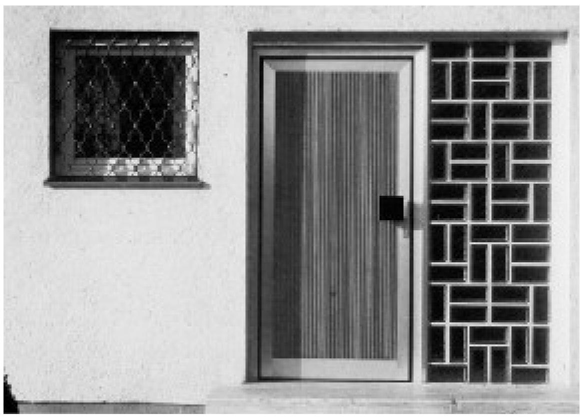
39_2.1.4 Alarm Glass

Multilaminated glass panes are inset with fine silver wires, and are integrated within an alarm system to sense penetration. Wires are configured in a continuous loop to maintain electrical continuity. When the glass is broken, the series circuit is interrupted.

Alarm glass consists of silicate panes, bonded with intermediate plastic layers with embedded wires, terminated at connecting points. Wires can be run horizontally or vertically with spacing of 20-35 mm. This is not the multilaminated wired glass that is discussed in **2.1.3** above. The difference is in the termination of the wires, which in the former case are laid in parallel and cut off at the edge of the pane. Alarm glass provides a higher level of resistance to smash-and-grab burglaries.

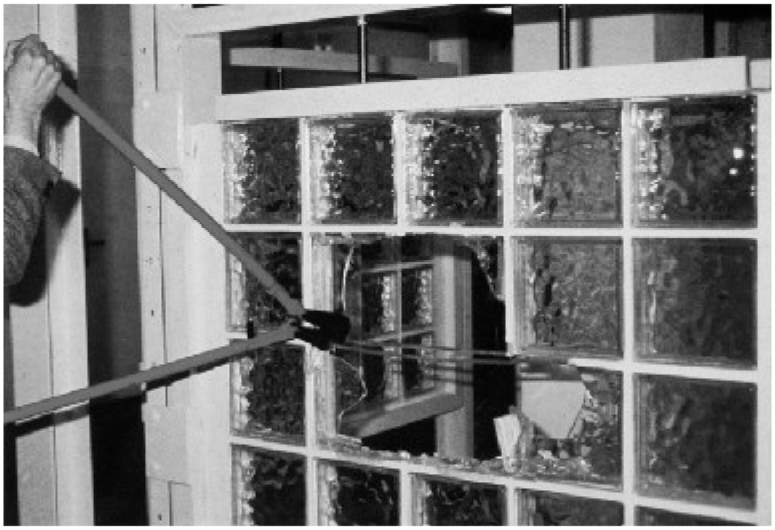
39_2.1.5 Security Alarm Glass

Security alarm glass provides more protection against forced-entry than alarm glass with a wire inset described above. A loop of alarm foil measuring approximately 7 x 5 cm is burnt into a pane of toughened prestressed glass. When the glass shatters, it breaks into very small fragments, causing a loss of electrical continuity. Security glass must be used with other translucent materials to prevent smash-and-grab attacks. The foil loop should be located on the inner face of the outer pane on the attack side. This will insure the earliest possible initiation of an alarm.



39_2.1.6 Toughened Safety Glass

This type of glass, known in Europe by the brand name Sekurit, is used in automobiles, doors, and gymnasiums. The silicon is prestressed by heating and air cooling during production. It can



be up to six times more elastic than ordinary panes and can withstand increased pressure from blunt objects. The material is sensitive to striking by pointed instruments and in such cases will shatter into small granular pieces.

39_2.1.7 Glass Bricks

Glass bricks are popular for use in both commercial buildings and residences. They allow the transmission of light and serve as a deterrent to burglars. The smaller the brick, the more security is provided. Both vertical and horizontal reinforcement in fine-grained concrete or mortar is required.

Round or flat steel bars can be used to augment the structural integrity of the brick lattice. They must be strong enough to withstand attack by bolt cutters and saws. The lattice should be such that at least four bricks must be destroyed in order for a person to climb through the hole. The bars are anchored securely, so that they cannot be removed.

39_2.1.8 Laminated-Isolated Glass

Laminated glass consists of two or more panes and is separated by plastic interlayers. This material is utilized to resist bullets, penetration, explosion, and perforation. If the glass is shattered, fragments are held in place by the interlayer. The security rating of laminated glass is based upon thickness, number of panes, and interlayer material. Based upon thickness and design, laminated glass should be resistant to the following forms of attack:

- **Chemicals;**
- **Temperature extremes;**
- **Mechanical attacks with hammers, chisels, picks, pickaxs, pendulums, axes, saws, diamond cutting tools, grinders, drills, and explosives. Extensive testing has demonstrated that a five-pound pickax is the most suitable weapon for attack.**

Laminated panes are also utilized where bullet resistance is required. Properties that determine the resistance to high-velocity projectiles include:

- **Total thickness of the panes;**
- **Number of interlayers or polycarbonate panes;**
- **Construction of the frame and fittings: material and dimensions;**
- **Means for securing the glass within the frame;**

- **Means of securing the frame to the surrounding structure;**
- **Direction and intensity of attack;**
- **Splinter projection properties.**

Laminated glass is provided in two primary configurations: **silicate glass panes** and **silicate-polycarbonate.**

39_2.1.8.1 Silicate Panes with Plastic Films

Silicate panes are interleaved with plastic layers made of polyvinyl butyral to form a cohesive bond. Thickness of the interlayer and ambient temperature will determine resistance to penetration. Reduced temperatures cause the interlayers to become brittle, which reduces their resistance to attack. Composite glass panes are extremely heavy. One square meter of glass, 400 mm thick, weights approximately 200 pounds.

39_2.1.8.2 Silicate-Polycarbonate Glass

Polycarbonate material is mainly used as a primary glazing, or as a moveable secondary pane. The chemistry allows the shape to be changed, allowing adaptation to diverse requirements. Silicate-polycarbonate panes are bonded with a gelatinous-type synthetic resin. This glass is produced in thin panes, with a high degree of resistance to forced attack. The size of the panes is limited, however, due to the differences in thermal expansion characteristics between the two substances.

Polycarbonate is a thermoplast material. Its color ranges from completely transparent to yellowish, and its translucency is about equal to standard glass. Specific gravity is 1.2 (expressed in g/cm^3), or 50% less than that of glass. The material was developed for its tough and elastic properties to resist blunt force penetration by bending, but not breaking. Thus, rocks and dull instruments will not destroy the integrity of the surface.

However, it is relatively simple to drill, saw, and shatter this type of glass with the proper tools, as it has higher notch sensitivity than other materials. There are differences in identical polycarbonate formulas which are caused by fluctuations in quality during manufacturing. The material is not adversely affected by temperature, unless it drops below -100C. At that point, it will lose some of its toughness and become brittle. It

has a heat-expansion coefficient that is eight times greater than glass.

Several drawbacks may be experienced when polycarbonate material is utilized. Careful attention should be paid to the following issues whenever this type of glass is installed:

- **Special and complicated frames are required due to the weight and thickness of the composite glass;**
- **The mountings for glass must be constructed to be stable on all sides;**
- **A greater depth of glass will require special mountings;**
- **Discoloration and reduced light transmission will occur;**
- **Polycarbonate panes can be easily cut using simple tools and without creating any noise;**
- **This material is not suitable for display windows without other protection and should only be used as a secondary pane of glass;**
- **Glass-breakage alarm systems do not work on this type of material;**
- **Based upon chemical properties of hardened glass, static loading occurs that can often lead to the panes becoming dirty;**
- **The material is more sensitive to chemicals than is regular glass;**
- **Once mounted, it is very difficult to determine if polycarbonate or acrylic material has been installed. The latter has a much lower resistance to blunt force instruments;**
- **The greater heat-expansion coefficient requires that special installation guidelines be followed;**
- **The size of the panes must be restricted;**
- **Carbonate glass can be drilled or sawn.**

39_2.1.9 Shatter-Resistant Films

Sheets of polyester film measuring .05-.1 mm thickness can provide an added shatter-resistant exterior surface to other forms of glass. They are tough, resistant to tearing, and absorb ultraviolet rays. Additional benefits include solar protection

and prevention of outsiders looking into a building.

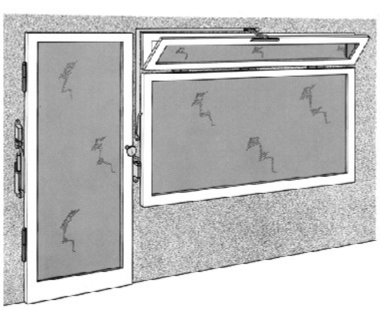
Available in clear or metalized films (coated with a thin film of precious metal), they are applied with a special adhesive to the inside surface of a window. There are four primary advantages to using these films:

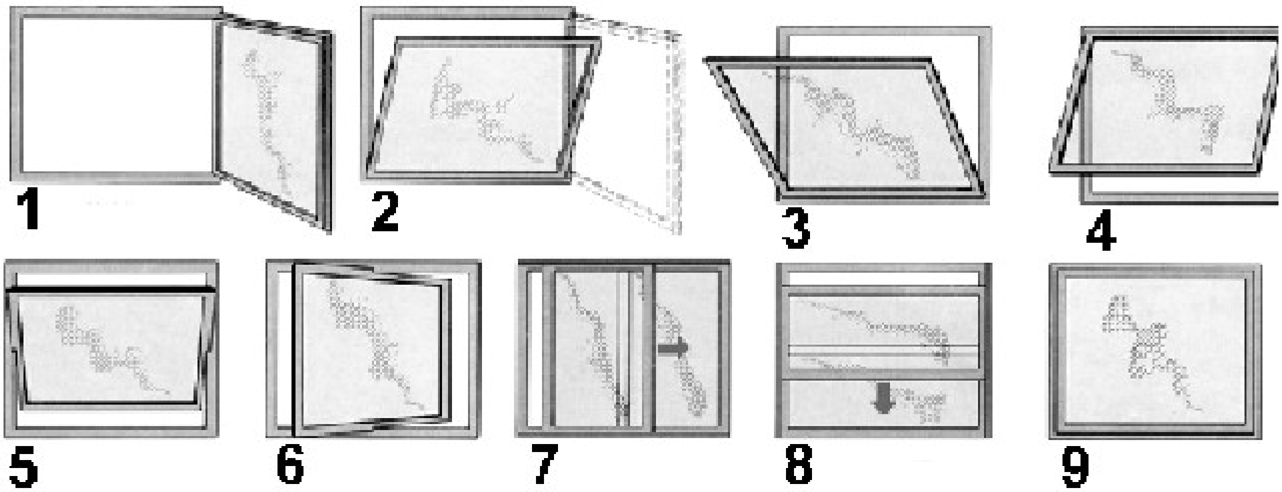
- **Material retains splinters from broken glass;**
- **Small improvements in ability to resist penetration;**
- **Can be applied to existing windows;**
- **A slight time delay can be caused to burglars.**

There are many disadvantages to shatter-resistant films:

- **Transmission of light is reduced;**
- **Cleaning can damage the surface of the film;**
- **Reduction of noise caused by the breaking of glass during a burglary;**
- **Surface can be pierced or slit with a sharp blade or knife once the pane has been broken;**
- **Glass-breakage detectors do not function properly;**
- **The setting time is 3 - 4 weeks;**
- **Based upon extensive tests at the German Property Insurers' Association in Cologne, there is little if any increased resistance to perforation, at impact energies of from 250 - 370 J. This contrasts with claims of manufacturers regarding perforation-resistance, burglary-resistance, and bullet-resistance characteristics of these films.**

Impact energy of 249 J is equivalent to the force delivered by a 4.1 kg steel ball dropped from a height of 6.2 meters (about 20 feet). In a test to determine resistance to impact, a projectile thrown at a first-floor window with 360 J of force would have broken through the film and fallen into the protected area.





39_2.1.10 Secondary Panes of Glass

Secondary panes of glass are utilized as an additional barrier to protect against smash-and-grab burglaries. The subject is covered in more detail in Section **19.0**.

39_2.2 Windows

A window used as a method of access is a prime target. This is because they are among the weakest parts of a building. Generally, the pane is shattered, then the door handle is manipulated to open the lock. Windows that cannot be opened or that are secured with a lock are not as inviting a target. The removal of glass shards and splinters prior to entry presents both a delay and danger of injury, to say nothing of the distinct noise.

Certain primary measures can be taken to secure windows against easy entry. These include:

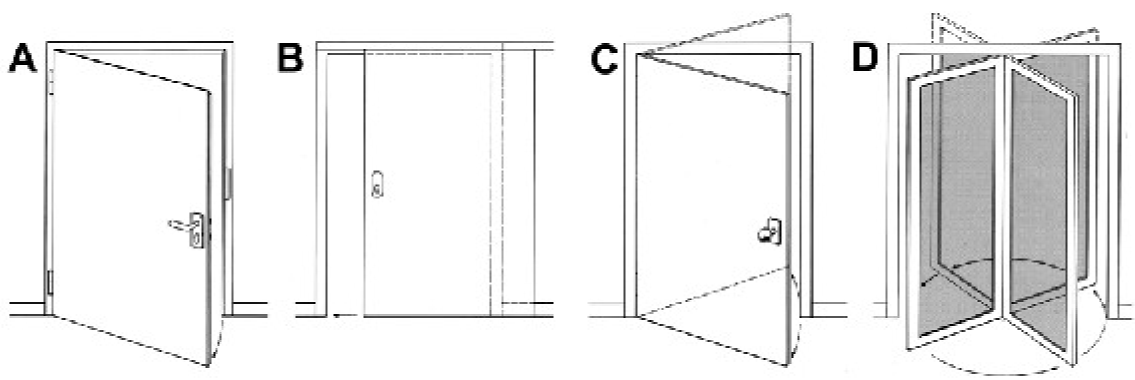
- **Windows should be well illuminated, especially on ground floor;**
- **Ground floor windows are particularly vulnerable, especially if set back from the street;**
- **Do not consider any windows as inaccessible, even on upper levels. The height of the window above ground floor must be considered;**
- **Key locks should be utilized on any window that can be easily reached from the outside, including those accessible to projecting walls, canopies, drainpipes, or ladders;**
- **Windows that are never opened should be secured with screws into the frame;**
- **Added security measures may be necessary in instances where windows cannot be observed or where noise from glass-breakage will not be heard. Such action might include:**
    - **Installation of alarm trips on windows, such as lead foil, high-frequency sensors, embedded wires, photoelectric beams, volumetric sensors, vibration detectors, and magnetic contacts;**
    - **Window bars or other physical security devices;**
    - **Folding and detachable shutters;**
    - **Roller shutters and locking device;**

- **Lexan or other synthetic polycarbonate glass;**
- **Glass bricks or honeycombed concrete;**
- **Panels made of acrylic (Plexiglas) can be easily melted with a soldering iron, torch, acid, or cigarette lighter. They must be protected by gratings;**
- **Verify the security rating of safety glass. There will be an identification stamp etched in one corner;**
- **Panes can often be forced out of their housing or dismantled from the outside. Gratings must be anchored in order to secure windows properly;**
- **If bars are utilized to protect windows, cross-joints must be constructed to prevent a car jack or other implement from prying them loose;**
- **Cellar windows must be protected due to their location and because they are often of simple construction. Burglars prefer them as a point of entry. If bars and gratings are utilized, they should be constructed to prevent the use of bolt cutters, saws, and other power tools.**

39_2.2.1 Display Windows and Showcases

Display windows and showcases are a prime target for smash-and-grab burglaries; they are rarely used for entry. Risk should be assessed based upon the value of items displayed, and the volume and quantity of such merchandise.

Physical protective measures as well as alarms are recommended. Devices and appliances that can augment security include the following:

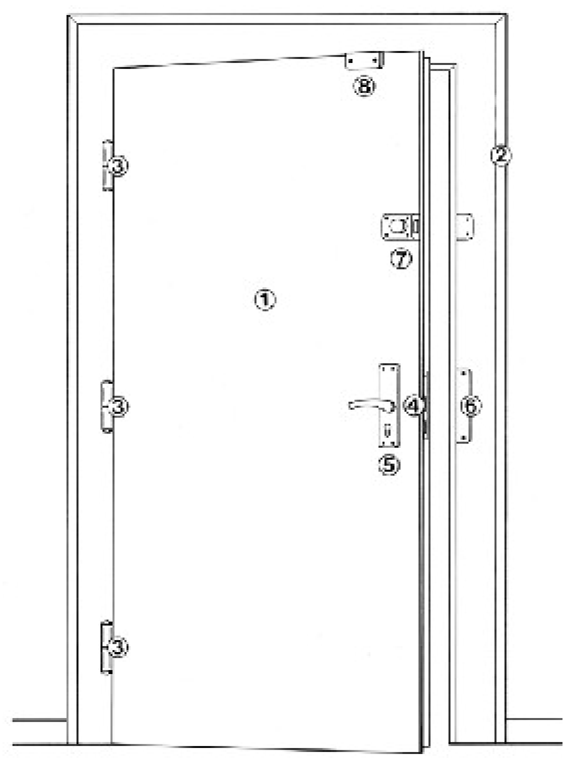


- **Lighting, especially halogen and strobe, when combined with local alarms can help to scare off burglars;**
- **Plainly visible cameras can also act as a deterrent and aid apprehension;**
- **Roller shutters with a blocking device to prevent their being raised;**
- **Roller or folding grating;**
- **Detachable grating that is inside or outside of the window;**
- **Falling grating;**
- **Laminated glass;**
- **Bullet-resistant glass;**
- **Secondary panes of glass;**
- **Fastening of objects using screws, chains, or other devices;**
- **High-quality locks;**
- **Prevention of removal of goods by "fishing" them between panes of glass.**

39_2.3 Doors

This section describes the different types of doors, based upon their design, construction, and vulnerability to attack. Unfortunately, criteria for choosing a door is usually based upon other factors such as space, intended use (passage of people or goods), design, and appearance. Security is often a secondary concern. A door is an obvious and favorite target of burglars for many reasons:

- **They provide the primary ingress and egress to most buildings;**
- **They provide the primary route for transport of stolen goods from the premises;**
- **They can be forced open, often quickly and with little difficulty;**
- **They can, in many cases, be bypassed inconspicuously;**
- **Little noise is created during forcible entry.**



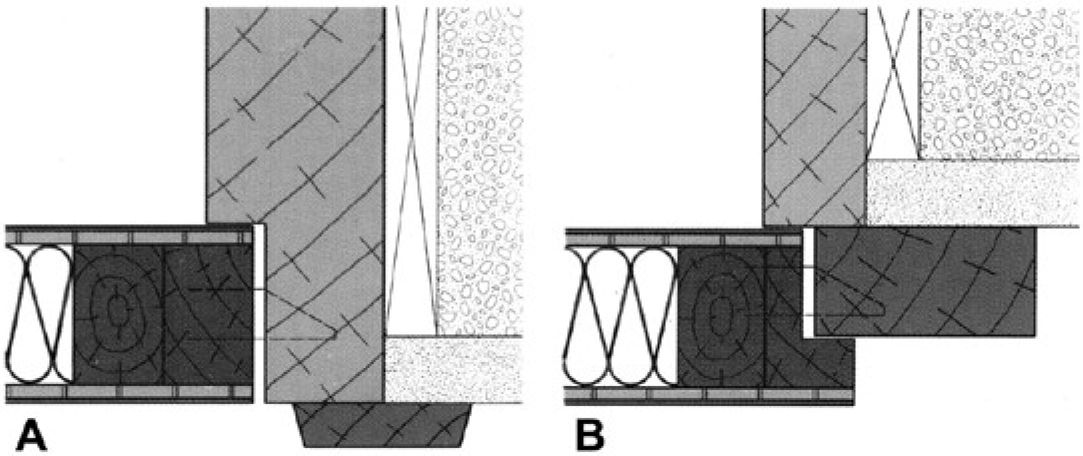
39_2.3.1 Types of Doors

The following primary classification of doors shall be considered in this chapter:

- **Standard door;**
- **Swinging door;**
- **Sliding door;**
- **Four-leaf revolving door.**

Within each classification, nine subcomponents and systems provide the capability for a door to perform its function:

- **Leaf;**
- **Frame;**
- **Hinges;**
- **Lock;**
- **Escutcheon;**
- **Strike plate;**
- **Security bolts;**
- **Method of engagement;**
- **Surveillance devices.**

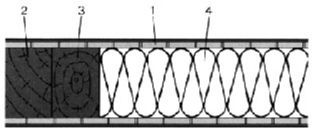


39_2.3.1.1 Method of Engagement

Doors can engage the frame and strike plate in two configurations: **flush mounted** and **offset.** A **flush-mounted** door has three advantages: simple leaf design, simple hinges, and low

cost. The disadvantages are that the lock bolt is unprotected and easy to reach when doors open to the outside.

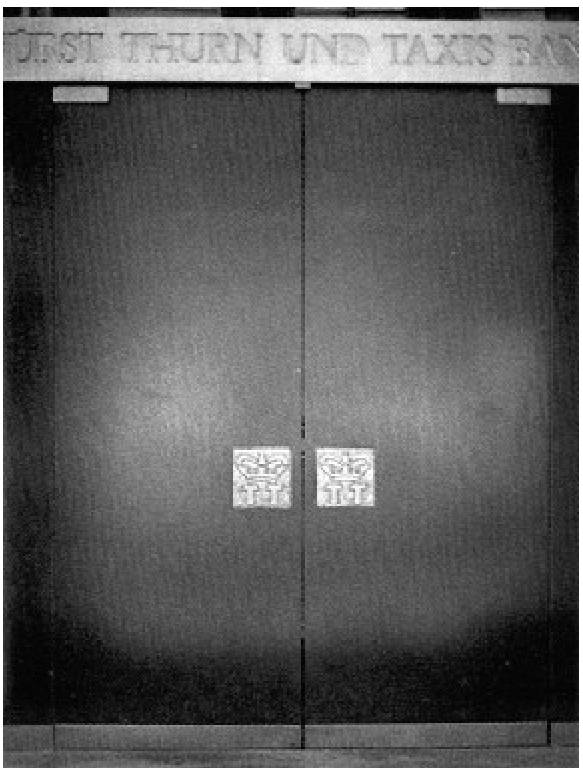
The design of an **offset door** protects the bolt and opening, making them difficult to break open. The leaf design is more complicated and thus more costly. In addition, the leaf is usually weakened on one side, based upon the installation of the lock.



39_2.3.2 Component Analysis: Construction and Security

This section evaluates the components of a door and their potential security deficiencies.

39_2.3.2.1 Leaves



The leaf comprises the major portion of the door. It is usually made of metal, glass, plastic and synthetics, or a combination of these materials. The security of door leaves depends in part on the profile, the strength of escutcheons, and the reinforcement of profiles.

39_2.3.2.1.1 Glass Leaves

A door that is made completely of glass is generally constructed with a single pane of **prestressed safety glass**, varying in thickness from 8 - 12 mm. Glass doors must be regarded in the same manner as windows with respect to security. If burglary-resistant laminated glass is utilized, it is not suitable as an all-glass leaf; framing is required on all sides.

There are three critical characteristics for prestressed safety glass:

- **The glass is up to six times more resistant to**

bending forces than ordinary glass;
- **It is harder at the surface than ordinary silicon-based glass;**
- **Shock from a pointed source will cause fracture and shatter.**

The reference to glass doors as “safety doors” is misleading and has nothing to do with security. It merely indicates that the glass, when shattered, will break into small blunt pieces to prevent injury.

Glass inserts are used in all forms of doors. The panes are generally supported by strips on both sides, surrounding notches or openings into which the glass is set, or by putty. Proper protection can be afforded by the use of a grid of burglar-resistant glass with retaining strips screwed into place.

39_2.3.2.1.2 Plywood Leaves

Multilayered plywood leaves are inexpensive, simple to produce, and are the most commonly used material within buildings and residences. Security is dependent upon the configuration of both the center and surface layers. Many different materials are used for inner layers of doors. These include:

- **Plywood;**
- **Honeycomb plastic;**
- **Cardboard;**
- **Paper;**
- **Hard fiber lattice;**
- **Chipboard sticks;**
- **Pressed straw;**
- **Glued solid wood sticks;**
- **Wood fiber plates;**
- **Chipboard;**
- **Solid frame and filling.**

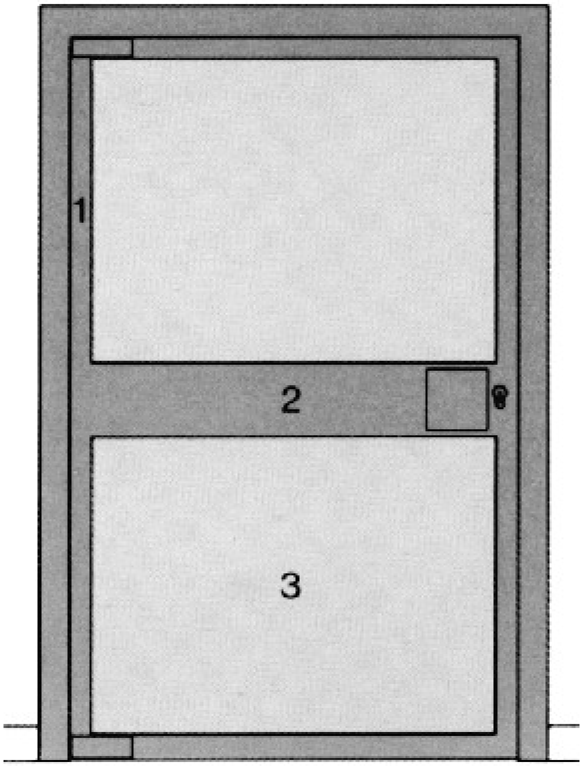
39_2.3.2.1.2.1 Glued Solid Wood Sticks or Chipboard

Center layers of glued solid wood sticks or chipboard sticks cannot be characterized as solid wood door leaves. They provide little security against forced attack from simple tools.

39_2.3.2.1.2.2 Honeycomb Layers

Honeycomb layers of material do not offer any security, unless they are reinforced with surface layers.

39_2.3.2.1.2.3 Solid Frame and Filling



Leaves may be constructed from smooth or compressed wood filling. In either case, they provide little security. Generally, smooth material is only 5 - 12 mm thick, and pressed wood fillings are 16 - 22 mm thick.

39_2.3.2.1.2.4 Solid Frame and Solid Panels

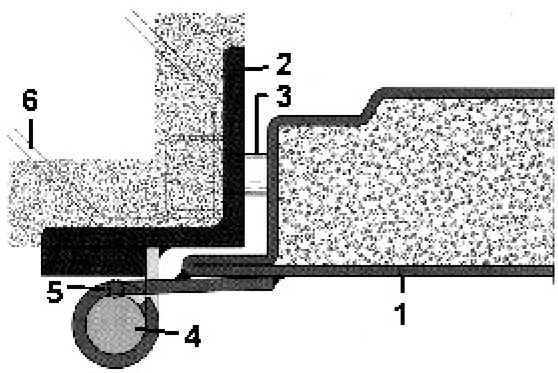
Door leaves having solid wooden panels provide resistance to attack and are used on perimeter doors. Materials such as steel plate or solid hard woods can be used as the core, sandwiched between outer panels. Other materials, such as plastic, metal, glass, or glued wood provide less protection and rely upon metal frames.

39_2.3.2.1.2.5 Metal Frames

Slender frame profiles made of aluminum or other light metals should have transverse reinforcements, and centerpieces surrounding the lock. These will increase the stability of the leaves and resist bending by levers, pry bars, and other wedges, thus keeping the lock bolt from being pried from the strike plate.

Certain design parameters of door leaves with metal frames can affect security. Issues that must be evaluated include:

- **There is often a large gap of up to 20 mm between the leaf and frame, offering access for wedges;**
- **Reinforced profile locks must be utilized with a small opening between the leaf and frame;**
- **Long security shields for profile locks are generally not available;**
- **Bolts are often relatively short (less than 20 mm), based upon the dimensions of the frame;**
- **Locks with swing, hook-type, or extra length bolts should be utilized to prevent jamb spreading;**
- **Penetration-resistant glazing should be utilized;**
- **Grids on the inside of doors may be employed. However, they are often made of light aluminum and provide little protection.**



39_2.3.2.1.2.6 Synthetic Door Leaves

Burglar-resistant door leaves can be produced with steel frames having glass-fiber reinforced plastic shells on both sides. These will provide security if they are at least 5 mm in thickness on each side. A reinforced shell behaves similarly to a polycarbonate panel, without the vulnerability to impact. Such leaves are often more than 60 mm thick and thus can be fitted with high-quality locks and escutcheons.

39_2.3.2.1.2.7 Steel Door Leaves

Doors with steel leaves are used for fire protection. These often contain double panels and will provide resistance to forced-entry. The following security measures should be taken to insure that doors would not fail during a forced-entry attempt.

- **Utilize high-security lock cylinders;**
- **Hinges should not be fitted externally;**
- **Hinge pins must be secured in position;**
- **Hinge bolts should be welded in place;**
- **Hinges must be mounted to protect them from cutting and blunt force attack;**
- **Steel plate, more than 2 mm thick, may be utilized as a surface covering for even greater security. Such plate should be bolted from the inside.**

39_2.3.2.2 Door frames

Frames can be manufactured from wood, metal or synthetic materials. Leaves and frame are often not made of the same material, and so each must be evaluated individually for strength and resistance factors. There are at least three types of frames:

- **Low security and internally mounted**

frames;
- **Frame and door leaf of same thickness;**
- **Steel-profile frames.**

39_2.3.2.2.1 Low Security and Internally Mounted Frames

These are provided to cover the interior surface of the masonry around the door openings and are used in conjunction with strips that cover joints of the door casing. Weak chipboard, rather than solid wood, is generally used. Frames are normally glued rather than bolted or nailed to the wall. A sharp tool can be used to separate the materials, allowing removal of the door from its hinges. Likewise, the hinges and locking plates are usually fastened to the strips, thus providing no security. Doors may also be hinged flush to the edge of the frame, leaving a gap between frame and leaf. This can provide direct access to the lock, bolt, and strike plate. It is also common for a gap to exist between the wall and frame, based upon the type of mounting.

39_2.3.2.2.2 Frame and Door Leaf of Same Thickness

Outer doors as well as heavy internal doors are often mounted in frames that are designed exclusively to secure the door leaf. Usually the leaf and frame are of the same thickness. Past construction practices required that such frames were cemented to the wall with masonry anchors. Today, dowel pins and long bolts are the primary means of fastening; the space between frame and masonry is filled with a soft material.

39_2.3.2.2.3 Steel-Profile Frames

Properly engineered and installed steel-profile frames are more resistant to forced-entry than their wooden counterpart. In order to ensure security, they must be reinforced and rigidly connected to the wall, with no leverage points. Single-leaf door frames must be fastened with flat anchor supports. Welded-on casings around bolts and latch openings, welded hinges, and metal exceeding 2 mm in thickness will improve the chances of surviving a forced attack.

39_2.3.2.2.3.1 Security Requirements for

Installing Frames

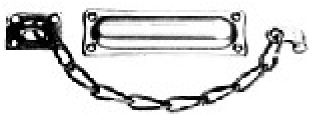
The following guidelines should apply for the installation of frames to insure maximum resistance against forced-entry:

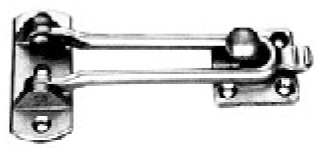
- **Door frame and leaf should be flush mounted, facing outward;**
- **Doors should open to the inside;**
- **Hinges should be located on the inside surface of the door;**
- **The door frame should be secured by a continuous bottom threshold;**
- **Steel-profile frames and cases may be utilized for added security. These can be built into the wall during construction or held in position by cast cement mortar.**

39_2.3.3 Supplemental Security Components for Doors and Associated Hardware

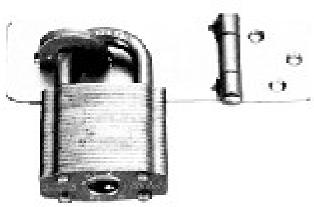
A wide range of additional security components is available for doors. In the following material, reference will be made only to the most common systems that are suitable for later installation.

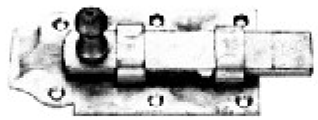
- **Door chains and brackets made of heat-treated steel must be securely fastened to the door, leaves, frames, or walls. If not properly attached, they may fail from the application of force, such as caused by kicking the door;**
- **There must be minimal clearance for the door to open with a chain attached. If sufficient room exists to insert an arm or manipulation device when the door is ajar, a rubber band may be attached to the end of a night chain to pull it to the unlocked position upon closing the door;**
- **Locking bars and padlocks can provide increased security to doors and gates. Safety hazards must be considered, because these devices can only be locked or unlocked from one side;**
- **Locking bars and sliding bolts must be fabricated with heat-treated materials;**
- **Panic bars on double doors can be easily bypassed by sliding a hooked tool between the doors and catching**





the moving arm. A device called an astragal can be installed to prevent the practice;





- **Fixing screws should be completely covered by a locking bar or should be designed to prevent bypass;**
- **Sliding bolts at the top and bottom of a door should be used on all entrances that do not require opening from the outside. Mounting screws must be installed at a right angle to the direction of the application of force;**
- **Bolts should be secured in a locked position with a padlock;**
- **Box locks may be utilized instead of mortised inset locks. These devices can pose special security concerns, including:**

    - **When mounted on hollow door leaves, the rear mounting screws must not extend into hollow cavities. The manufacturer may provide outer cover plates that are screwed on from the inside;**
    - **Box locks cannot be securely mounted on frames made of chipboard. Steel plate or angle plate should be utilized;**
    - **If mounted on doors with glass panels, the box lock must be capable of being locked from the inside;**
    - **Mortise bolt locks are preferred to box locks.**

- **Supplemental locks must have the housing fitted securely on the frame or in the wall;**
- **If electromagnetic locks are utilized, the release button must be protected by some form of shield. This will prevent a flexible wire from being routed under or around the door to activate the button;**
- **Electromagnetic locks must be tested frequently to insure that they have not been surreptitiously bypassed. A thin piece of paper or plastic covering of the surface will defeat the magnetic field and render the lock ineffective;**
- **Double bolt or cross-bolt locks can be fitted to the inside of a door to increase security with the addition of the following hardware:**

- **Solid steel bolts on both sides;**
- **Bolt projection by 80 - 100 mm, controlled by a gear-wheel;**
- **Use of profile cylinders.**

39_2.3.4 Burglary-Resistance Standards

Based upon extensive testing, the following security standards apply to doors:

- **The frame must be securely fastened in the wall;**
- **The leaves, whether made of wood, metal, or plastic, must offer adequate resistance to burglary attempts;**
- **Wooden-leaf doors should not have hollow cavities;**
- **Doors should have at least three heavy hinges;**
- **Any door that opens to the outside should have suitable security devices or hinge bolts;**
- **Primary and supplemental locks must be capable of withstanding a substantial load;**
- **The lock must be protected from external tampering;**
- **Cylinder locks must always be fitted with a drillproof escutcheon. It must be bolted on from the inside with screws measuring at least 8 mm in diameter;**
- **Strike plates must be constructed of high-quality steel;**
- **Strike plates must be properly fastened;**

- **Openings in steel-profile frames for latches and bolts must be suitably reinforced;**
- **There should not be any glazed openings or letterboxes in the door leaf.**

39_2.3.5 Balcony and Patio Doors

Balcony and patio entrances are favorite targets of burglars because they usually have inferior doors and locks. Generally, entry is effected by breaking a pane of glass in an unprotected door near to a locking handle or by defeating the locking mechanism. Bypass of locks is often accomplished by drilling into the frame.

Swinging doors and windows present a higher risk of bypass, especially if found in the tilted position. If the brace is severed or forcibly disengaged, the door can be easily opened. Locking handles and bolts offer no protection in such case. It is suggested that energy-saving mountings that provide a very narrow gap be utilized.

Lifting doors are easily compromised. A hole is drilled above or next to the lever, then a rod is inserted. The lever is released and the door is raised with a crowbar. The best solution appears to be a lockable "shoe" that fits over the actuating lever on doors and windows. Lockable shoes must cover the lever, thereby preventing its movement. Additionally, the shoe or other device must be incapable of being unscrewed or broken. It is recommended that such devices be utilized on all locks that control sliding or lifting doors.

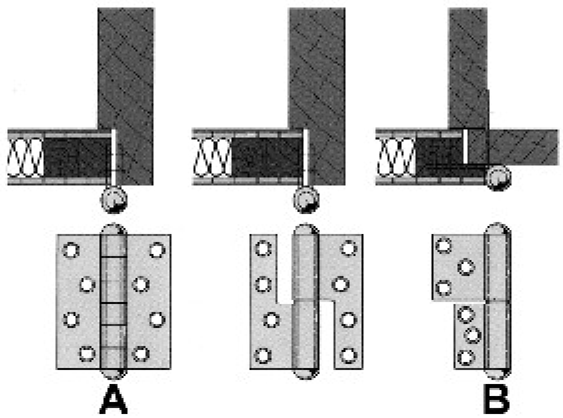
39_2.3.6 Sliding Windows and Doors

- **Sliding glass doors and windows move horizontally within a track. They can be removed by lifting out of that track. This practice can be prevented by installing two panhead metal screws in the top of the track at each end of the door. They should almost touch the top of the moving frame when the door is in the closed position;**
- **If an obstacle, such as a board or broomstick is utilized to keep a sliding door in place, it should be high enough to prevent the door from being lifted above the obstacle;**

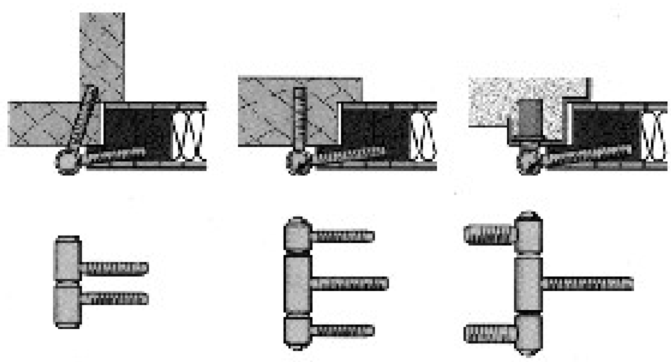
- **Inexpensive latches on windows should be replaced due to their simplicity in design and bypass capability;**
- **Be certain that latches on sliding doors are not installed upside down. In such cases, they can be vibrated to the open position;**
- **The catches or locking pins on double-hung windows can often be compromised with a thin blade knife or by drilling. Secondary locks should be installed;**
- **French window locks should always be protected to prevent the insertion of a thin blade to lift the locking lever;**

Case example: removal of sliding glass door. Courtesy of Don Shiles.

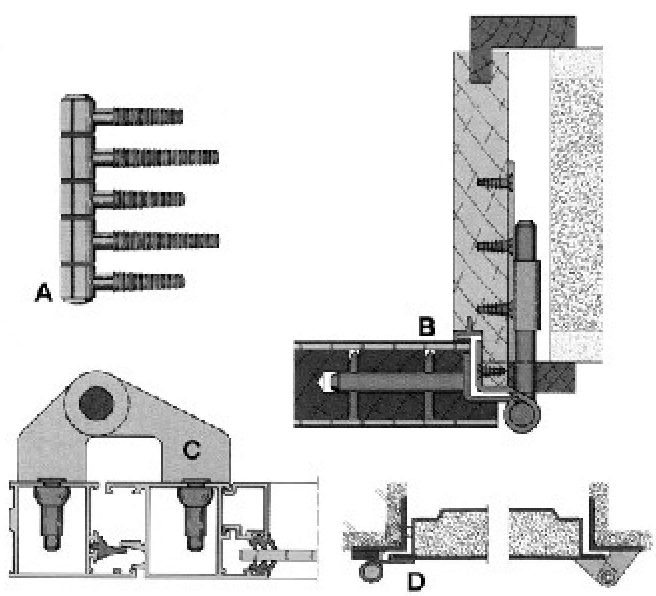
39_2.4 Hinges



Hinges are comprised of interleaved metal plates that rotate around a central axis and are used to connect a door with its frame. Their design and attachment is important and contributes to the overall security of the door and frame. Simple hinges do not provide sufficient security against unauthorized opening; they should be augmented with hinge bolts. They must be anchored to the wall like a strike plate, independently of both the door and frame to provide added support.



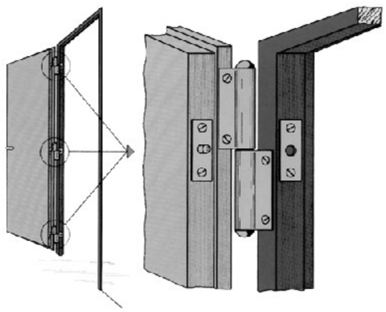
Hinges and forensic evidence. Courtesy Don Shiles.



39_2.4.1 Classification of Hinges

Hinges are available in many configurations, based upon their method of fastening. The basic designs include:

- **Screw-on hinges for door leaves flush with the frame;**
- **Force-fit hinges for offset door leaves;**
- **Drill-in hinges for various types of door frames;**
- **Weld-on hinges.**



39_2.4.2 Installation Requirements and Security

The following guidelines relate to the security of doors, frames, and hinges.

- **Three hinges should be utilized;**
- **The door must not be subject to distortion or being forced out of position;**
- **The sealing and heat-insulating effect of the door can be improved by the proper installation of hinges;**
- **Drill-in hinges should have five or more bolts;**
- **Door leaves should be as strong as the hinges and fastenings;**
- **Heavy studs and bolts may be butt-welded to the hinge;**
- **Special hinges may be used with chipboard frames;**
- **>12 mm hardened bolts can increase the load that hinges can bear;**
- **Fastening plates should be utilized on the other side of the frame with bearing bolts or studs, reducing the likelihood that the door can be pulled loose;**
- **High-security hinges must be fitted while the door is being hung;**
- **Insure the proper fitting of hinges on doors made of wooden-profile sections;**
- **Reinforcement plates or fastening bolts must be utilized and fitted properly;**
- **Weld-on hinges will offer the maximum security on metal doors;**
- **Hinge pins should be welded in place, or hinges should be equipped with special pins to prevent their removal.**

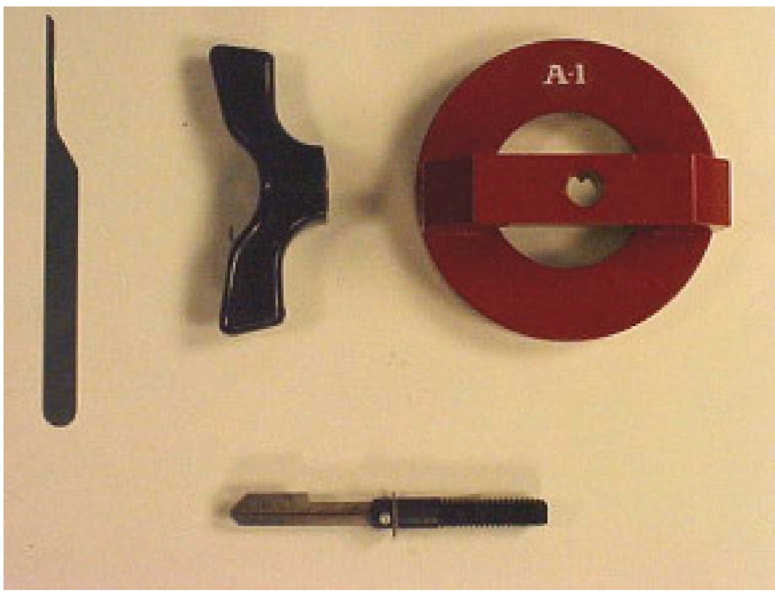
39_2.4.3 Hinge Bolts

The purpose of a hinge bolt is to reinforce the hinges between door leaf and frame when the door is closed. Hinge bolts are essential, especially when used with poorly designed hinges or with doors opening outwards. Bolts should be positioned near the hinges, as this area is the least subject to pulling, torque, and other forces. Two and preferably three hinge bolts should be utilized per door.

All hinge bolts work on the same principle: a cylinder or disc fits into a drilled hole or slit exactly opposite. When mated, the male and female portion of the bolt will provide additional structural integrity to the hinges.

39_2.5 Door locks

Our discussion of door locks shall relate to bolts, strikes, latches, and related components. For commercial applications, mortise configurations are most common and will be used as the example for the following discussion. Internal locking mechanisms, such as wafer, lever, and pin tumbler, are described in **Chapters 13-16.**



39_2.5.1 Security Guidelines for Locks and Locksets

See **Chapter 10** for detailed evaluation criteria of high-security cylinders. UL and European security standards are set forth in **Chapter 37.** Design parameters and security enhancements for locks and locksets can provide increased resistance to forced-entry, including:

- **Prevent tampering by completely enclosing the lock housing;**
- **Lock housing should be made of heat-treated steel, at least on the side that is exposed to attack;**
- **Heat-treated bushings must be used for the escutcheon to provide adequate support and protection;**
- **The locking bolt should be heat-treated;**
- **The bolt should extend into the lock housing to prevent shearing;**
- **Warded mechanisms should never be used, as they**

offer no security;

- **Lever locks should contain at least seven or more levers to offer pick resistance;**
- **Lever locks should utilize asymmetrical double-bitted keys;**
- **Escutcheons often have one-piece bolts of insufficient thickness on tubular frame locks;**
- **Kwikset, Weslock and similar locksets should be augmented with dead bolts to prevent manipulation of the spindle-tab or spring release;**
- **Be certain that all cylindrical locksets are tightly fastened to the door so they cannot be unscrewed.**

A-1

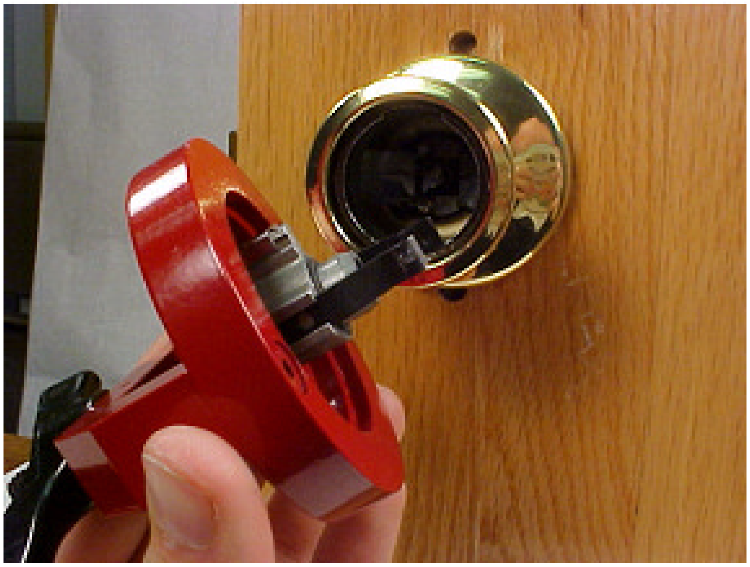


Figure LSS+3901 The Kwikset cylinder key-in-knob assembly may be removed quickly and easily with a special tool to release the two retaining clips. A vicegrips or pliers may then be inserted to manipulate the bolt. Courtesy of Medeco.

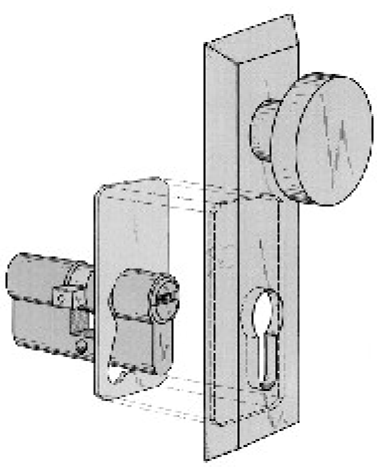
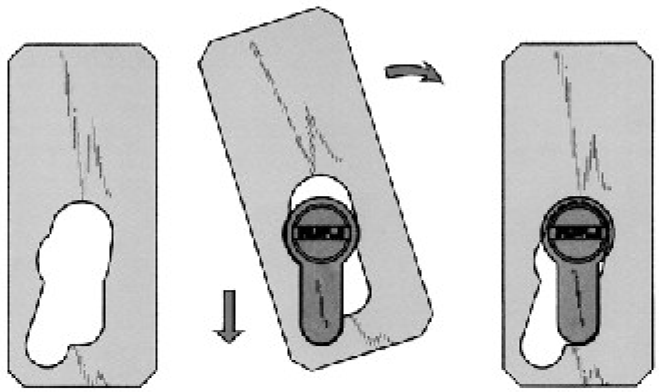


39_2.5.1.1 Supporting Hardened Metal Plates for Cylinder Locks

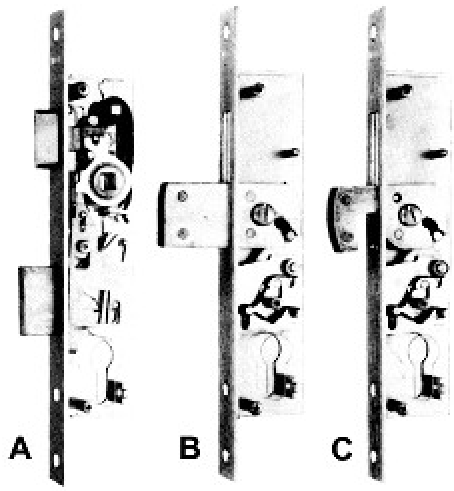


As has been described in **Chapter 32**, cylinder locks can be forcibly removed from their mountings unless properly anchored and protected. There are several methods to accomplish this,

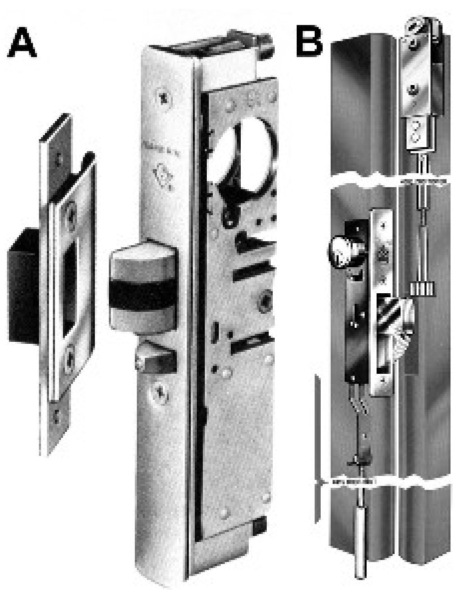
including:

- **The cylinder can be wrenched loose by attaching to the protruding portion of the lock from the handle mounting or rosette. Once the outer lock has been removed in this manner, the bolt can be withdrawn with a hook-wire, screwdriver, or other simple tool;**
- **A hole can be drilled into the lock above the pins, then a piercer can be inserted to drive the internal mechanism away from the bolt;**
- **A dent puller can be used to forcibly remove the plug or entire assembly. This requires that a metal screw be tapped into the keyway, then withdrawn;**
- **A metal screw can be tapped into the keyhole, then violently removed with a nail puller;**
- **Using a long wedge-shaped tool that has a slot slightly larger than the outline of the profile lock, the cylinder can be worked loose.**

These methods of attack can be made more difficult or frustrated by the installation of a supporting hardened metal plate that is at least 2 mm thick. A notch is cut into the cylinder, which keeps the lock from being removed by pushing, pulling, or twisting.



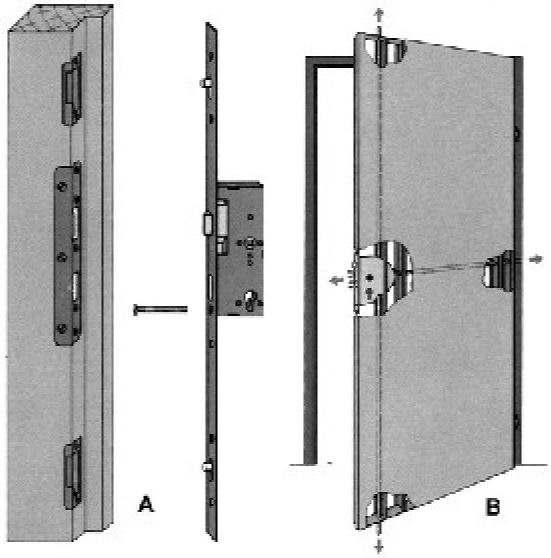
39_2.5.2 Bolt Systems



The use of a particular bolt will depend upon the design of the door, frame, and lock.

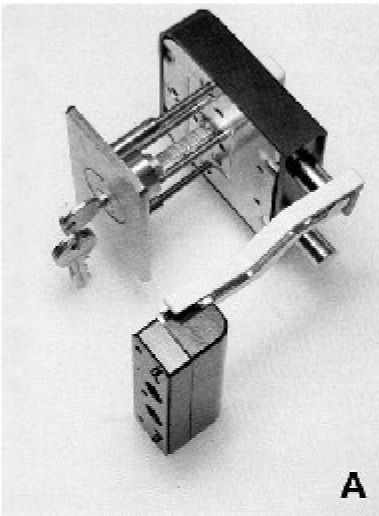
39_2.5.2.1 Bolt Systems for Tubular Frame Locks

Mortise locks used on slender metal frame doors can have three different kinds of bolts: **dead, hook,** or **swing.** The characteristics of each bolt will determine the security against forced methods of attack. The following guidelines apply to tubular frame lock bolts:

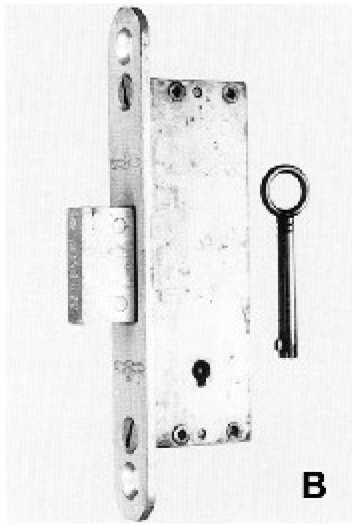


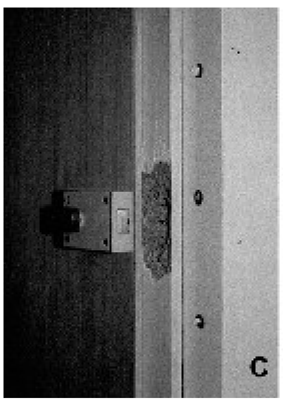
- **Dead bolts can usually be thrown once to a length of 10-12 mm., although some may reach 20 mm. This is often insufficient to overcome the potential for jamb spreading of metal door frames and leaf, and the gap between the two. The bolt may only extend a few millimeters into the strike;**
- **Swing bolts usually have a vertical orientation within the housing when in the unlocked position. Their length is not restricted by the characteristics of the frame, allowing them to be extended up to 30 mm. Bolts are usually of laminated design, especially when employed in swinging doors. Heat-treated steel or aluminum ceramics are often used;**
- **Swing bolts with a hook-bolt are popular for use on sliding doors and allow solid linking to the strike plate.**

39_2.5.2.2 Rollstud and Multipoint Bolt Locking

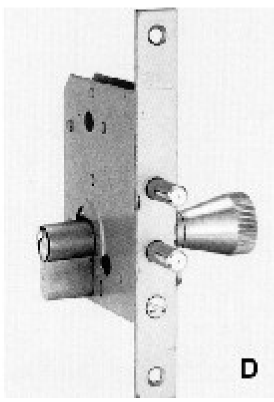


A rollstud or multipoint locking design provides for a central locking mechanism to control several bolts or locking pins. These systems can improve the odds of surviving a forced-entry attempt. They can also enhance thermal insulation and soundproofing characteristics of the door.





Security issues regarding these forms of bolt systems include:



- **Bolt systems may not provide the required security, based upon a throw length of less than 8 mm;**
- **Improper fitting of door and bolts or studs will reduce overall security;**
- **Lock openings can often be forced out and removed in chipboard frames;**
- **Central point or multipoint vertical and horizontal bolt systems should not be retrofit to doors for several reasons:**
    - **The housing is sometimes wider than the recess in the door-leaf reinforcement frame;**
    - **Bolts cannot be properly fitted into doors with fillings due to lack of space availability;**
    - **Special tools are required for such installations;**
    - **Horizontal bolts do not offer adequate support for hinges;**
    - **Locks and escutcheons often cannot withstand a heavy load;**
    - **One cylinder that controls a multipoint bolt system may require excessive torque to turn the key, resulting in fracture. A better system utilizes a separate control of the secondary**

bolts, with the main bolt being locked by the key;
- **The strike plate, its fastenings, and escutcheon, all must be sufficiently strong to provide security for a multipoint locking system.**

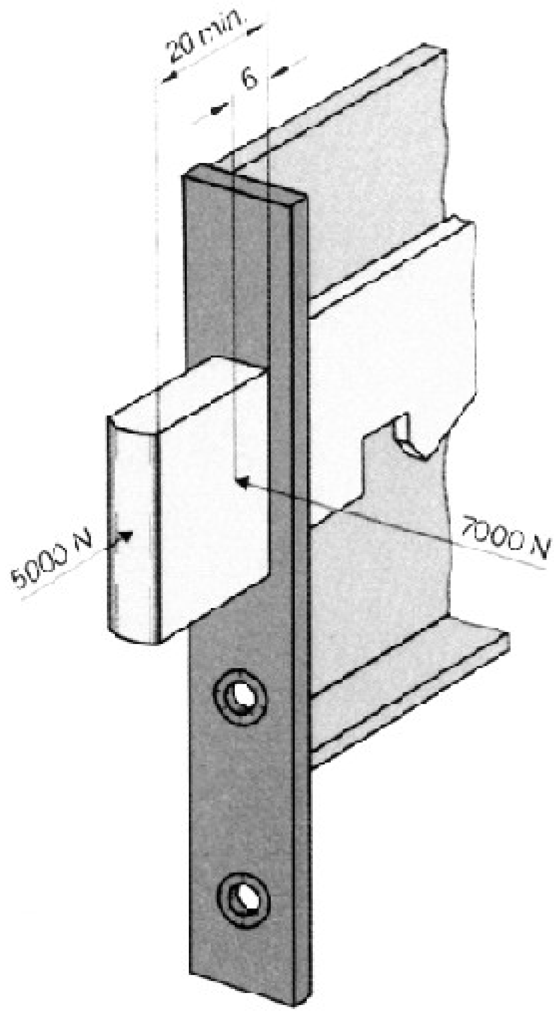
39_2.5.2.3 Compromise of Lock Bolts

There are several common techniques for bypassing bolts on cylinder locks. An analysis should be undertaken to insure that the following techniques cannot be applied:

- **Bolts on inactive double doors should be incapable of being unlocked when both doors are closed;**
- **Automatic door-closing mechanisms can be bypassed by**

the placement of a pad to prevent proper alignment of the latch with the strike. The door will close but not lock;

- **Clear tape can be placed over the strike in order to prevent entry of the latch;**
- **Obstructions can be placed in the strike hole, preventing full extension of the bolt. Even a dead bolt can be worked to the open position if it does not fully enter the strike;**
- **Jamb spreaders, described in Chapter 32, can be utilized to bypass short-throw bolts and secondary bolts. One solution is the three-point locking system;**
- **If sufficient clearance can be created, a shove-knife or linoleum knife can be utilized to bypass a latch bolt;**
- **If the secondary bolt on a spring latch is defective, then the primary bolt can be withdrawn with a "Z" tool or flexible loid. The "Z" tool is a bent piece of wire that is inserted between the door and stop. The end will catch the bevel and force it into its housing. The loid tool is formed from a piece of celluloid and is used to push the bolt out of the way of the strike;**
- **Mail slots, transoms above doors, and pet doors can provide a point of entry to reach doorknobs, latches, and other release mechanisms;**
- **A threshold under a door can provide access to allow manipulation of a knob, handle, or latch from the outside. The remedy is to place a lip or other obstruction to block entry of a wire or shim.**

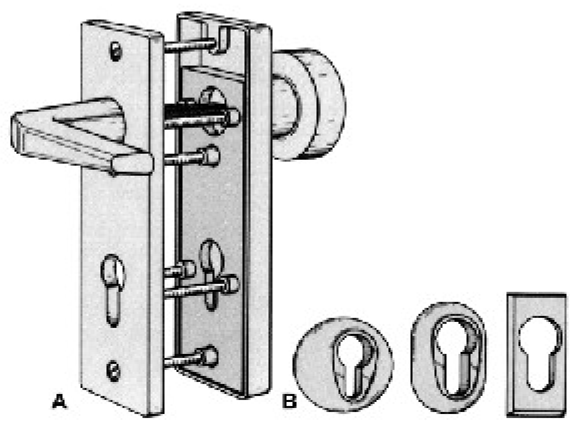


39_2.5.2.3.1   Forces Applied to the Lock Bolt

Standards have been adopted based upon forces that are encountered by lock bolts. Typically, these guidelines will specify the following requirements for each component:

- **Door frames constructed of wood or steel profiles must withstand a force of 7,000 N applied to the frame at the strike plate or recesses in the strike plates, hinges, or hinge bolts;**

- **Door leaves must withstand a force of 7,000 N that is applied to primary or secondary locks, hinges, and hinge fastenings;**



- **At the intersection of the diagonal lines across the door from top to bottom, the leaf must withstand three impacts of 2,000 J each.**

39_2.6 Escutcheon

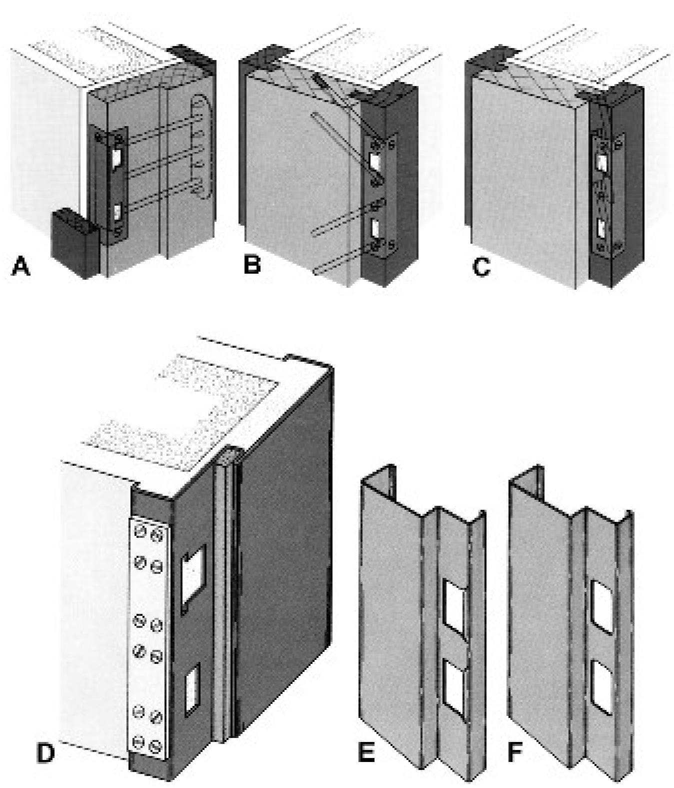
Were it not for a security escutcheon or brace covering the mortise lock, any cylinder could be quickly removed and the bolt retracted. Guidelines for escutcheons include:

- **Rosettes or shields must not be screwed to the outside front of a lock;**
- **Rosettes often fail to provide adequate security;**
- **A cylinder must not protrude from the escutcheon by more than 2 mm;**
- **A security escutcheon should create a narrow close-fitting sleeve around a cylinder;**
- **It must be difficult to use a tool to obtain access to a cylinder.**

Escutcheons must:

- **Be affixed from the inside with bolts of at least 8 mm in diameter;**
- **Provide added support for the lock;**
- **Protect the lock from being drilled;**
- **Be made of solid, heat-treated steel.**

39_2.6.1 Security Escutcheon (short shield) and Security Rosettes



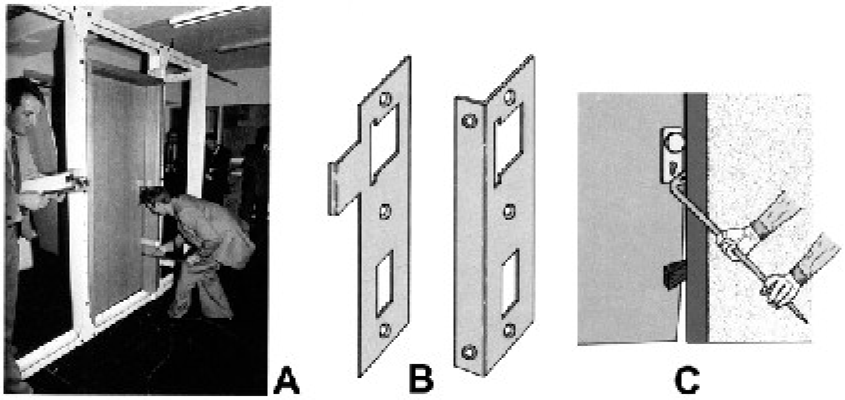
Security escutcheons are also referred to as short shields. These covers can usually accommodate only small-diameter bolts of not more than 6 mm. Using several bolts through all of the holes in the housing does not increase security. Additional risks are presented by light-alloy shields with support cams and steel-threaded inserts, because they may break when torque is applied.

Locks and cylinders can best be protected by using a long

rectangular shield that is made of solid steel. In the alternative, a steel base-plate that is bolted from the inside above and below the lock housing will often suffice. This shield should be affixed with long bolts that have a diameter of 8 mm. Solid steel escutcheons are hard to drill and will retain the cylinder tightly in position, making it more difficult to force loose. If light alloys must be used, then inserted cast-steel plates can be added.

39_2.6.2 Lock and Strike Plate

The strike plate is considered as part of the escutcheon and must be specifically made for the door upon which it is installed. If fitted in a solid frame made of high-quality wood, a security strike plate without any additional support in the wall (or frame) can provide adequate security. Even a light load of approximately 1.0 kN can be enough to wrench loose a simple strike plate. As a comparison, shoulder pressure generates a load of about 2.0 kN and a forceful kick will amount to approximately 5.0 kN. A dog-spike bar and wedge can produce a force of more than 10 kN.



39_2.6.3 Strike Plate Security Deficiencies

The following security deficiencies occur with inadequate strike plate hardware:

- **The fact that a large number of screws are used to fasten a strike plate does not guarantee security. Nor does the length of the strike plate provide a reliable index as to strength. In fact, long plates tend to be weaker than short ones. The optimum length is less than 20 cm;**
- **There is often too small a distance between the recesses for the bolts. This can weaken the frame, making it more susceptible to forced-entry;**
- **Strike plates should be fitted prior to assembly of metal frames. Installing them later can cause damage to the frame;**
- **Strike plates should be made of high-quality materials, such as stainless steel;**
- **Security strike plates should have additional anchors in the wall. These can offer resistance to forced-entry and provide reinforcement for the frame;**
- **If added anchors are utilized, damage can be caused to walls, necessitating major repairs. This is especially true if they are made of brick. If holes are drilled into reinforced concrete, rebar may be encountered. If this occurs, the strike plate cannot be properly fitted because of inadequate anchor depth;**
- **Reinforcement members can be welded to steel-profile frames around the strike plate recess. This can provide increased security;**
- **Aluminum frames without strike plate reinforcement are weaker than steel. They must be thicker near the strike plate and reinforced by the plate itself;**
- **Recesses in strike plates mounted on steel-profile or metal frames should have rounded corners. Sharp corners can crack or fracture;**
- **Stainless steel reinforcement plates, measuring about 5 mm in thickness, should be utilized in steel-profile frames that have simple recesses for**

the bolt and latch.

A B C

PART D: Internal Protection

Internal Access Protection

The following discussion identifies critical areas within a facility that usually require special protective measures. Security hardware, construction techniques, organizational procedures, and installation guidelines are examined.

39_3.0 Access Control

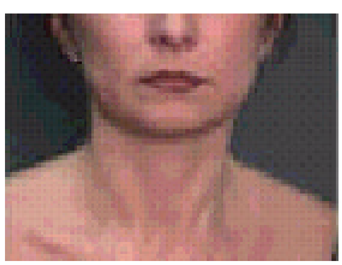
Access control provides primary protection of property and persons against burglary, robbery, sabotage and espionage. It is inherent in any security program and must be considered for entrance and exits to all buildings, as well as for vehicles used for transporting high-value items. See the discussion in section 23_3.0.

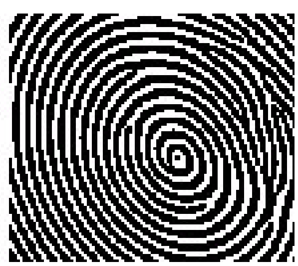
The concept of access control can take many forms, from the simple distribution of keys, codes, and identity cards, to complex systems. Today, sophisticated computer-based systems are available to meet any access security requirement. These include mechanical and electromechanical locks, proximity identification cards, magnetic coded cards, biometric sensing systems, retinal scans, and alarms.

Access control is dependent upon and customized for a particular business and its unique characteristics. Placement of facilities and staff, location of valuables, design of the building or structure, and traffic patterns must all be taken into account.

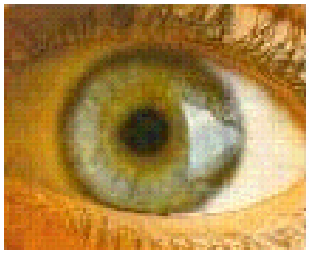
Ultimately, people, including criminals, must pass through access points. The correct hardware and supporting policies and procedures must be properly implemented to restrict access, yet not impede it.

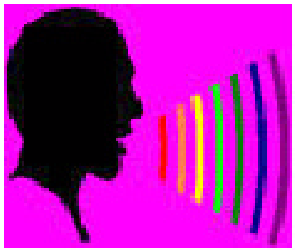
39_3.1 Biometrics





LSS202: Ross Anderson on biometrics





Biometrics involves the use of a security protocol wherein authentication or identification relies upon a human property:

- Some aspect of an individuals anatomy or physiology;
    - hand geometry
    - fingerprint
- Deeply ingrained skill;
- Behavioral characteristic;
    - hand written signature
- Combination of features
    - voice

The use of biometrics certainly predates the computer era, and generally involved the use of voice, signatures, facial features and fingerprints. In fact, early criminologists such as **Bertillion(439)** thought they could identify criminals by the shapes of their heads. Other forms of identification in relation to biometrics helped to form the basis for the **New York State Bureau of Identification.** The primary biometric technologies are described in the sections below. During the past twenty five years, many systems have made their debut into the marketplace, now becoming a multi-billion dollar a year industry.

The primary biometric indicators are:

There are a number of general issues that can affect the validity and reliability of any biometric system, and which must be understood by anyone implementing biometric technology for user identification or authentication. Certain issues are technology dependent and some relate to the environment into which a system is placed. Generally, attended biometric systems are more reliable than those that are unattended. The deterrent affect cannot be understated with regard to criminal conduct.

Issues that may affect the validity of any system include:

- **Environmental conditions**
  - noise
  - dirt
  - vibration
  - unreliable lighting
- **Alcohol or drug intake;**
- **Stress levels;**
- **Changes in environmental assumptions**
  - closed to open systems
  - small to large systems
  - attended to unattended (can be very tricky to implement for valid results)
  - cooperative to recalcitrant subjects
  - verification to identification
- **Methods that are used to index biometric data;**
- **Age and freshness of a sample (such as a fingerprint);**
- **Forged signature;**

- **Use of a recording or facsimile:**
    - voice recording or synthesizer
    - photographs (iris codes)
    - imprints on contact lenses (iris codes)
    - molds (fingerprints)
- **System is not accurate for all people, and some segments of the population may not be suitable candidates:**
    - elderly
    - manual workers
    - dark colored eyes, large pupils
    - disabled people and amputees
    - illiterates
    - poor
    - ethnic minorities
- **Legal challenges;**

- **Political and religious challenges:**
    - religious, Christian Fundamentalists (Revelation 13:16-18
- **Collusion;**
    - employee and user
    - disloyalty

- **Degrading of samples provided as the constant value for a user;**

- **False repudiation (signatures that appear different but pass for identical);**

- **Statistical errors in accuracy of a particular system. There is one chance to get it right, but N chances to get it wrong;**

- **Stacking of biometric systems may not increase reliability and lower error rates.** A combination may improve either the **false accept(440)** (FAR) or **false reject rate(441)** (FRR), but not both. This is especially true when a very precise technology is combined with an imprecise one;

- **Improper use of a system for identification, rather than for authentication or verification.** A system that has been designed for authentication may fail when it is used to introduce evidence

for another purpose;

39_3.1.1.0 General Defeat Strategies for Biometric Systems

There are three primary methods to attack a biometric system, summarized below. Each type of technology is subject to specific defeat techniques, detailed in subsequent sections.

- **Spoof the system by using data that has been created or synthesized. This attack requires that biometric information be obtain from the target, such as fingerprint or photograph;**
- **Utilize artificial data in a "replay attack." This involves sniffing of input lines to the sensor, then replaying that information to the system. It can be a relatively simple matter to capture information from the biometric sensor, via USB lines. USB Snoop for Windows (software based) and USB Agent (Hiltex) which is a hardware based device. The USB Agent is essentially invisible, and records all exchanged information on a foreign PC. The process will allow reconstruction of information and images sufficient for successful log in to the biometric device;**
- **Attack the data base directly, by exchanging information used as a reference for authentication within the system. Forged user data may be input into the system, so long as administrative rights with the proper permission sets have been obtained. Failure to encrypt all information within the data base can aid an attacker.**

39_3.1.1 Handwritten Signatures

The use of the handwritten signature dates back to China and is perhaps the second earliest form of biometric authentication of the individual, facial recognition being the first. Over time, carved seals replaced the use of signatures for the elite and wealthy in the Orient. In Europe, the reverse was true; seals were first utilized to confirm transactions, and later, signatures became predominant. Today, most commercial transactions are executed with handwritten signatures. The issue now is their replacement with electronic signature authentication.

Fraud through forgery is often easily accomplished, and depends

in large measure upon the examination of signatures for authenticity by the accepting party. In banks, this is essentially non-existent except for large drafts. Even with credit card signature panels, few clerks really pay attention, at least in America. Depending upon the country and local custom, there are special security conventions that surround the acceptance of signatures for certain types of transactions. In some cases, authentication must be secured from a recognized party, such as a lawyer or notary.

There are three key issues with regard to the authentication of a signature: **form, ease of forgery, and legal validity.**

39_3.1.1.1 Automatic Signature Recognition and Verification

Banks have a need to automatically and accurately verify large numbers of handwritten signatures on checks. This can be a very difficult image processing task. Presently, the procedure is often accomplished manually by an on-screen comparison of the check with the account holders original signature. As a consequence of the difficulty in correctly recognizing signatures, the use of ***signature tablets*** has gained acceptance. These devices digitally record the characteristics of the lines as well as the dynamics of the writer. That is, the velocity of the hand, at what point the pen was lifted from the tablet, interruption of strokes, and other criteria. Such tablets are used in high value transactions, but their use is also widespread in credit card transactions in order to capture, but not validate the signature.

False accept and reject rates are not yet acceptable for mass commercial transaction processing at the retail level. Referred to in the banking industry as the fraud (accept) and reject (insult) rates, it means the probability of accepting a false signature, or rejecting a valid one. Generally, a low false insult rate will result in a high false acceptance rate, unless a biometric indicator is combined with human monitoring. Then, a higher reject rate can be tolerated because it can be verified through other means.

39_3.1.2 Face Recognition

Facial recognition is probably the earliest form of personal identification. It is believed that much of our cognitive functions developed in order that we might recognize each other.

We can surely do it better than any automated process. Today, the facsimile of this process drives identification and authentication. That is, a photograph that is attached to a drivers license, passport or other official form is relied upon as prime identification, which then allows the issuance of other security clearances and devices (keys, access cards, smart cards, identification). Unfortunately, identification of individuals in person is much more reliable than from a photograph.

Automatic facial recognition is fraught with problems due to the nature of the photographs. Those taken for identification utilize proper lighting, angles, and recording media. Mistakes can still easily be made. Images from video tape, or even more difficult, from surveillance cameras, can prove of minimal value. Movement, lighting, viewing angle, perspective, and expressions all contribute to unreliability. Unfortunately, an error rate of one percent or less is almost impossible to achieve with facial recognition, in comparison with other forms of biometrics. Countermeasures to defeating these systems have been implemented, including reaction to bright light (pupil contraction) and blinking to indicate a live subject. This system may foil the use of laptops that display a video in front of the detector.

39_3.1.2 Defeat of Facial Recognition Systems

Facial recognition systems are subject to compromise through the use of photographs and video images of the authenticated user. In one scenario, notebook compuers with images that are displayed in front of the sensor in a facial recognition system can easily defeat security. To combat this, some manufacturers have introduced "live checks." However, these too can be defeated by adding motion to a short video clip. This implicates that information from an individual that is captured by a video camera in public can be used to simulate that individual at a secure facility;

39_3.1.3 Fingerprints

Fingerprint recognition currently represents a high percentage of biometric technology implementation, such as shown in the photographs below. These safe locks utilize fingerprints, with or without entry of a number, as the means of authentication. These particular devices are manufactured by **STB microtechniques SA** in Switzerland. Readers are utilized in a wide range of access control functions, even including desktop computer access.

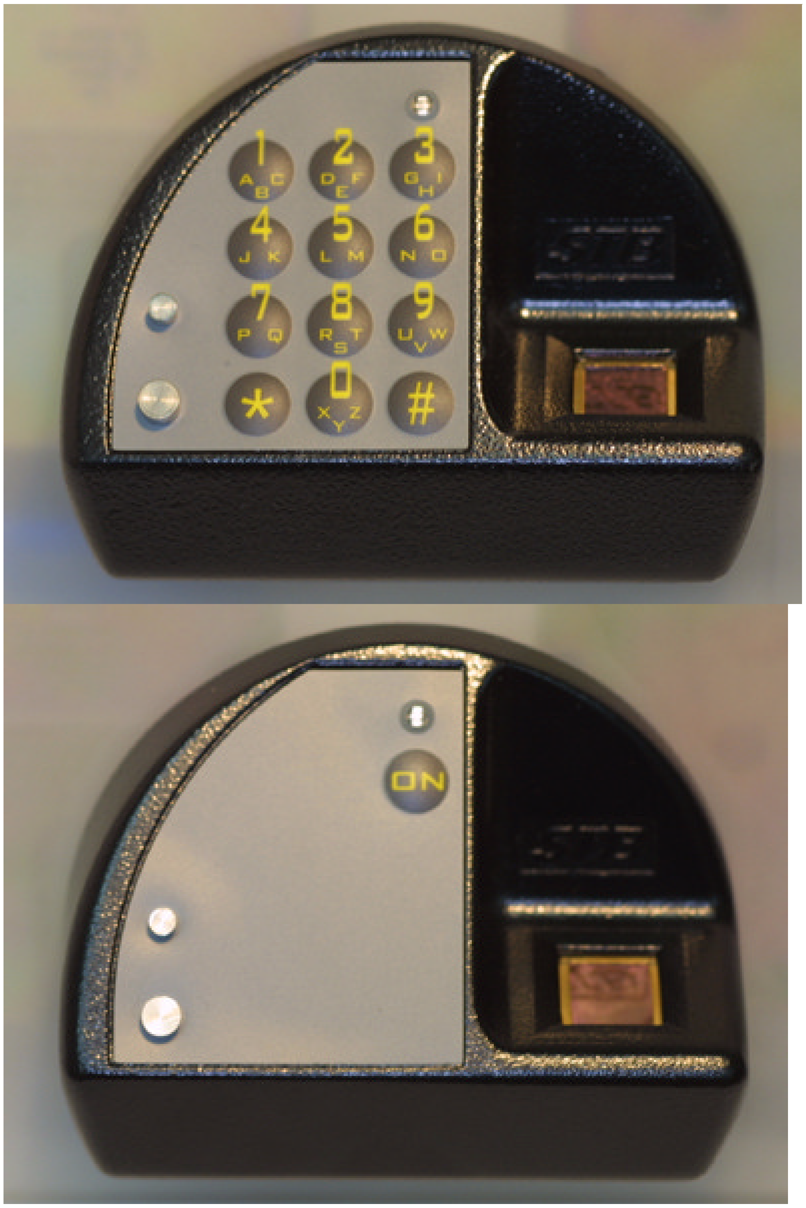


Figure LSS+3902 Fingerprint recognition is utilized in the STB electronic combination lock for safes.

Fingerprint readers utilize CMOS capacitive arrays, optical scanners, or thermal recognition systems. The chips that utilize capacitance typically have 65,000 pixels, abd they analyze ridges that cover the finger tips, called ***minutiae***. The sensor detects lines or troughs and translate this into capacitance values. Differences in patterns (arches, tents, whorls and loops, branches, and end points) allow for automatic identification by converting the individual values into an 8-bit gray scale, then

extracting about 20 minutiae. Optical scanners utilize prisms or diffracting grids that are illuminated by light from color LEDs and photographed by a CCD or CMOS camera. Another type of optical array utilizes a light-conducting fiberglass surface directly linked to a CMOS chip element. The finger is placed on the array and is illuminated from below. In the thermal design, a CMOS-Finger-Chip sensor, such as Atmel's FCD4B14, consists of a total of eight parallel rows with 240 sensor pixels each. As the finger is moved **across** the sensor, heat is applied to the finger tip. Very small variances in temperature are measured between ridges and valleys of the fingerprint.

Fingerprints were originally developed as a means of criminal identification by a number of individuals working independently. In the seventh century, the Chinese legal code allowed their acceptance as an alternative to a seal or signature. They were utilized in Japan in the eighth century, in Ireland and in Italy in the seventeenth century. The first systematic implementation for identification appears to have been in India in the middle nineteenth century, when William Herschel used them to stop pensioner fraud and to prevent rich criminals from hiring poor people to serve their sentences in jail. In the 1870s, Henry Faulds, a medical missionary in Japan, discovered fingerprints and made Darwin aware of them. Darwin then contacted Galton to develop a classification scheme. The police began using fingerprints in 1900 when Edward Henry became Chief of the Metropolitan Police in London. Henry improved upon Galton's classification system through a technique known as binning (use of individual bins to hold classification information). Henry assigned one bit for each of ten fingers when a whorl was present in that finger. A total of 1024 bins were created (2^{10}). This technique reduced the number of records that would have to be manually searched when attempting to match a print.

There are many automated fingerprint classification systems in use by law enforcement agencies today. For security applications, there are readers, such as shown above, that can authenticate an individual in real-time for access control and verification of credit and banking transactions. In Europe and North America, there has been resistance to the use of fingerprints in commercial transactions as an invasion of privacy.

There is a probability of false matches, given the huge data bases that have now been developed. Impressions can also be obscured by "noise" from dirt, oils, mode of impression, the nature of the surface material, and the skill of the examiner.

Although the accepted number of match points is 16, this number may in fact be too low in certain instances. The identification by fingerprint is not infallible, which can also lead to erroneous conclusions. There have been instances of false fingerprint evidence that has been used to convict a criminal defendant. Prints can be transferred using adhesive tape or from the use of molds.

Automated systems can have problems recognizing prints from certain individuals, such as those with scars, manual workers who routinely damage their finger tips, young and elderly with faint prints, amputees, those with birth defects, or the rare instance where an individual does not have fingerprints.

39_3.1.3.1 Defeating Fingerprint Systems

Fingerprint readers, especially earlier generations, have been defeated through a variety of methods. These include:

- **Breathing on the sensor, thus making the previous image visible;**
- **Use of a mold to recreate a fingerprint;**
- **Placement of a thin-walled water-filled plastic bag onto the sensor surface;**
- **Dusting of the sensor with fingerprint powder or graphite powder, then using adhesive tape or film to lift the print from the source material. The fingerprint can then be superimposed onto the scanner and will be read a high percentage of the time;**
- **Some optical scanners can be bypassed through the use of a simulated finger, rather than a two dimensional image:**
    - Use of photo-sensitive lacquer to reproduce the image of a fingerprint in a three dimensional configuration;
    - warm candle wax can be used as a mold to impress a fingerprint, then a silicone impression can be taken, much like that described in other sections of this book for making keys;
    - use of a lifted fingerprint on cellophane tape or film, overlaid onto the scanner, with a halogen light source that is directed onto the scanner from about 30cm, causing intense back-lighting and increased contrast;

39_3.1.4 Iris Codes

Recognition of iris code patterns as a means of personal authentication appears to present the most reliable and secure method of biometric access control. Like fingerprints, every human iris has unique characteristics that are capable of measurement. Such codes are set after about one year from birth and will never change. They cannot be altered and are easy to capture for the purpose of identification. The iris code may be many times more complicated and random than a fingerprint, and thus presents the potential of a very low error rate in detection. Iris codes are formed between the third and eight month of gestation and do not appear to be influenced by genetics; formation follows no guidelines. Thus, patterns for identical twins will differ, and for each eye of one individual will vary.

In practice, a 256-byte code is generated from an extraction process utilizing a signal processing technique (Gabor filters) by analyzing a series of concentric rings that extend from the pupil to the outside of the iris. There is a high repeat rate when the same iris is computed more than one time, which may not be the case with fingerprints. Because of the coding technique, there are several commercially available iris recognition sensors that can process the information in real-time. Iris codes offer the lowest false accept rate for any biometric authentication system. The Department of Energy has conducted extensive tests and found a false accept rate of zero. The equal error rate is better than one in one million. If a false reject rate of one in ten thousand can be tolerated, then the theoretical false accept rate would be less than one in a trillion.

In order to capture an acceptable image for processing, several hundred pixels must be available. This means that the individual must be fairly close to the scanner, which has raised certain issues with respect to privacy and intrusiveness. Distances between eye and scanner can vary from a few inches to two or three feet. Within a controlled environment, the distance between individual and scanner is not relevant, but in a retail or commercial setting, it can become a problem. Other issues that can cause problems would include blinking, eyelashes over the eye, nystagmus, and sunglasses.

39_3.1.4.1 Defeat Techniques for Iris Code Recognition Systems

Specific defeat techniques for iris code systems include:

- Photograph presented to the scanner of the target iris, in an unattended operation. This may become a problem if iris codes are widely used in commercial and banking applications, because code data will be obtainable and can be replicated;
- Print the target pattern on contact lenses;
- Print a high resolution iris image on paper, then cut a small hole for the pupil area and utilize a live subject for the pupil;

39_3.1.5 Voice Recognition

Voice recognition systems are utilized in a number of application including telephone banking, identification of military personnel, secure telephone systems, NSA applications, and access control into critical areas. The goal of such systems is quite different than in forensic applications (forensic phonology), such as the identification of an individual who made a telephone bomb threat, or the analysis of many speech exemplars to identify one speaker.

Two terms are often confused with regard to voice recognition systems. In regard to user identification and authentication, ***speaker recognition*** is a synonym, and denotes a technology of identifying a speaker from one or more spoken words. ***Speech recognition*** systems have been developed to translate the spoken word into text, and to ignore individual characteristics that are utilized in voice recognition. Several complicating factors must be accounted for in any biometric system that utilizes voice as a means of authentication:

- Noisy environment;
- Real-time decipher;
- Verification of the speaker, or recognition of one speaker from a larger group;
- Whether recognition is text-dependent.

39_3.1.5.1 Defeat of Voice Recognition Systems

There are potential defeats for these systems:

- **A speaker may train himself to replicate another's voice that would be acceptable to the recognition equipment;**
- **Intercepted audio samples could be segmented by each syllable, utterance, or word, then reconfigured to form different words;**
- **Use of digital signal processing (DSP) to accomplish real-time voice forgery;**
- **Voice morphing systems that could be utilized to alter components of a speakers voice to match that of a target.**

39_3.1.6 Other Systems

There are many other biometric systems that are in development. These include:

- Facial thermograms, utilizing infrared images, that map the surface temperature of the face;
- Unique shape or characteristic of a body part or movement:
    - shape of the ear
    - gait
    - lip prints
    - vein patterns in the hand
    - scent recognition
    - keystroke dynamics (typing patterns)
    - hand geometry (originally from anthropometrics, developed by Alphonse Bertillion)
- DNA typing

39_4.0 Blocking Time Relay on Vaults and Strong rooms

A blocking time relay is utilized on vaults and strong room within a bank to thwart holdups. They should be considered as a supplement to other forms of burglar alarms and electronic monitoring systems and are used in conjunction with time locks that protect locking mechanisms. These systems are designed to detect unauthorized entry into secure areas and may be programmed for up to nine or more days. An alarm is triggered whenever primary locks are opened or the alarm system is deactivated during times when entry is not allowed. Holdup switches are routinely incorporated within the control panel in case of

hostage situations.

39_5.0 Central Cash Area Design

The design of this area must be carefully planned to prevent holdup. The physical facility must not be adjacent to external walls, nor should it allow exterior access.

39_5.1 Holdups

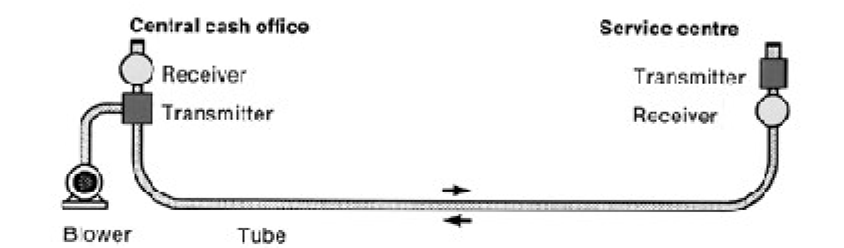
Holdups or the threat of violence against employees cannot be prevented by the use of central cash handling. However, the system does provide a delay to signal an alarm. In addition, special bait money can be sent to the robbers.

Closed-circuit video will often connect the cash office with counter areas serving the public. Personnel in the cash office are thus in a position to provide direct information to police in the case of a holdup. Isolation locks should always be installed into access points leading to the central cash rooms. In addition, day time-delay locks, such as the S&G CS401, should be utilized. Thieves are then confronted with an insurmountable problem.

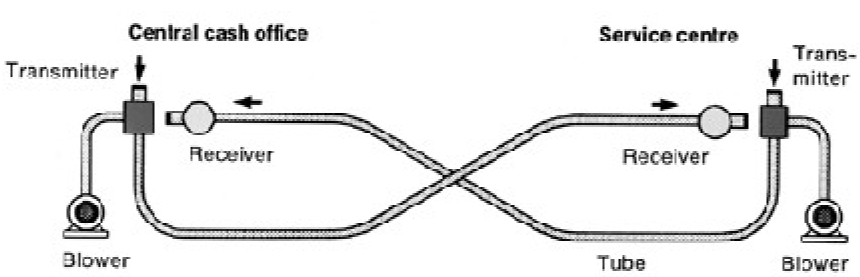
39_6.0 Centralized Money Supply for Banks (Pneumatic Dispatch Tubes)

The concept of centralized counting rooms became popular in the 1970s in order to combat robberies. Their primary purpose is to remove large amounts of cash from open counter areas, and prevent access by robbers. During business hours, currency is stored in a central cash office that is within a secure area that is inaccessible to all but authorized employees. Pneumatic tubes are utilized to transport cash and supporting documents between the counting area and tellers, drive-in counters, night safes, and ATMs. Service areas in many locations are further protected by bullet-resistant glass. When large amounts of cash are required, the teller will order the currency from the central cash office.

The normal procedure for obtaining cash from the central facility can entail:



- **The customer initiates a withdrawal request directly into the pneumatic system, through an automatic**



teller machine, or the customer service agent can enter the transaction into a computer terminal that is responded to by personnel in the cash center;

- **The requested amount is returned to the service center after appropriate internal verification;**
- **The amount is given to the customer by a teller, or the customer receives the money directly from the transport tube;**
- **The deposit of cash requires the reverse procedure.**

39_6.1 Pneumatic Tube Systems

Simplex and duplex transmission systems are used in pneumatic transport. In a simplex design, one tube is utilized for two-way transmission. A blower switches from pressure to suction, depending upon where the tube is going. In the duplex mode, two separate tubes are utilized. Transfer speed is usually about twenty feet per second. Disruption of transport by robbers is difficult because only one tube is sent at a time, and receipt is registered on the system. Thus, the cash center can interrupt the transfer of additional containers.

39_7.0 Daytime Cash Dispenser

The use of daytime cash dispensers can reduce the risk of daylight robbery by limiting the amount of cash that is in the control of tellers. Such devices allow large deposits and

withdrawals of cash by customers, without the necessity of transporting currency from the central cash vault.

The systems resemble a vending machine, except they dispense different denomination bank notes. Security is enhanced by electronic time lock control of each dispensing slot so that access to currency is mechanically prevented. In operation, bundles of bank notes of various denominations are placed within individual pigeonholes by a teller. They are then dispensed to customers upon demand. Deposits are made in the same fashion. Daylight cash dispensers can be thought of as safe-deposit boxes for currency and which are under the control of the bank. They prevent access by robbers to increased amounts of currency that is usually on hand during business hours.

39_8.0 Desks and File Cabinets

Desks and filing cabinets are particularly vulnerable to simple bypass techniques.

- **Drawers can be pried open if the lock vertically engages the fixed portion of the desk. A long screwdriver or wedge can be inserted between the top edge of the drawer in order to force sufficient clearance to pass the bolt;**
- **Gang-locking bars on desks can be raised to release all drawers;**
- **File cabinet locks can be bypassed using a stick knife to release a spring-loaded locking dog at the rear of the keyway;**
- **The back of file cabinets should be checked to determine if they are solid or if they will allow bypass of the boltwork;**
- **Long thin metal strips can often be inserted to the side or above a drawer in order to release a gang locking system.**

39_9.0 Electric Strikes

Certain electric strike designs may be bypassed by simulating a magnetic field near their release mechanism. For this reason, only strikes with solenoids should be utilized. Some of these devices may also be circumvented with a thin wire that is used to

activate the release mechanism or bolt release block. This problem can be resolved by installing a metal plate on the outside edge of the door.

Rapping is another technique to withdraw the locking bolt. This can occur because in certain models there is limited internal travel of the release mechanism, making it subject to shock.

39_10.0 Locking Systems

A description of different locking systems is presented in **Chapters 13 - 16**. Keying systems are described in **Chapter 11**. A locking system is a combination of devices that provide for access control on several different levels. The implementation of such schemes is done for three reasons:

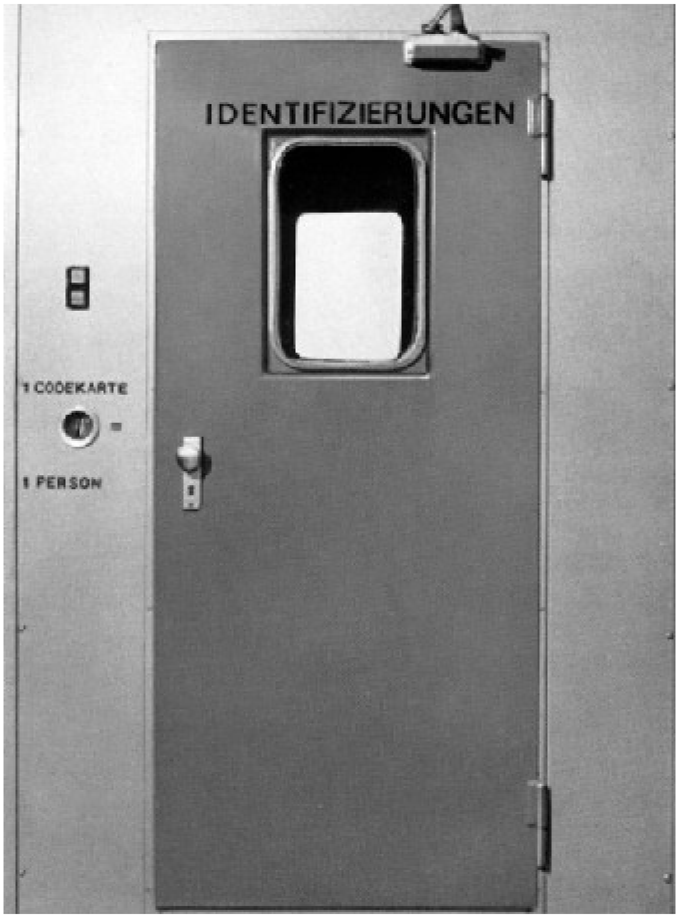
- **Increase in key security;**
- **Simplified organization;**
- **Greater ease of access.**

Keying systems may include many levels of access. These are normally identified as:

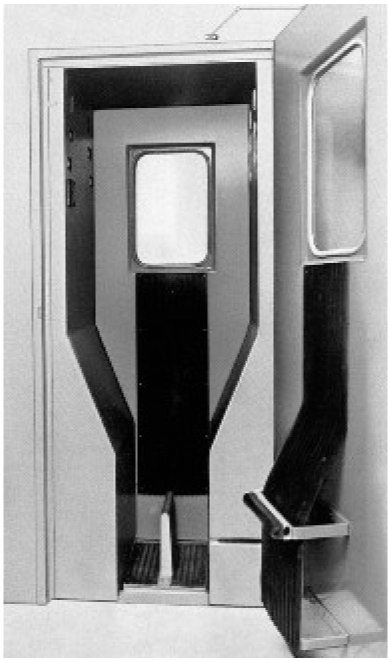
- **Grand master key system;**
- **Master key system;**
- **Central locking system (Maison);**
- **Combined central locking system with master key.**

39_10.1 Unauthorized Access to Keys and Locks

Keys, locks, keying systems, locking systems, and secure containers can be compromised in many ways which is described in **Chapters 29-32, 35-36**. Primary methods include:



- **Decoding;**
- **Picking;**
- **Impressioning;**
- **Failure to change the combination of locks for new tenants;**



- **Failure to change factory combinations in safes and vaults;**
- **Failure to change digital combination for access control points, such as gates, garage doors, loading docks;**
- **Code numbers on keys and locks;**
- **Observation of combinations.**

39_10.2 Compromise of Locks on Entry or Exit Doors

Unless properly designed, entry and exit points can be easily compromised. Such bypass usually occurs when doors are left open or there is poor key control. A **siphon** or **isolation** door or lock is often the solution to access control problems. This is comprised of a chamber that has one entry and exit door. Each operates independently and is mutually exclusive. It is the same scheme used in prisons to prevent escape. In high-security applications, only one person at a time is permitted to enter; taking of hostages is impossible.

Isolation locks are utilized in high-security installations where a high risk of espionage, sabotage, or terrorist threat exists. Such locations include transportation control centers, power generation, water and waste processing, industrial, military, and communications facilities. Banks, cash offices, and armored car installations can also utilize the technology to prevent robbery.

IDENTIFIZIERUNGEN
1 CODEKARTE
=
1 PERSON

An isolation lock requires a specified sequence for access:

- **Open the access point with a key, code, card, fingerprint, retinal scan, or other secure means;**
- **Enter the chamber;**
- **Entry door automatically locks;**
- **Verification of authority to enter;**
- **Exit door released and opens;**
- **Individual passes through the exit point.**

Security can be heightened by taking the following steps:

- **Limitation of time when the entry point can be opened or accessed;**
- **Depress two separate control buttons simultaneously on each side of the chamber;**
- **Metal detectors;**
- **Sensors to detect presence, such as floor mats that must be touched prior to the exit door opening.**

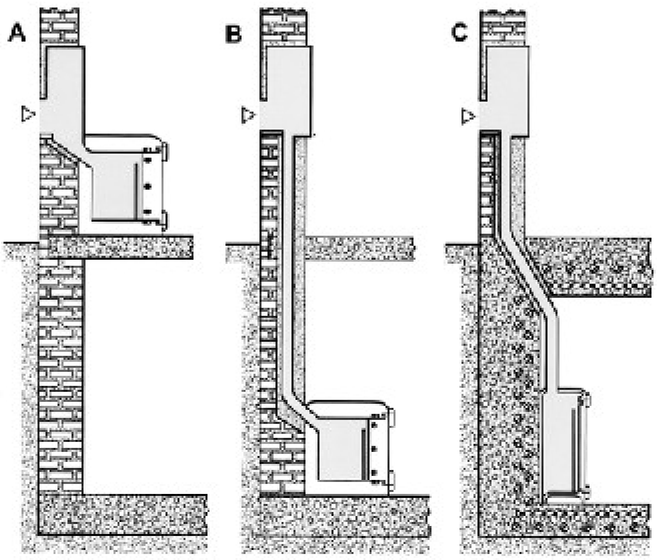
39_10.3 Money Locks for Armored Cars

Any vehicle that carries currency and negotiable instruments is

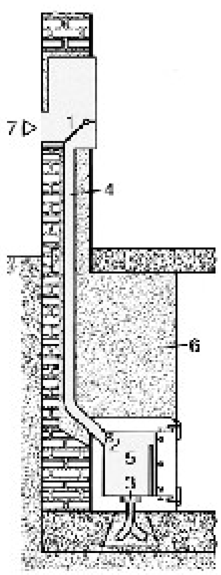
an obvious target. Most robberies occur during loading and unloading of armored cars at a customer premises or central banking facility. The safest way to transfer cash requires transport vehicles to load and unload within secure areas called money locks. These are designed much the same as the locations within detention facilities that are used for loading and unloading of prisoners. Money locks are specifically designated locations that allow control of ingress and egress. They are equipped with heavy-duty electrically controlled gates that can only be activated from within the secure area. Ideally, a second perimeter gate must be passed through before gaining access to the money lock. Much like a prison, the facility should have electrically interlocking mutually exclusive gates. Only one can be opened at a time.

The proper procedure requires that the vehicle is driven into the lock and the entry gate is closed. After a security check, the vehicle is loaded or unloaded and then allowed to exit. Surveillance of approach routes must be easy to maintain and should not involve traffic through underground garages. An escape route must also be provided for transport staff in case of holdup or other emergency. Entry and exit should only be possible with proper identification and should never be accessible to the public.

39_10.3.1 Specific Security Guidelines for the Use of Money Locks



- **Approach of the courier vehicle should be announced to the bank prior to its arrival in order to avoid dangerous delays of entry;**
- **Courier staff should not be able to gain direct access to the security center that controls the money lock. Even when the vehicle is inside the lock, staff should not be allowed to exit until cleared to do so;**
- **Transfer of valuables should be accomplished through a one-way transfer counter that is controlled from a secure vantage. Bullet-resistant glass should always divide such areas;**
- **Currency and other valuables should not be stored in any location that is subject to access by staff who could be taken hostage by armed robbers;**
- **Holdup alarms should be installed at several**



locations within the lock and control center;

- **Internal money transport from the lock should not lead through areas accessible to the public.**

39_11.0 Night Depository Safes

Banks and other institutions utilize night safes to allow customers to make deposits after hours, in the form of currency contained in envelopes, money bags or cash boxes. Night depositories can be accessed by using a key or code card.

Although there are many different designs, these security containers usually contain the following components:

- **A vault door with a deposit drawer;**
- **A shaft leading to the receiving safe;**
- **An armored stand-alone safe to receive and store currency, or a vault contained within a strong room.**

Night safes are modeled after three basic designs:

- **A deposit drawer and receiving safe in which the customer directly makes the deposit. The stand-alone safe is usually located on the ground floor;**
- **The deposit is transmitted to the receiving safe through a shaft and is not directly connected;**
- **A deposit drawer is placed at a remote point, and the receiving safe is located inside a strong room.**

39_11.1 Security Guidelines

Certain security guidelines must be followed to insure the integrity and safety of the receipt and storage of customer deposits. These include:

- **The safe must be placed in an observable position, preferably visible through a front window;**
- **The deposit point should be located in a well-lit position;**
- **Drive-up deposit facilities are popular and lower the incidence of robbery of patrons;**
- **The entry point should contain a mechanism that places the deposit envelope, bag, or box at a steep angle in order to insure that it is dropped into the safe;**
- **The connecting shaft between entry point and safe should be constructed of a minimum of 4 mm steel pipe to insure resistance to forced attack. The shaft should be surrounded with reinforced concrete of at least 20 cm thickness;**
- **A high-security cylinder must be utilized on the**

access door to the vault;

- Safes should be bolted to the floor or set in concrete in order to prevent removal or forced access;
- An automatic flap should be installed to prevent removal of contents through the deposit slot;
- If cash containers are deposited into the safe, then they should be made of non-magnetic material;
- Holes should be bored into the depository to prevent the use of water as a means to floating out the contents;
- An electronic monitoring system should be installed to include:
    - Panic alarm inside of the vault door and accessible to a customer making a deposit;
    - Surface monitoring of the shaft as well as joints between deposit slot and shaft;
  - Magnetic contacts should be used on safes not located within a strong room;
- Seismic detectors should not be utilized, as they may be set off frequently as a result of containers hitting the walls of the shaft or safe;
- Capacitance and proximity systems should be used on safes not located within strong rooms.

39_12.0 Padlocks

Poorly designed padlocks and hasps can offer the thief many opportunities for bypass. If padlocks are utilized to protect a secure area, the following assessment of vulnerabilities should be undertaken:

- A stick knife, straight knife, or stiff wire can often be manipulated through the keyway to retract the locking dog to release the shackle;
- A stiff wire or hairpin can be used in certain padlocks to rotate the locking mechanism that extends ball bearings toward the shackle;
- Failure to change factory combinations;
- Certain padlocks are programmed with progressive combinations. These number sequences are easy to test;

- **Gate locations can be tested by applying pressure to the shackle and then rotating the dial past every number. Likewise, the third number in a combination sequence can be determined by pulling on the shackle as the dial is rotated;**
- **Hasp design and hinge pins can be compromised by cutting, requiring that hasps be anchored with heavy bolts;**
- **Combinations can be easily decoded in Corbin Sessamee and other thumbwheel locks on briefcases and padlocks;**
- **Code numbers stamped on the padlock can be interpolated and used to produce keys or the correct combination;**
- **On certain thumbwheel mechanisms, the combination can be viewed when the lock is in the open position;**
- **Warded locks can be easily picked or bypassed with skeleton keys;**
- **Padlocks can often be rapped open by striking the side of the case with the shackle depressed. This will cause locking balls or dogs to "bounce" momentarily;**
- **Curved stiff shims or "sneakers" can be used to bypass locking dogs. They are wedged between the shackle and body and then rotated to separate the dog from the recessed portion of the shackle. They will not work with ball bearing locking.**

39_13.0 Peepholes (Viewing Lenses) in Doors

Peepholes are a simple and inexpensive addition to any security program. They have been employed in the hotel industry for many years and should be installed in secure areas where video monitoring is not available. They allow an employee to observe activity in front of a door, with a typical viewing angle of approximately 120°. Sufficient lighting should be available to allow all areas to be clearly seen. Mounting of peepholes should be done in such a way as to insure that they cannot be removed from the outside of the door and used as an access point for manipulation of locks.

39_14.0 Push-Button Access Locks

Mechanical and electronic push button locks are a popular form of access control. They require the proper sequence of depressions to actuate them. These devices can be compromised by observing deformities, wear, shiny spots, or dirt on the buttons that occur over time. Buttons may also be fingerprinted with UV indicating powder. The remedy for these techniques is to depress extra buttons after the combination has been entered or utilize a Hirsch scrambled keypad. In this configuration, the position of the buttons changes for each entry, making useless any information derived from dusting.

39_15.0 Radio Frequency Interference

The author has compromised certain mechanical and electronic locks and related devices with strong RF fields generated from a two-way radio. This can be an extremely effective method of bypass. In secure areas, locks should always be tested for this design deficiency. In one investigation, the author was able to circumvent an electronic parking meter system with RF at 800 MHz. In another case, several different magnetic locks were neutralized in the same manner.

39_16.0 Safe-Deposit Boxes

Every bank maintains safe-deposit vaults for the convenience of their customers. The containers provide little security and can be rapidly compromised with nose pullers. Thus, boxes must be stored in a secure strong room in order to afford maximum protection. See **Chapter 33-34**.

There are two types of locking systems used on safe-deposit boxes, depending upon the banking institution:

- **Dual locking system: Renter's lock and bank lock;**
- **Dual Locking System: Renter's lock and electronically controlled lock.**

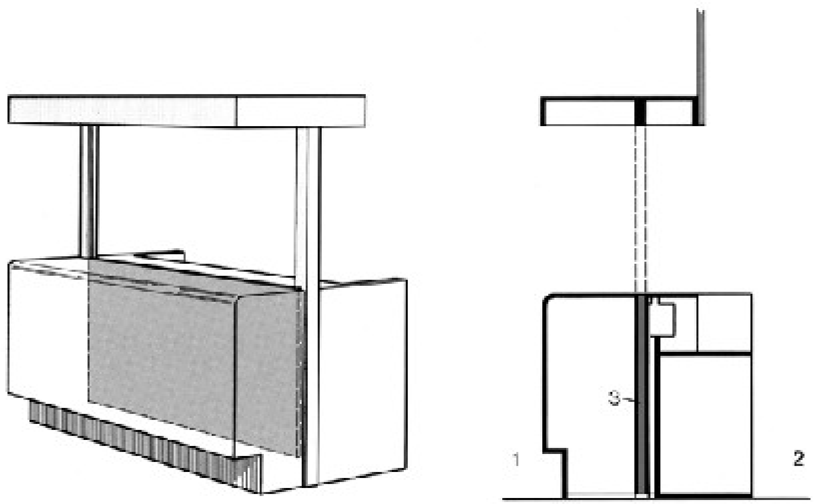
Dual-control mechanical lever locks have been used in banks for over 100 years. However, in Europe some locations have installed electronically controlled devices to increase administrative control and security. In the electronic system, the bank employee enters the client’s data into the computer, which then releases

the lock. The box may be opened within a specified timing window, if the renter has the proper key. If not, the entire procedure will be cancelled. A complete audit of the transaction is stored for legal documentation. There are certain advantages to such centralized control systems. These include:

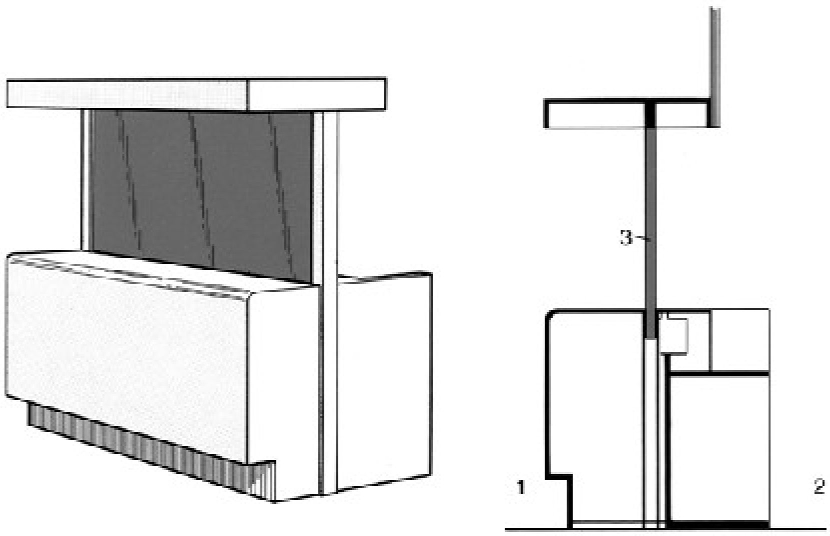
- **Fewer staff required;**
- **The client can open his box without the need to be accompanied by staff;**
- **Complete audit trail;**
- **The entire system is electronically monitored for tampering, failure to properly secure a box, or a customer attempting to open another box.**

39_17.0 Safes and Combination Locks: Compromise and Bypass

As detailed in **Chapters 34-36,38**, there are many methods to compromise and bypass combination locks, safes, and vaults. **Bypass** techniques pertain to physical methods of manipulation and forced-entry. **Compromise** relates to techniques that circumvent the normal security of the lock and container. Methods of compromise include:



- **Failure to change factory combinations;**
- **Failure to maintain security of the combination. Many people cannot remember number sequences. In such cases, they ignore security procedures and leave the information where it can be found by unauthorized persons;**
- **Failure to properly secure combination locks by utilizing day-locking;**
- **Failure to utilize key-locking dials and dial rings;**
- **Improper use of key-locking dials and dial rings in lieu of actually engaging the combination lock;**
- **Failures to lock drawers that control secondary drawers. GSA specifications require that all drawers must individually lock in security containers;**
- **Drilling and replacement of components in order to hide the fact of entry;**
- **Covert acquisition of combination through**

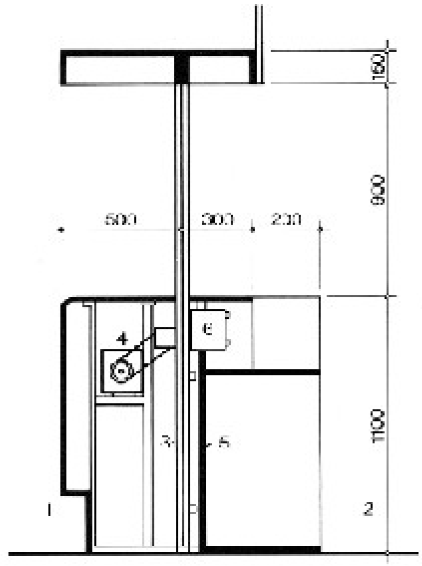


surveillance;

- **Acquisition of combination by reading position of wheel pack or changeable wheels while the safe is open;**
- **Failure to monitor the status of open safes and their combination locks;**
- **Failure to utilize spyproof dials;**
- **Fingerprinting of dials;**
- **Manual manipulation;**
- **Use of robot dialers;**
- **Radiographic imaging.**

39_18.0 Safety Counters in Banks

Special protection can be afforded to cashiers by the use of anti-bandit glazing systems. These optical and acoustic isolating safety counters are designed to separate the bank staff from customers in case of a robbery. They are not intended to protect customers but to prevent robbers from gaining access to cash and internal areas.



The systems require that a sufficient number of counter units are deployed to insure that all openings connecting staff and customer areas can be sealed. When an alarm is activated, a steel-plated bullet-resistant panel is raised from within the counter. This action requires less than one second from the initiation of an alarm. There are several advantages to such systems:

- **Robbers cannot gain direct access to staff. This also reduces the danger to customers;**
- **The panels are only raised in an emergency. Otherwise, normal operations are not affected;**
- **There is a greater chance that an alarm will be activated during a holdup, because the staff is protected.**

Disadvantages of such systems include:

- **High installation costs;**
- **Space utilization and design parameters may be limited, due to the shape of the counter elements;**
- **Moving panels may be blocked through jamming or by objects placed in their path. Glass panels may be installed on the customer side of the counter in order to eliminate this problem.**

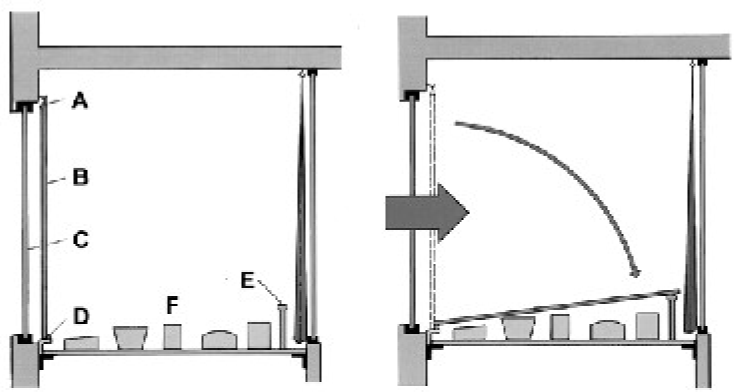
39_19.0 Secondary Panes

Secondary panes of translucent material offer an economical and effective way of protecting display windows. They are often employed when laminated panes, roller shutters or bars are impractical. In many cases, it is difficult to tell that they are in place, because they do not interfere with the view of the objects on display. Secondary panes also can make electronic monitoring of display windows more effective. Glass-breakage detectors, vibration contacts, magnetic trips, or thin trip wires can be utilized to insure an immediate alarm in the case of forced-entry.

39_19.1 Mounting of Secondary Panes

Secondary panes can be mounted in three configurations: **immovable**, **wire-suspended**, and **moveable**.

39_19.1.1 Immovable Secondary Panes



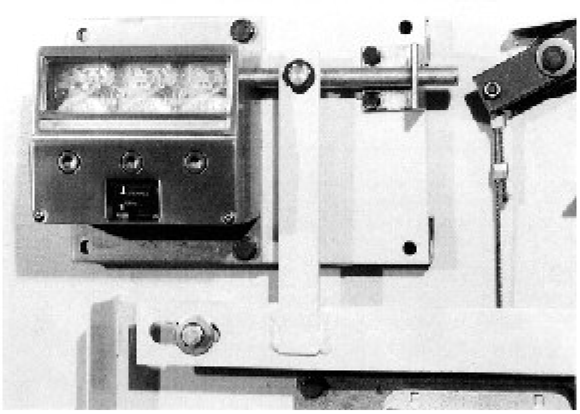
They are positioned in a frame behind the display window itself and consist of largely shock-absorbing material, preferably a polymer. The pane must be firmly affixed within the frame and the frame securely anchored in the display window. Physically, the panel must be high enough to insure that a burglar cannot climb or move over it.

39_19.1.2 Wire-Suspended Secondary Panes

A wire-suspended secondary pane is subject to circumvention by cutting the support wires.

39_19.1.3 Moveable Secondary Panes

A moveable pane, made of polycarbonate such as Lexan, is attached to the bottom end of the display window frame with a strong hinge properly fastened. A fine wire or magnet is utilized to move the pane into position. The panel is set to fall onto the objects displayed, thereby providing a cover. If the pane fully covers the display area, it is impossible for a burglar to reach the merchandise. To be effective, moveable panes must also be installed on any side-windows.



The separating wall that isolates the display window with the interior of the premises must be solid and stable in order to prevent an intruder from climbing into the premises, then lifting the secondary pane. Another barrier of translucent material, mounted in a solid frame, should present a further obstacle to entry to the building **through** the display window.

39_20.0 Time Locks

The origin and use of time locks was discussed in **Chapters 33** and **34.** The focus of the following discussion is on their use in preventing robbery and unauthorized access to secure areas. Time locks were invented to reduce the incidence of robberies and kidnappings involving the forcing of employees to open safes and vaults. They are an American invention and are extremely effective. It is important that the public be aware that time

locks are in use within the bank or other facility; signs are usually posted as a deterrent.

A time lock will block the boltwork for a predetermined time and can allow it to be actuated during a specified period. Entering the correct combination will not defeat the lockout, thus knowing the code or having the key will do no good. Time locks will not allow an unscheduled opening, even in an emergency.

The movements are usually equipped with two, three, or four individual clocks. Most are still mechanical, although electronic systems are gaining popularity because of the many options they offer. The devices are fail-safe, because each clock operates independently; each can release the block on the boltwork. Sometimes, one of the backup clocks is set to a lesser opening period in case of failure.

Mechanical time locks can usually be programmed for up to 144 hours. The microprocessor-based systems can be set for a year in advance, to include special dates and holidays. It is also possible to install blocking time relays as an alternative to time locks. These are remotely controlled and thus can be bypassed. They are not suitable to prevent hostage-taking during a robbery.

39_21.0   Tubular (Axial) Pin Tumbler Locks

Tubular locks are extremely popular in vending, alarm, and access control applications as described in **Chapter 17**. They are a pin tumbler mechanism and are configured so that the pins are oriented around a 360° circumference. When a key is inserted, it

depresses each of the pins to shear line in order that the core may rotate.

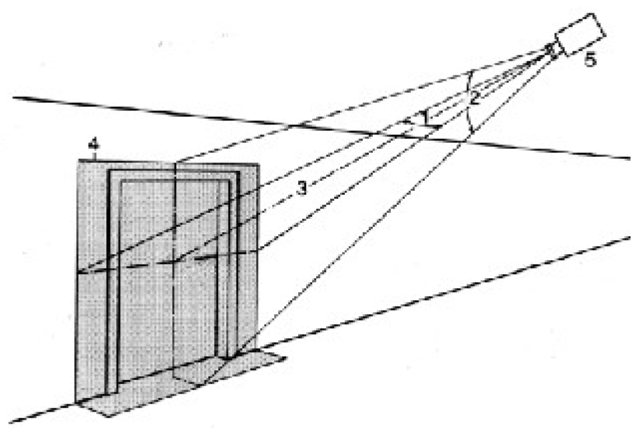
Some of these locks may be defeated by applying hair spray or 3M Spray-Ment adhesive to the pins to overcome the spring bias. When the proper key is inserted, the tumblers will stick at shear line. This will allow the plug to be turned later by using a torque wrench.

39_22.0 Video Surveillance Systems

The use of video has become an integral part of electronic security systems anytime local or remote monitoring of high-security areas is required. Video systems accomplish three essential functions: surveillance, identification, and documentation.

39_22.1 Components of the System

There are five primary components to any video system:



- **Camera;**
- **Encoding system;**
- **Transmission system;**
- **Monitor;**
- **Recorder.**

39_22.1.1 Camera

The function of any camera is to capture and convert visual images into an analog or digital signal. Today, cameras are based upon charge coupled device (CCD) technology. This integrated circuit is capable of converting a focused image into digital information on a single chip. A video camera consists of a lens, CCD, microprocessor to control synchronization, video amplifier, and impedance matching device to conform the output to a transmission link.

In older camera systems, an image was captured with a pickup tube. Depending upon vintage, these were known as a Vidicon, Newicon, Plumbicon, or Ultracon. The Vidicon is perhaps the most popular and is still in service in thousands of cameras. In any pickup-tube, a light-sensitive layer was activated by an electron beam, called a cathode ray. The beam was horizontally and vertically controlled through electromagnetic deflection coils.

Focus (mm)	⅔" pick-up tube Angle of image (degrees) horizontal	vertical	1" pick-up tube Angle of image (degrees) horizontal	vertical
4.5	89	72	-	-
6.0	72	58	94	77
8.0	58	45	77	62
12.5	39	30	54	42
16.0	31	23	44	33
25.0	20	15	29	22
50.0	10	7.5	15	11
75.0	6.7	5	10	7.3
100.0	5	3.8	7.3	5.5
150.0	1	0.75	1.5	1.1

39_22.1.1.1 Vidicon Tubes

Although today they are obsolete, the Vidicon was predominant for almost twenty years. Because many of the cameras are still in service, a brief amount of information will be provided here. The Vidicon offered the means of providing video cameras for the security industry, because the tubes had a long service life at relatively low cost. Consequently, the use of video became extremely popular and cost effective.

The tube is based upon a technology that builds an electronic image by interlaced scanning of individual lines. In the United States system (NTSC), each **field** is comprised of 262 lines. A **frame** is made up of two fields, for 525 lines. A Vidicon requires suitable illumination; it is not responsive to low light levels.

The tube also suffered from a high degree of inertia, wherein moving images could smear or appear to be sluggish. It also has a serious burn-in problem; a powerful light source focused on the same location can cause permanent damage. This was one reason for the camera failure during a transmission from the Moon; it was inadvertently pointed at the sun.

39_22.1.1.2 Other Pickup Tube Technology

The Newicon tube was an enhancement that allowed for both indoor and outdoor surveillance. It was light sensitive, with a low burning sensitivity and inertia. The device did not suffer from another common problem called blooming, wherein light dots would expand. Unfortunately, the Newicon was very expensive as compared to the Vidicon and was not practical for most applications. Infrared sensitivity was not particularly good, either.

The Ultricon was yet another replacement for the Vidicon and offered several advantages. It had high sensitivity to light across the entire spectrum, from ultraviolet to infrared. It did not suffer from burn-in and had a low degree of inertia.

The silicon intensifier target (SIT) is an image intensifier having an extremely high sensitivity to light. It is used in available-illumination cameras and early-generation night-viewing devices.

The Plumbicon was the most expensive pickup tube available and was used exclusively in studio cameras. It offered the highest image quality and could cost up to $100,000. The tube had very low inertia, low burn-in sensitivity, and fine resolution.

39_22.1.1.3 Charge Coupled Device

Today, virtually all cameras utilize CCD technology. This chip set contains a light-sensitive photo array that generates different signals based upon intensity and color. A microprocessor scans the individual elements at a rate of about 250,000 or more times per second. The CCD requires very low power levels and is quite small. Cameras can be built into any item and are ideally suited for undercover and surveillance work.

39_22.1.1.4 Camera Location

Cameras must be placed to provide the desired view without interference from external sources. Several issues must be

evaluated and considered in choosing the proper camera and placement location:

- **Type of camera: color or monochrome;**
- **Resolution of pickup tube;**
- **Correct lens, with focal length that will allow sufficient clarity of target area;**
- **Select location to provide an unobstructed view of target area;**
- **Avoidance of bright light sources that will interfere with the picture;**
- **Camera should not face windows;**
- **Outdoor cameras must be mounted at a sufficient height to prevent tampering;**
- **Utilization of a secure housing for outdoor placement.**

39_22.1.2 Encoding System

Video may be encoded in a number of different formats, depending upon transmission medium, storage requirements, and national standards. In the United States and many other North American countries, NTSC is the accepted format. In most of the rest of the world, PAL or SECAM has been adopted as the encoding protocol. These systems are all analog rather than digital. The difference in these formats relates to scanning rates, lines per field, bandwidth, and the method by which color is interpreted. NTSC and PAL cameras are utilized for surveillance applications, with the appropriate recorders.

In the future, images may be encoded in digital format, with high definition television (HDTV) on the horizon. Within a few years, HDTV may become the transmission standard in all industrial countries. It appears that the new system will provide superior resolution but requires a great deal of bandwidth to do so.

In surveillance applications, both analog and digital cameras are prevalent today. The NTSC format is still the most popular and cost effective, although this is expected to change in the next few years.

39_22.1.3 Transmission Link

The image output from a camera must be transported to a monitor

and recording device. The mode of transmission depends in part upon whether the signal is analog or digital, and if it consists of full motion video or a series of still images. There are several means to transmit a video image, including coaxial cable, fiber optic link, twisted pair, RF, Intranet network, or the Internet.

39_22.1.3.1 Cable

Coaxial cable is the primary means of transmission for video signals, because it is capable of transporting the required wide bandwidth associated with images. Coax is inexpensive and easy to work with and is usually terminated in “F” style crimp connectors. These are the same as used in the cable television industry. Images can be carried on cable for hundreds of feet without appreciable loss and attenuation. Depending upon the grade of coax, a run of up to approximately 800 meters (2,624 feet) can be utilized without an amplifier or repeater. With such equipment, signals can be transported up to three miles.

39_22.1.3.2 Fiber Optic Link

Converters and direct fiber outputs are now available on some video cameras. Using a fiber optic link, signals can be carried up to 30,000 feet without need for additional line amplifiers or equalization equipment. FO cable has extremely low loss characteristics and has the capability of carrying many video and audio signals within one fiber bundle.

Fiber is inexpensive, secure, and easy to terminate. It is also impervious to electrical noise and interference that may affect signals carried on coaxial cable. This characteristic is especially important in environments where equipment radiates such energy.

39_22.1.3.3 Twisted Pair

Twisted pair and two-pair systems have been utilized for many years to feed video signals a short distance. Standard telephone circuits can be employed to transmit still images and slow-scan video, negating the need for coaxial cable or fiber. Useable transmission distances may be up to one mile. Several vendors now produce equipment that allows a small encoding and impedance-matching unit to interface with cameras and recorders at each end of a twisted pair. Excellent quality can be obtained with these systems at a relatively low cost.

39_22.1.3.4 Intranet or Internet

Surveillance video is now being transported on internal computer networks (Intranets) and on the Internet. These systems offer many advantages, including:

- **Ease in transmission;**
- **Transmission infrastructure is already in place;**
- **High-quality digital images;**
- **Polling of locations;**
- **Increased range over traditional systems;**
- **Remote access and control functions;**
- **Dial-up access from remote locations;**
- **Transmission of images anywhere in the world over the Internet;**
- **Software for viewing, capturing and recording of images is readily available.**

39_22.1.3.5 Radio Frequency (RF)

Video signals can be transmitted with a carrier frequency on cable or in free space. If a carrier-frequency system is utilized on cable, then video signals are modulated on high-frequency carriers, so that many different sources can be carried on one link. These systems are utilized by cable television operators who may carry 100 channels on one coax.

Microwave link systems at 2.4 GHz and 8 GHz are also in wide use by government agencies. These provide for broadcast-quality video to be transmitted for a range of up to five miles. The author is routinely involved in covert surveillance operations that utilize 2.4 GHz body transmitters and cameras. These are used to feed video and audio from undercover operatives to remote receiving equipment. In such a system, the transmitter weighs a few ounces and is easily concealed. This same technology is utilized in fixed surveillance operations where cameras must be placed at remote locations not suitable for wiring.

Internet enabled wireless cameras are now quite prevalent and inexpensive. These generally systems utilize 802.11b protocol at 2.4 GHz and will allow for remote control of all functions. Each camera is assigned an IP address and can be addressed from anywhere in the world.

39_22.1.4 Monitor and Reproduction Technologies

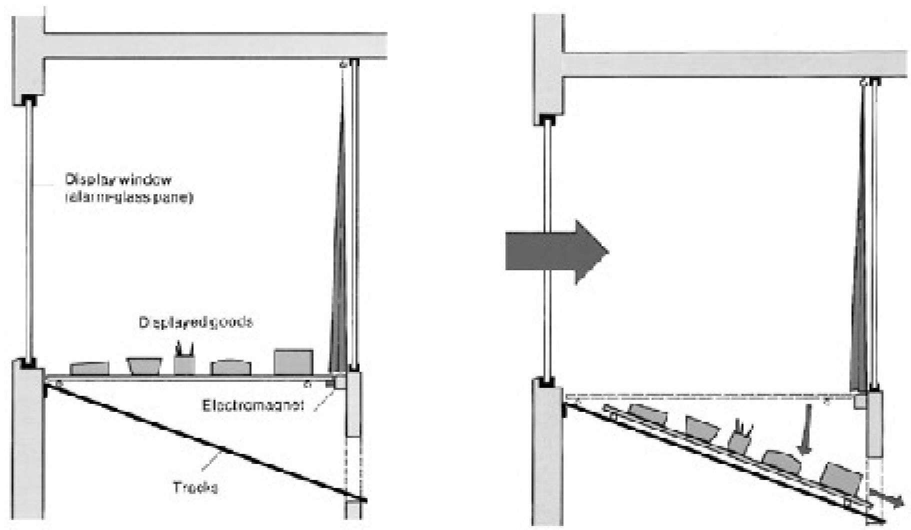
A means to monitor and record surveillance video must be provided. These functions are usually combined within a control room or secure operations area. Traditionally, a bank of monitors coupled to video recorders allows security personnel to observe special locations within a facility. Although more expensive, color camera and monitor equipment is recommended for almost every application. The exception may be low light level situations that require increased sensitivity. Color cameras provide less operator fatigue and greater capability for identification. Differences in color can become extremely important, especially where there are many potential targets in one image.

Screen size and monitor location must be considered in terms of convenience, functionality, and ability to observe displayed information. The general rule is that the distance between monitor and observer should not be more than four to six times the diagonal size of the screen. The location of the monitor is important in order to reduce glare and enhance the ability to observe images.

Any video surveillance system must incorporate a time-date generator and identification of camera location. This data must be imprinted on the tape for evidentiary purposes. If a multiplex system is utilized wherein several cameras are integrated into one screen, then camera identification is especially important. Many recording systems capture quad frames that are composed of four different video segments. Each can be viewed as a full screen image, if desired. Each frame will contain its own identification information as to location and time/date.

39_22.1.4.1 Image Analysis Systems

Image analysis systems provide an alarm when there are definable changes in a video image. The technology allows one security guard to effectively observe many different locations by providing the means to target portions of an image for movement or difference. Any change will trigger an alarm, and activate a recorder. Certain areas of an image may be excluded from monitoring, also. These systems do not respond to gradual changes in the picture, such as caused by lighting level differences from clouds or transition from day to night. They will alarm in case of tampering or loss of supervision of the transmission medium.



39_22.1.4.2 Video Recording

Video images and audio may be recorded on magnetic tape, hard drive, optical or magnetic disc. VHS and 8 mm magnetic tape is the most popular and cost effective. Recording may be done in real-time or time-lapse up to one month on one cassette. If time-lapse recording is utilized, it is recommended that 8 mm format be employed rather than VHS. In the author's experience, these systems provide superior picture stability and playback resolution.

39_23.0 Trapdoor Security Devices

Trapdoors are popular in Europe for the protection of merchandise in display windows. They are utilized to automatically remove goods in case of a smash-and-grab burglary. The platform is constructed as a moveable display surface that rolls into the interior premises upon initiation of an alarm. The panels are held in their normal position by an electromagnetic bolt. In case of glass- breakage, a signal is transmitted to the release system and the platform containing the goods roll into the store. Certain guidelines apply to the use of security trapdoors:

- **The display surface should not be larger than 4 square feet (1.5 m^2);**
- **The display merchandise must not exceed the height of the opening into the store, so that the platform is not stopped from moving;**
- **The entry point for the moving platform must be secure to prevent access from the window side.**

40_1.0 Introduction

LSS403: DOE on a typical plan of attack on a facility

The function of any alarm system is to reliably signal the entry of intruders or an irregular event within a protected area as soon as possible. Alarm systems do not prevent or hinder intrusion; they just provide an immediate notification so that action can be taken.

Alarms are now an integral part of most security systems. They utilize state-of-the-art electronics that offer a sophisticated array of technologies to sense intrusion or irregular events. This chapter will examine electronic monitoring systems, with an emphasis on procedures, functions, and individual components. To be effective, alarm systems must work in conjunction with other security measures that are based upon sound design and organizational practices. Adjunct security measures (defense in depth) include lighting, video monitoring, access control, physical security hardware, and guards.

Extensive materials have been added to this chapter regarding specific types of alarm sensors that did not appear in the Second

Edition. Much of this material has been excerpted from the ***Perimeter Security Sensor Technologies Handbook***, prepared by Naval Command, Control and Ocean Surveillance Center, In Service Engineering (NISE East), Electronic Security Systems Division. Materials and technical assistance have also been provided by Don McInnes PSP, SET, Jerrold Antoon, CPP, RL, and Ken Wippich, recognized physical security consultants in the alarm industry. Appreciation is also expressed to Fox Valley Technical College (Appleton, Wisconsin), ADT Security Services, Inc., Denning Electronics, and Nuclear Security Services Corporation for their input and assistance. Other materials were received from Ross Anderson, Cambridge Computer Laboratory, in England. Finally, video, graphics, and procedures manuals were supplied by the United States Department of Energy and the **DOE(442)** Office of Security and Safety Performance Assurance. Their assistance is greatly appreciated.

40_1.1 Alarm System Overview

LSS403: Ross Anderson on alarm system monitoring

Electronic monitoring is an indispensable part of perimeter and internal security. The primary goals and design parameters of any alarm system include:

- **Supplant physical barriers;**
- **Detect intrusion as soon as the event occurs;**
- **Notify authorities as soon as detection occurs;**
- **Complicate and delay ingress;**
- **Delay access and the collection of stolen goods or property or ability to reach a target;**
- **Require more time for egress;**
- **Make each phase of an intrusion more risky in terms of apprehension.**

Alarm systems should be designed to detect and signal an intrusion as soon as possible. This should provide a sufficient response time for personnel, commensurate with the value of the protected property. Each sensing device must be reliable, and subject to continuous monitoring for integrity. All critical points or targets of ingress and egress should be protected electronically.

Alarm reporting may occur by direct supervised connection (leased dedicated circuit or sub carrier circuit) to a central station, dial-up to a monitoring facility, wireless link, or local alarm to an internal control center. Local audible or optical warning systems may also be implemented as a deterrent. The effectiveness of any alarm system is based upon the following criteria:

- **Competent design;**
- **Redundant and overlapping coverage;**
- **Proper installation;**
- **Reliability of each component;**
- **Correct operation by employees;**
- **Protection against unauthorized bypass;**
- **Response time.**

Alarm systems should either be automatically activated, or have a fail-safe mechanism if staff forgets to activate them. Logs should be provided to indicate any alarm faults or activity. Inexpensive stand-alone devices on doors, often battery powered, cannot be considered as burglar alarms. An alarm **system** is comprised of sensors, control unit with backup power, and links to a central station or other monitoring facility.

Preliminary evaluation of alarm systems must include the following issues:

- **Type and design of control unit;**
- **Number of control units;**
- **Number of circuits to the central facility;**
- **Emergency power supply type and duty cycle;**
- **Complexity of the alarm system;**
- **Type and number of sensors;**
- **Vulnerabilities of each sensor;**
- **Identification of individual sensors, and analysis of each alarm condition that they are designed to detect;**
- **Anti-tamper and integrity circuits;**
- **Verification that all trips are functioning properly before the system can be activated;**
- **Electronic supervision of all alarm circuits.**

40_1.1.1 Operational Requirements

The utilization of security hardware and procedures depends upon the specific facility and unique requirements that it may dictate. Any **perimeter** security system has four primary goals: **deter**, **detect**, **document**, and **deny** or **delay** intrusion. Operational requirements must balance the factors listed below with respect to protection, technology and cost. Factors that influence the application of security measures include:

- **Type of facility or material to be protected;**
- **Existing culture and security awareness;**
- **Willingness to accept security countermeasures and follow procedures;**
- **Nature of the environment;**
- **Client's previous security experience and threat history;**
- **Any perceived threat;**
- **Nature and tempo of activity in and around the facility;**
- **Physical configuration of the facility to be secured;**
- **Surrounding natural and human environment;**
- **Weather variations;**
- **Traffic patterns;**
- **Access to the facility;**
- **Personnel and vehicle screening requirements and barriers;**
- **Potential threats that are unique to the type of facility;**
- **Budgetary considerations, including:**
    - **cost of hardware in relation to protected area;**
    - **cost of installation and maintenance;**
    - **construction costs;**
    - **alarm center modification that may be required.**

40_1.2 Regulations Regarding Alarms

The regulations and stipulations regarding the manner in which an alarm is to be activated are different for every jurisdiction. For example, in some places it is not permitted to combine silent alarms and audible alarms. Information about the relevant requirements can usually be obtained from the police. Many cities have enacted comprehensive ordinances and regulations regarding the installation, maintenance, programming, and reporting of

burglary and fire alarms. Failure to follow specified technical requirements can subject business owners to fines.

40_1.3 Alarm System Procedures

Organizational procedures must be adopted to insure reliable operation with a minimization of the potential for false alarms. In some jurisdictions, penalties are assessed for malfunctions that result in a law enforcement response. Alarm systems must be properly set by employees in order to function reliably. Those responsible for activation must be correctly trained in procedures relating to setup, malfunction, bypass of zones, and reporting. A system must be designed so that areas can be segmented and certain rooms deactivated for cleaning, maintenance, and other tasks. After-hours entry must also be considered.

Individual passwords for each employee should be mandatory so that entry and exit tracking logs are maintained. Access codes should be routinely changed, especially in the case of termination in employment status. Routine inspection of trips for bypass and to test all trips, especially normally open types, is essential.

40_1.4 Alarm System Considerations and Planning

Alarm sensors and systems must be selected and installed based upon the requirements of the specific location and object or area of protection. Suitable devices must provide adequate monitoring to insure the security of the asset or area and eliminate the prospect of compromise.

Certain types of alarm trips can be bypassed without much difficulty. For that reason, the planning and implementation of electronic protection should be done by knowledgeable technicians who thoroughly understand bypass techniques and idiosyncrasies of each classification of trip, as shown in the accompanying videos. Any alarm system that protects exposed objects must be designed so that it cannot be circumvented or avoided and that the correct device for the intended purpose is chosen.

Many considerations must be taken into account when planning and implementing an alarm system. Preliminary determinations include:

- **Will volumetric sensors are subject to false trips due to the construction materials utilized in protected areas. Microwave devices see through walls. Thus, it is important that proper tests be conducted to insure that movement in adjacent areas does not create false alarms;**
- **Has the appropriate classification of sensor been deployed for a specific application;**
- **Concentration of exposed objects within a limited area can lessen the cost of protection, although this can also make it easier for a burglar to collect goods;**
- **Physical security devices (fences, barriers) are just as important to an electronic monitoring system as sensors;**
- **Special precautions should be taken when electronic holdup switches and push buttons are used to manually signal an emergency because of the incidence of false alarms;**
- **Sensors that are tripped in the normal course of a robbery or burglary, such as bait money contacts, are desirable;**
- **The use of any detection device should not disturb work processes;**
- **Layers of perimeter security must be employed to delay or prevent entry. These include fence lines, in-ground sensors, and volumetric devices such as microwave and infrared.**

40_1.5 System Reliability

One of the most common problems with intrusion detection systems is that they can generate an inordinate number of false alarms. A high rate of false and/or nuisance alarms may cause the protective force to ignore or improperly assess an unauthorized intrusion. If a system is not planned and implemented properly, increased susceptibility to false and nuisance alarms will be the result. This is especially true when microwave sensors, infrared sensors, electric field sensors, seismic sensors, and buried sensors are employed.

False alarms result from many factors. Such issues can also be used as a cover for intruders in order to cause the protection staff to believe that a false alarm has occurred. Thus, lightning is a perfect cover for initiating multiple alarms to defeat a system. Specific vulnerabilities include:

- **High winds;**
- **Telephone ringing;**
- **Noise;**
- **Lights;**
- **RF interference;**
- **Heavy rain;**
- **Temperature extremes;**
- **Terrain irregularities;**
- **Animals (sounds and movement);**
- **Heavy snow;**
- **Air turbulence;**
- **Lightning;**
- **Vehicular vibration;**
- **Wind-blown dust and debris.**

System reliability, in terms of sensors, transmission links, and the central processor is critical. A reliability factor of 100 percent would mean that there were no false alarms and that the system would only react to a real intrusion or violation. Sabotage or compromise would always trigger an alarm. Unfortunately, this level of reliability is unattainable. Presently, over 90 percent of all alarms are false. This results from many factors, including employee error, environmental considerations, poor system design, and other issues that cannot be controlled.

In metropolitan areas, false alarm rates as high as 98 percent are common. The result: law enforcement is less willing to respond in a timely manner. Many jurisdictions now charge the property owner for false alarms. They have also enacted comprehensive ordinances for the installation and maintenance of all burglary and fire reporting systems.

Many factors and parameters contribute to a reliability rating. These include:

- **Resistance to tempering and compromise of any**

component within the system;

- **Supervision of all transmission circuits including internal links to each trip, and externally to a central station facility;**
- **Protection from malicious interference;**
- **Reliability of sensing device and immunity to false trips;**
- **Alternate power supply. Reliability requires that a system be capable of operating for up to 72 hours from a battery or other backup power supply. Automatic and uninterrupted switching to alternate power sources must occur;**
- **Wireless trips should be avoided, as they may not be reliable and can be subject to interference. Systems that use wireless technology that operate in the 305-316 MHz band or on carrier-current over power mains should be avoided, if possible;**
- **If wireless links to monitoring facilities are employed, redundancy must be built into the system.**

40_1.6 Intrusion Detection and Assessment, Threats, and Inspection

Assessment is often given the lowest priority in security system planning. The process provides an evaluation of a possible alarm condition and a response, which may include the deployment of a protective force, verification of an alarm with a sophisticated video monitoring system, sealing of certain areas, or the initiation of other procedures. High tech sensors, fancy consoles, and other sophisticated systems may cause one to lose sight of the fact that in the end analysis, a human must make a decision as to whether there is an intrusion, and react accordingly with an appropriate response. An intrusion detection and assessment system has four primary functions:

- **To alert the protective force to intrusion;**
- **Aid in alarm assessment;**
- **Allow the protective force to track intruder progress toward a target;**
- **Aid in assessing intruder activity and characteristics (for example, the number of intruders and whether they are armed).**

40_1.6.1 Failure to Properly Assess and Respond

Many design deficiencies in an intrusion detection and assessment system can lead to a breach in security and a failure to respond to a valid alarm appropriately. Such design errors can include:

- **A high rate of nuisance and false alarms may degrade operator response to real alarm conditions;**
- **Failure of a system to adequately identify alarm type and specific location can also degrade response;**
- **Failure of a system to clearly differentiate between tamper-indication, line supervision, and intrusion alarms;**
- **Multiple sensors are monitored by a single circuit;**
- **Computer-based systems are also vulnerable. Problems can arise because of erroneous software modifications and system configurations that cause program errors;**
- **Failure of the received signal from the detection device to provide identifiable evidence of the actual occurrence so that an operator can properly assess the situation and respond accordingly.**

40_1.6.1.1 Inspection Protocol

In order to properly assess the security of a specific site, inspectors must plan their method of evaluation, and gather a significant amount of information so that they are certain that they are properly assessing site-specific security risks and how they are being addressed. The individuals that are responsible for the site survey must accomplish the following tasks, prior to actually examining each component that makes up a security system. Specific issues that must be considered include:

- **Review of the site mission (obtained from a review of the documents and from interviews with operations office personnel and site representatives);**

- **Review of all documentation relating to a site, systems, and security. This would include:**

    - Organization charts;
    - Site security plans and procedures;
    - Security plans for temporary secure areas;

- Incident reports;
- Site/facility asset list;

- **Site maps indicating the location of layered security areas;**
- **Critical or sensitive areas that require special attention, including:**

    - vaults and vault-type rooms;
    - critical facilities;
    - controlled areas;
    - location of security posts;
    - classified areas;
    - vital equipment areas;
    - hazardous materials storage areas, including toxic and flammable chemicals and nuclear materials;
    - transfer routes for critical materials and assets;

- **Listing of the types of sensors employed;**

- **Local alarm reporting devices;**

- **Data transmission systems:**

- **Site lighting diagrams;**

- **Console equipment descriptions;**

- **All alarm procedures;**

- **Review of the assessment methodology employed (CCTV, video, and/or patrol response);**

- **Review of the vulnerability analysis, including consideration of:**

- Application of the design basis threat. In other words, what specific threats were identified for the specific site, and what system design components were integrated into the security system in order to protect against such threats;
- Review of site-specific threats to determine whether they

address local characteristics, including the insider threat;

- **Priority of site-specific threats target definitions and specific locations that are graded as to defense-in-depth measures that have been implemented. Specifically:**

- Type and location of potential targets;

- Compile a list of site assets, group them into appropriate categories, and determine potential impacts related to their loss;

- Pathways that can provide the lowest level of detection and/or shortest delay to ingress and egress;

- Listing of the protective elements identified in the vulnerability analysis for each security interest;

- **Review the validity of threat assumptions for current accuracy. This would include consideration of:**
    - Comparison of vulnerabilities against findings and resolution of past inspections and security surveys;
    - Review of protective methods employed at the location to be inspected;

40_1.6.1.2 Performance Tests

The following performance tests are recommended for alarms and intrusion-detection devices:

- **Exterior perimeter sensors;**
- **Interior sensors;**
- **Perimeter CCTV;**
- **Interior CCTV;**
- **Alarm processing and display equipment;**
- **Emergency auxiliary power supplies;**
- **Tamper protection and line supervision;**
- **Data collection activities;**
- **Alarm annunciation and sensitivity;**

40_1.6.1.2.1 Exterior and Interior Sensors

During inspection of any **perimeter intrusion detection assessment system** (PIDAS), inspectors should verify the following:

- **Examine the various types of sensors to determine whether they are complementary. They must consist of different sensor types that cannot be defeated by the same means, rather than just multiple layers of the same sensor;**

- **Confirm the existence of an effective testing and maintenance program for the PIDAS;**

- **Check the condition of the PIDAS ground for obstructions, mounds and valleys, and other terrain features that an adversary could use to avoid the detectors;**

- **Crossover and interface points should be checked to determine whether there are voids or blind spots in sensor coverage;**

- **Identification of PIDAS sectors that are susceptible to bridging as a result of their close proximity to tall buildings, fences, telephone poles, or light and camera structures;**

- **Evaluate any unsecured or unprotected access ways that could allow tunneling beneath PIDAS sectors;**

- **Within each alarm monitoring center, visually inspect all equipment, interview the operators, and verify information gathered during document reviews. Check the following:**

    - Operability of equipment;
    - Operators' familiarity with equipment;
    - Measures to protect equipment from tampering;
    - Determine if all alarms that are reported from the field are properly recognized and acknowledged, and that appropriate responses are made. Insure that all personnel understand their responsibilities with regard to assessment and reporitng;

- **At each exterior security sector or area where a PIDAS is employed, determine:**

    - Number and configuration of sensors;
    - Sensor alarm logic;

- Test frequency and methods;
- Preventive maintenance frequency and methods;
- Tamper-indicating provisions;

- **Provisions for repairing component failures;**

- **Determine the methodology utilized by staff to detect an intrusion at each security area. If more than one method of detection is used at a security area (for example, an electronic alarm system and direct observation from guard towers), determine how each system complements the other;**

- **Determine which system is considered the primary means of detection, and whether the combination (primary and backup) is effective;**

- **At selected interior security areas and storage areas, determine:**

  - Types of sensors that are used to protect building perimeters (including doors, windows, and other penetrations);
  - Testing and preventive maintenance and their frequency and methods;
  - Tamper-indicating provisions;
  - Provisions for repairing component failures.

- **Determine whether the facility has more than one central alarm system and, if so, the geographic area that each system covers. For each separate alarm system, verify:**

  - Central processing unit switching capability;
  - Tamper alarm features;
  - Adequate primary and backup power supply;

- **Determine the technical aspects of the system;**

- **Determine what the capability is for intrusion detection when the primary systems are out of service.**

- **Power Supplies:** Backup or emergency auxiliary supplies are required for all security systems. Verify the operability of these supplies. This procedure is normally accomplished in

conjunction with tests of lighting systems.

40_1.6.2 Assessment and Response

An evaluation of assessment and response of the system to various alarm conditions is essential in order to insure that security objectives of the facility are met.

A perimeter system, to be effective, must provide complete coverage. This is especially important in areas with alarmed fence lines that form a boundary between security area perimeters, and that also rely upon visual observation to assess alarms. One person should walk the perimeter fence line while others are stationed in the alarm center or observation posts (that are assigned responsibility for that portion of the perimeter). Each sector of the perimeter can be checked sequentially. In this way, the staff can verify that there are no blind spots. Moving randomly from post to post by inspectors is recommended.

- **Observe and verify the operation of CCTV systems, including:**

- Display monitors, during a range of lighting and weather conditions

- At different times of the day and night;
- Under various weather conditions. It may be wise to review tapes that have been produced on each video recorder that were made during different weather conditions;.

- Verify that camera and recorded video review capabilities are rapid enough to capture adversary activity. Generally, this is accomplished once during the day, and once at night;

- Fields of view;
- Adequacy of lighting;
- Blind spots or obstructions;
- Overlap with adjacent zones.

- **Identify the areas where direct visual observation is the primary means of detecting intrusion or assessing alarms. Determine:**

- Type of observation post (tower, portal, continuous patrol);
- Assessment aids available to protective force personnel (search lights, night vision devices, binoculars, camera zoom capability);
- Methods used by the facility to test effectiveness and maintain the requisite level of vigilance;
- Determine the operability of equipment and power supplies;
- Measures that have been implemented to protect equipment from tampering;

40_2.1 Primary System Components

Alarm systems that are available today can be simple and self contained, or highly sophisticated with many types of sensors. The inherent security within any system varies greatly. Every alarm system has four primary elements; **sensors, a central processor, transmission link,** and **local or remote method to receive and annunciate an alarm.**

Sensor Technologies Handbook.**

40_2.1.0 Technology Solutions

The sophistication of sensing equipment allows for the design of intrusion detection systems to meet virtually any requirements. The importance of the human element, combined with proper procedures, cannot be overstressed. It is the responsibility of personnel to monitor, operate and maintain all systems. Even more importantly, they must respond to each alarm and properly assess its validity.

Intrusion detection sensors have been designed to provide for perimeter and interior security, and include sensors for use in the ground, open areas, inside rooms and buildings, doors, and windows. They can be used as stand-alone devices with other sensors. In most applications, intrusion detection sensors are employed in conjunction with a set of physical barriers, personnel, and access control systems. The selection of sensors begins with a determination of what has to be protected, its current vulnerabilities, and the potential threat. All of these factors are elements of a risk assessment.

40_2.1.1 Sensor

This component is designed to detect changes based upon force and movement within a protected area. As will be described subsequently, there are many classifications of sensors, based upon the required level of surveillance and the environment. Although the proper integration of sensor technology into a coherent security system is relatively straightforward, it requires a system design analysis in concert with a review of parameters dealing with operational, installation, and specific security requirements.

Often, sensors have the capability of being utilized for both interior and exterior protection. Others have very specific limitations and function. The exterior sensor is utilized to detect entry into zones that create a perimeter of protection. In contrast, the interior sensor will be employed to detect penetration within an enclosed area, or movement within that

area.

In most applications, two or more sensors complement each other to provide added coverage, reliability, and a reduction in false alarms. Sensors can be set to work in tandem; their detection must be coincidental to verify an alarm condition.

The output configuration for most sensors is fairly standard: relay contacts to indicate alarm and tamper conditions. The output is generally linked by two or four wire conductors, often protected by a resistor network (end-of-line resistor) to indicate a change in line characteristics that would indicate tampering, opening or shorting of the circuit. In this way, monitoring and supervision can thus be assured.

40_2.1.1.1 Detection Factors

There are seven primary factors that will affect the Probability of Detection (PD) for most sensors (including volumetric). Each factor must be analyzed in choosing the appropriate sensing technology for a given location. The critical factors include:

- **Amount and pattern of emitted energy:** The sensor will perform more effectively as the more definitive is the energy pattern;

- **Size of the object:** A larger sensed object will result in a higher reliability that it will be detected;

- **Distance to the object:** The sensitivity of the sensor is optimized at shorter distances;

- **Speed of the object:** The greater the movement of the target, the more reliable will be the detection;

- **Direction of movement:** A target that is moving faster and laterally from the sensor will be detected more reliably than a target that is moving slowly and straight-on. As will be seen, this is dependent upon the characteristics of each sensor;

- **Reflection/absorption characteristics of the energy waves produced by the intruder and the environment (e.g. open area, shrubbery, or wooded);**

- **Contrast between the target and the environment:** The greater

the contrast between the target object and the overall reflection/absorption characteristics of the environment (area under surveillance), the greater the probability of detection.

40_2.1.1.2 Sensor Applications

Sensors are generally classified by their application and sensitivity to certain kinds of events. They are designed for specific environments and for exterior or interior deployment. Throughout this chapter, different applications are described, together with possible countermeasures to reliable operation.

40_2.1.2 Central Processor and Control Unit

A central processing unit receives information from one or more sensors, analyzes the data, and initiates the appropriate action by sending a valid alarm to a responding agency or local alerting device. There are many different kinds of monitoring systems, all with varying options. Regardless of the brand, most processors perform the same functions: they interface with a variety of sensors, evaluate the information, annunciate an alarm, and display the trip and location. Today, most system are computer-based and utilize Windows, DOS, or UNIX operating systems. Some rely upon proprietary software, developed by a specific vendor.

Most units contain one or more microprocessors to provide sophisticated functions that include:

- **Ability to simultaneously monitor up to 128 or more individual trips;**
- **Simple operation of control functions;**
- **Clear layout of instruments and components;**
- **Sophisticated and reliable anti-tamper systems;**
- **A logic evaluation unit that analyzes the status of many different types of sensors and properly responds to signals or signatures that are based upon preprogrammed criteria;**
- **Supervision of internal transmission links between sensors and the central processor. These monitoring facilities must constantly evaluate the wiring or links between detectors, processors, and local activating devices. The monitoring system may be based upon a constant signal, fluctuating signal, or**

a combination of each. The processor must be capable of measuring interference with transmission links by sensing a change in loop resistance, differences in line current, or other parameter. All components, including detector housings, junction boxes, conduit, alarm units, and wiring must be continually monitored;

- **It must be impossible for the user to place the system in an armed mode unless all trips are functioning properly;**
- **It must be impossible for the user to cause a false alarm by placing the system in an armed mode because a trip is not properly set or is malfunctioning;**
- **The processor must have the ability to evaluate the coincidence of signals from complex trips that incorporate more than one sensing technology, to insure device redundancy and reliability;**
- **Ability for programming of individual trips for entry-exit, perimeter, interior, fire, burglary, holdup, temperature, water and other hazards;**
- **Ability to create different zones of protection for immediate or delayed perimeter, interior, and entry-exit;**
- **Ability to program specific criteria for a trip within any zone;**
- **Ability to determine the method of signal transmission, including local alarm, direct central station connection, dial-up, and wireless;**
- **Ability to individually authorize any number of employees for entry and exit into specific zones and to track log-in;**
- **The processor can be activated with a keypad, key switch, door lock, wireless device, from a remote center, or automatically, based upon a preset time or event.**

40_2.1.3 Transmission of Alarm Signal

One of the primary functions of a central processor is to alert responsible individuals or agencies that there is an alarm. Reporting can take many forms that is based upon individual security requirements. The options for reporting include:

- **Local alarm to a light, bell, siren, pager, radio system, or internal control panel;**
- **Wireless transmission to central station;**
- **UL central station alarm that is connected by a direct link to the processor;**
- **Dedicated central station monitoring facility that is connected with a dial-up circuit, direct hardwire circuit, cellular radio connection, carrier current, dedicated radio system, or satellite link;**
- **Police department or answering service termination on a dial-up or direct connection basis.**

40_2.1.3.1 Wireless Links

There is an increasing use of wireless devices to link sensors with alarm processors, either on premises, or at a central station. Some of these devices are quite simple in design, while others utilize cellular or spread spectrum, digital encoding, and code hopping. However, many can be compromised through various means, including:

- **Code grabbers;**
- **Grounding an exposed antenna;**
- **Jammer transmitters to blind or desensitize the receiver;**
- **Cutting or removing the antenna;**
- **Simulation of acknowledgement from alarm processor or central station;**
- **Denial of service attacks.**

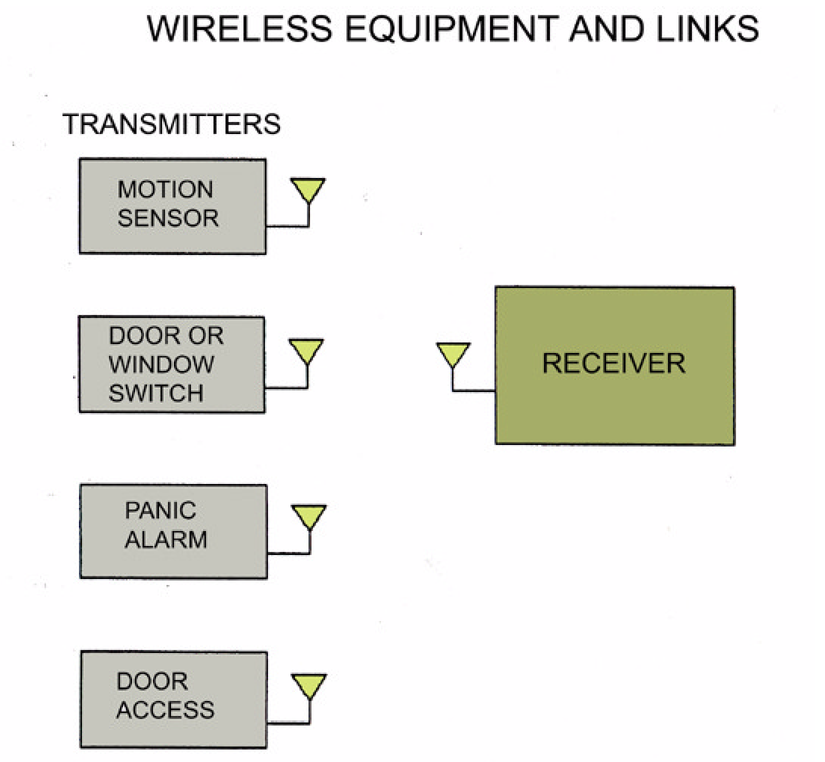

Figure LSS+4037. One of the original dial-up alarm reporting devices, used in

the nineteenth century.

40_2.1.4 Reporting Systems

The signaling format by which an alarm signal is actually transmitted varies by equipment manufacturer, although there is industry standardization to some extent. Reporting systems include:

- **Analog tape dialers or solid state devices5///////5555555555555555555555/ that provide a non-supervised verbal message as to the type of alarm and location to a specific telephone number. These are usually transmitted by dial-up and are not reliable;**
- **Digital dial-up systems that transmit information regarding location, subscriber account, and identification of trips, using a variety of signaling formats, including:**
  - **DTMF (touch tone, high and low speed);**
  - **FSK (frequency shift keying);**
  - **SF (single-frequency pulse tone);**
  - **Data (serial);**
  - **Proprietary data format;**
  - **Encrypted data;**
- **Voltage and current sensitive loop monitoring at direct-wire central station;**
- **Voltage reversal or current sensitive loop monitoring at direct-connect monitoring center;**
- **Wireless protocols:**
  - **spread spectrum**
  - **packet**
  - **discreet frequencies**
- **20 Hz sub carrier.**

Sometimes, a manufacturer will utilize a proprietary transmission protocol that can severely reduce future system expansion or upgrade, and will limit the choice of competing equipment. In such systems, special processors may be required to interface between central and field processing elements of the system.

40_2.1.5 Alarm Signal Receiver or Annunciator

LSS402: Alarm monitoring systems

LSS402: Alarm sounders and notification devices

The receipt and resultant display or announcement of an alarm depends upon whether the termination is local or remote and silent or audible. There are many alarm assessment systems that can provide both visual and audible alerts. Today, many systems are computer-based and will display alarm status on a flat panel display, CRT, LCD, or a detailed multilevel map of a protected area. The status of a trip and the immediacy or priority of required action is also an option on many systems. The integrated reporting systems can provide an excellent comprehensive view of the status of protected premises or facilities.

40_2.1.5.1 Local Alarms

Local alarms are of limited value, especially in rural areas, and are usually installed as a deterrence in order to reduce damage or loss. Typically, the system may sound a loud bell or siren, turn on lights, lock doors, or alert a pager. They are particularly valuable for signaling fire, flood, temperature, and environmental conditions. The local alarm must be loud and denote by its sound that it requires action. The system should also have some sort of automatic reset or shut-off feature to provide for false trips. Unfortunately, local alarms are largely ignored in major cities due to the high false alarm rate.

40_2.1.5.2 Remote Central Stations

The alarm signal may be directly transmitted to a monitoring center. Although a local indication may also be provided, silent alarms are often the rule, especially in banks and other facilities where the threat of hostage-taking is of concern.

The central station operation offers twenty-four hour service, security, repair facility in most cases, and assurance that the system is working properly. Central stations usually have direct links to the radio rooms of the area police departments to alert them immediately of incoming alarms and to reduce response time. In addition, many of the companies have their own radio dispatched vehicles and armed guards to respond to the alarm. The personnel are trained to interpret the validity of alarm signals and can make a determination as to whether or not to dispatch

police cover. Many remote monitoring sites are now using video over TCP/IP to verify alarms. The use of a central station will often lower the insurance rates for a particular business.

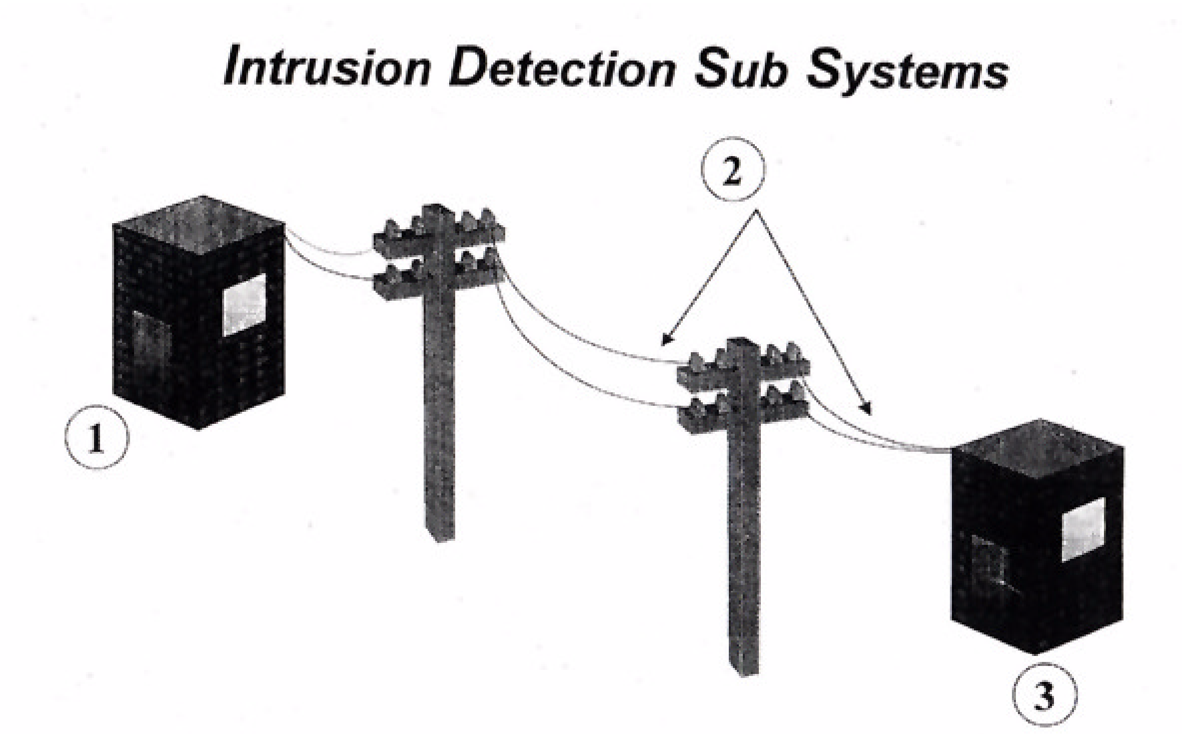

Figure LSS+4070 Intrusion detection sub systems are concerned with three primary areas: (1) protected premises, (2) transmission links, and (3) security command and monitoring center.

UL certified central station monitoring facilities exist in every major city. Many companies also monitor alarm circuits on a nationwide basis by dial-up over telephone lines. These facilities receive detailed information regarding the location of the alarm and identification and designation of trips. Upon receipt of a signal, the alarm center will notify the proper agencies and individuals from a list provided by the customer. This process can usually be performed in less than one minute.

Links to central monitoring facilities can take many forms: dial-up, wireless, or direct connection. Multiplexing of signals may also occur over a single link, channel, pair of wires or path. This allows data transmission from several sources to utilize one link, through a combination of polling, sampling, monitoring and interrogation. There are two primary multiplexing schemes that utilize one common path for transmission: **frequency**

division and **time division.** Frequency division multiplexing is a process for the transmission of two or more signals by sending each signal at a different frequency. Time division multiplexing allows transmission of two or more signals at different time segments.

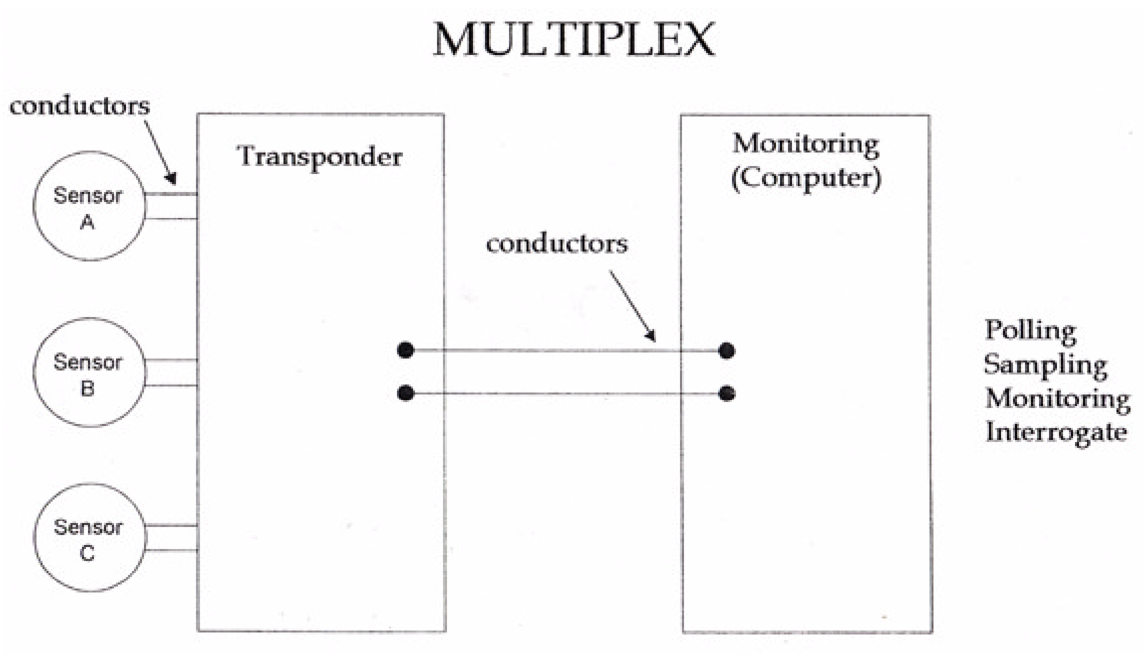

Figure LSS+4071 Signals can be multiplexed over one transmission path from several different sources.

40_2.1.5.2.1 Transmission Security and Supervision

Circuits to central station facilities are directly connected, dial-up, RF link, or sub carrier. Line supervision is inherent in direct-wire links and will vary, depending upon the security that is required. There are three recognized levels of supervision: **high security electronic line supervision** (HSELS), **medium security electronic line supervision** (MSELS), and **low security electronic live supervision** (LSELS). Whatever degree of supervision is implemented, the system should be capable of detecting cutting, shorting, and spoofing.

- **High Security Electronic Line Supervision (HSELS)**

HSELS is line supervision that either cannot be compromised or can only be compromised by a person with technical expertise and

knowledge of the system, using intensive pre-attack computer analysis. The only line security technique meeting HSELS requirements is full data encryption using, at the minimum, the National Bureau of Standards (NBS) Data Encryption System (DES II), or equivalent, with a user changeable key. It is recommended that HSELS only be employed in installations that protect critical assets where the associated sensor system normally provides security comparable to that of the HSELS. This level of encryption is only effective if the key is changed on a periodic basis and the associated sensor system provides comparable security to that of the HSELS.

The use of HSELS for transmission links result in:

- Line security that generally far exceeds the security of the underlying system;
- Higher initial equipment cost;
- Higher operating costs because of the requirement to periodically change the encryption key.

- **Medium Security Electronic Line Supervision MSELS)**

MSELS refers to line supervision that can only be compromised by a person with technical expertise and knowledge of the system, substituting a complex device (microprocessor, microcomputer, or multiple active logic devices) on the data lines. MSELS requirements can be met by using polling or multiplexing techniques. This form of line supervision can further be enhanced by: using a randomly selected start point for each polling cycle and randomly selecting whether to poll in an ascending or descending order on each polling cycle. Polling in a random sequence assumes that the polling time is not degraded.

MSELS provides line security that is comparable to the security afforded by most sensor systems. Therefore, use of MSELS is recommended for all but the most critical installations. Security of systems that employ MSELS can be further enhanced by making data lines less accessible (burying and installing in rigid conduit) and by ensuring that all sensor lines between the remote collection device and the sensors are kept within the protected area.

- **Low Security Electronic Line Supervision (LSELS)**

LSELS can be compromised by a person with technical expertise and

knowledge of the system, substituting a simple passive device (resistor, capacitor, inductor, or combination of these) or active device (tape or digital recorder or simple filter) on the data lines. Line security techniques meeting LSELS requirements are voltage and current loops using end-of-line termination impedances, tone, and phase systems. These techniques are normally utilized in systems with a separate data line that is run to each sensor zone.

LSELS is recommendation for use only in the simplest of installations which are small in size, and entirely within a protected structure. Security of systems using LSELS can be further enhanced by making data lines less accessible (burying and installing in rigid conduit).

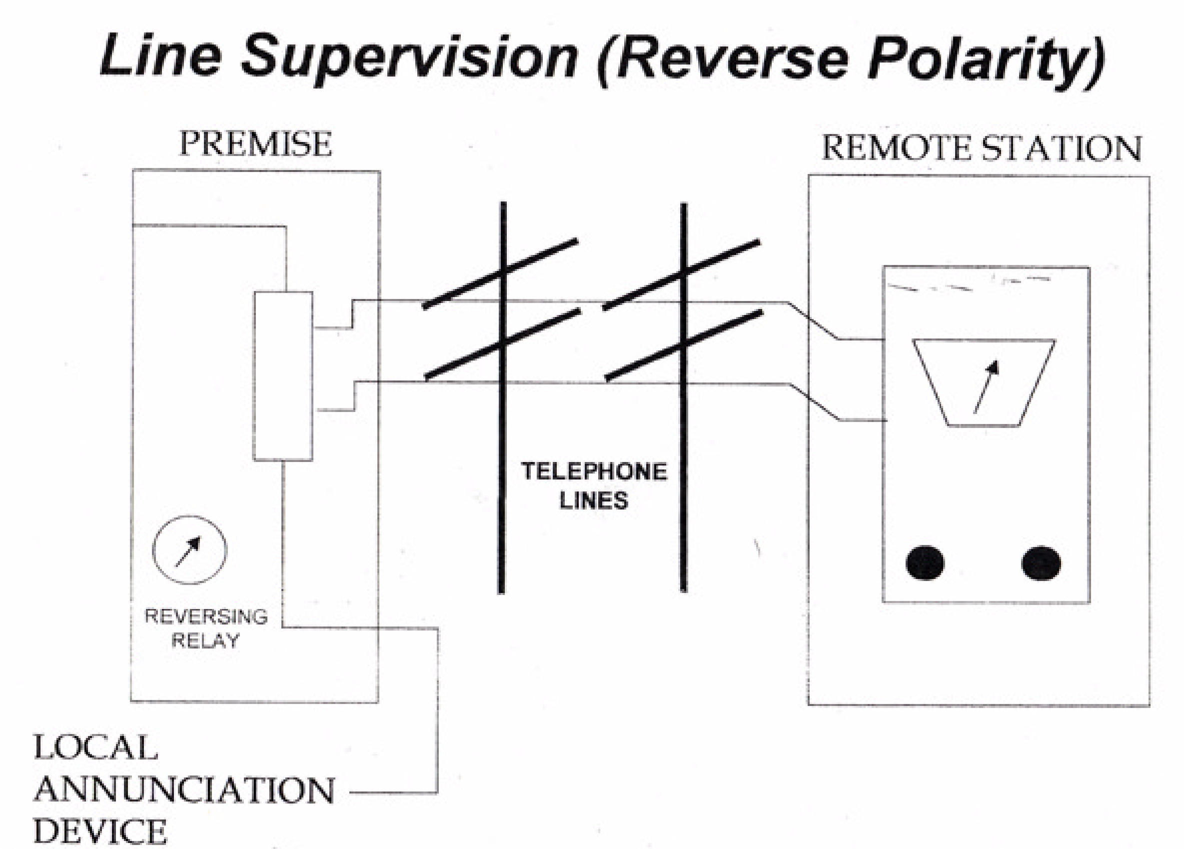

Figure LSS+4072 Line supervision can take many forms. Reverse polarity is a very old technique that requires the DC polarity of the circuit to reversed upon an alarm condition.

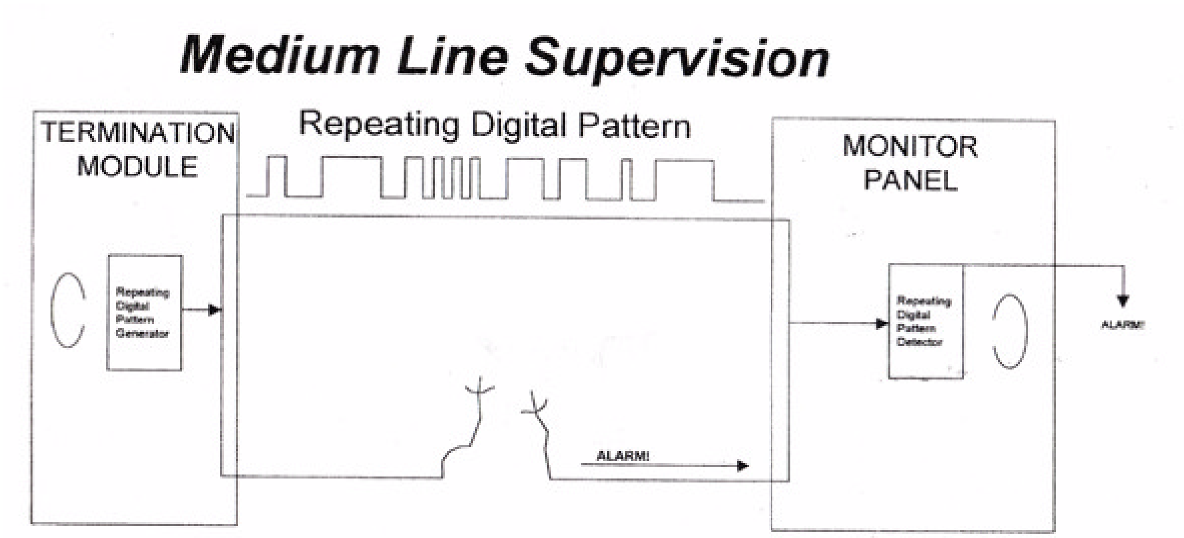

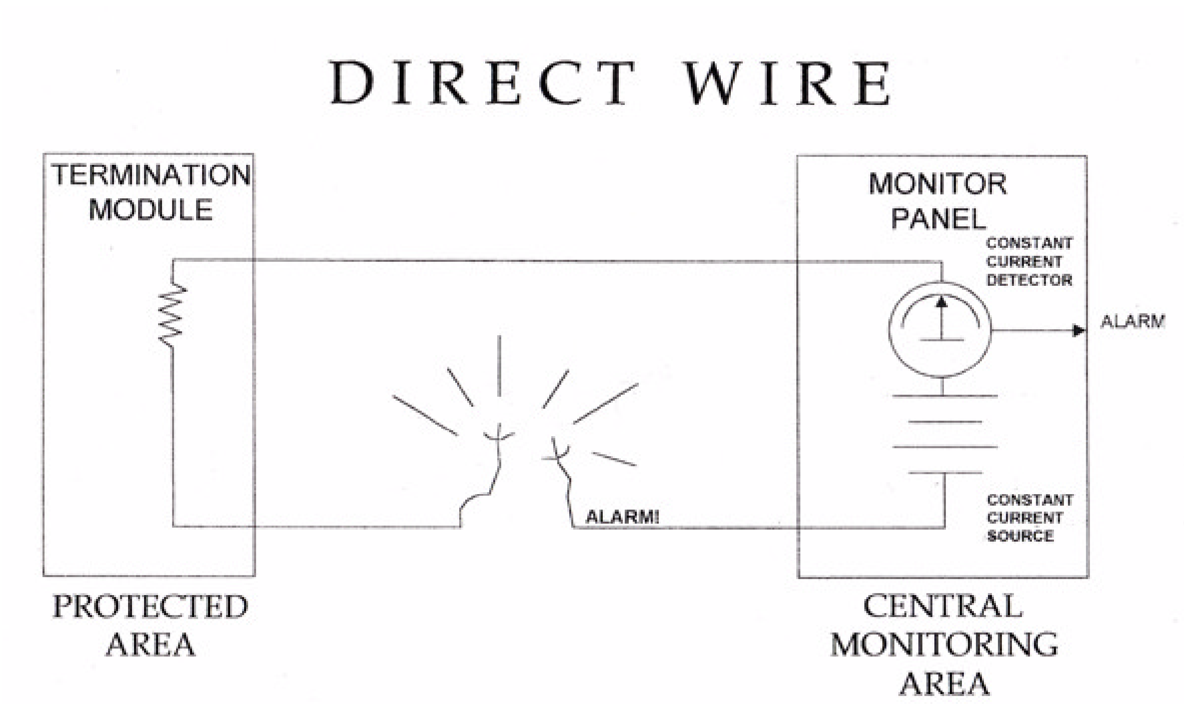

Figure LSS+4073 Medium line supervision provides a level of security that requires an intruder to have technical expertise and knowledge of the system to be able to bypass it. These systems can often be sniffed and spoofed by inserting devices along the transmission path, as shown in the diagram.

40_2.1.5.2.1.1 Direct Connection

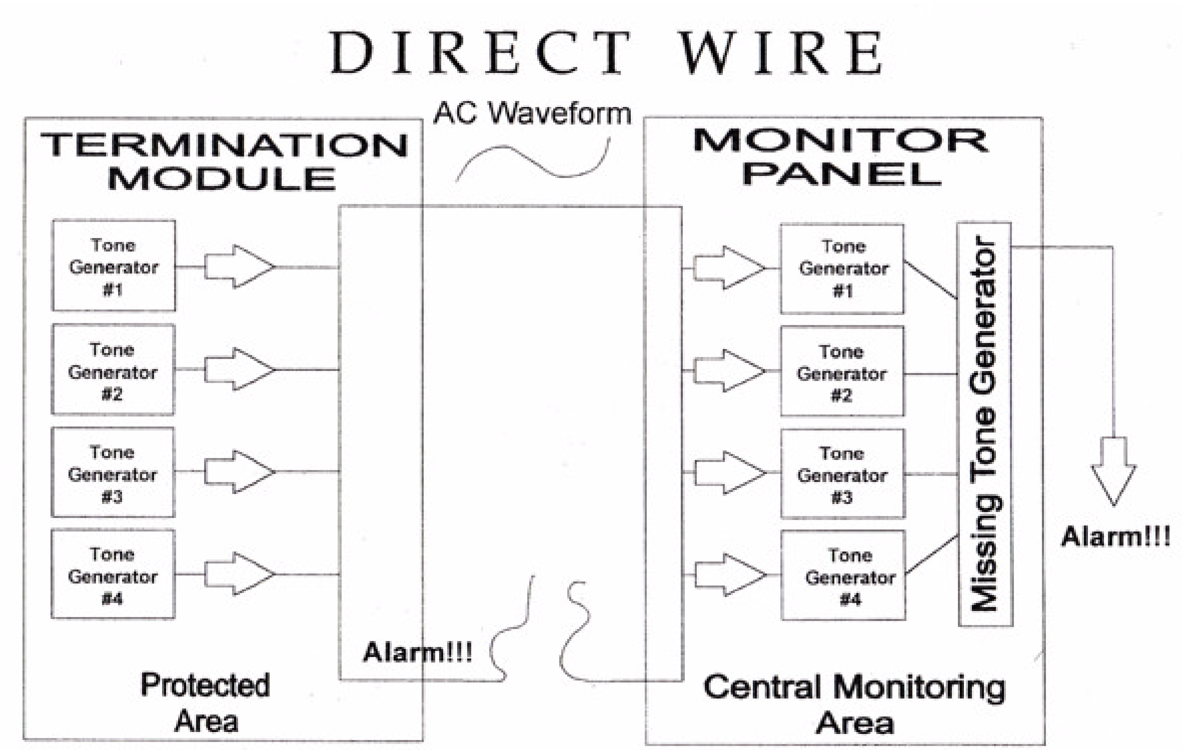

Figure LSS+4074 Direct wire line supervision provides for continuous electrical monitoring of the circuit. These circuits can be easily evaluated and spoofed. The diagram (top) shows a basic circuit that would allow an intruder to measure the DC current on the loop and insert a supply to simulate a normal condition.

Direct connection central stations or monitoring centers provide a higher level of security monitoring. In such instances, the transmission security or resistance to compromise depends upon the transmission method, as well as the level and type of line security. The level of line security and method of supervision to the circuit is determined by the anticipated threat and security level that is needed. False alarms may still be experienced, and these are generally due to telephone company maintenance, wiring errors, weather conditions, or routing failures.

Direct-wire circuits require a dedicated path between the local alarm processor at the premises and the central station facility. Circuits are electrically monitored for continuity using current, voltage, or digital signaling and periodic handshake. In older systems, up to fifty subscribers were tied to one pair of wires. Each location would have an encoder or sender that would generate a specific electrical address, much the same as in the older telephone step-relay offices. A series of pulses would identify

the location to the central station.

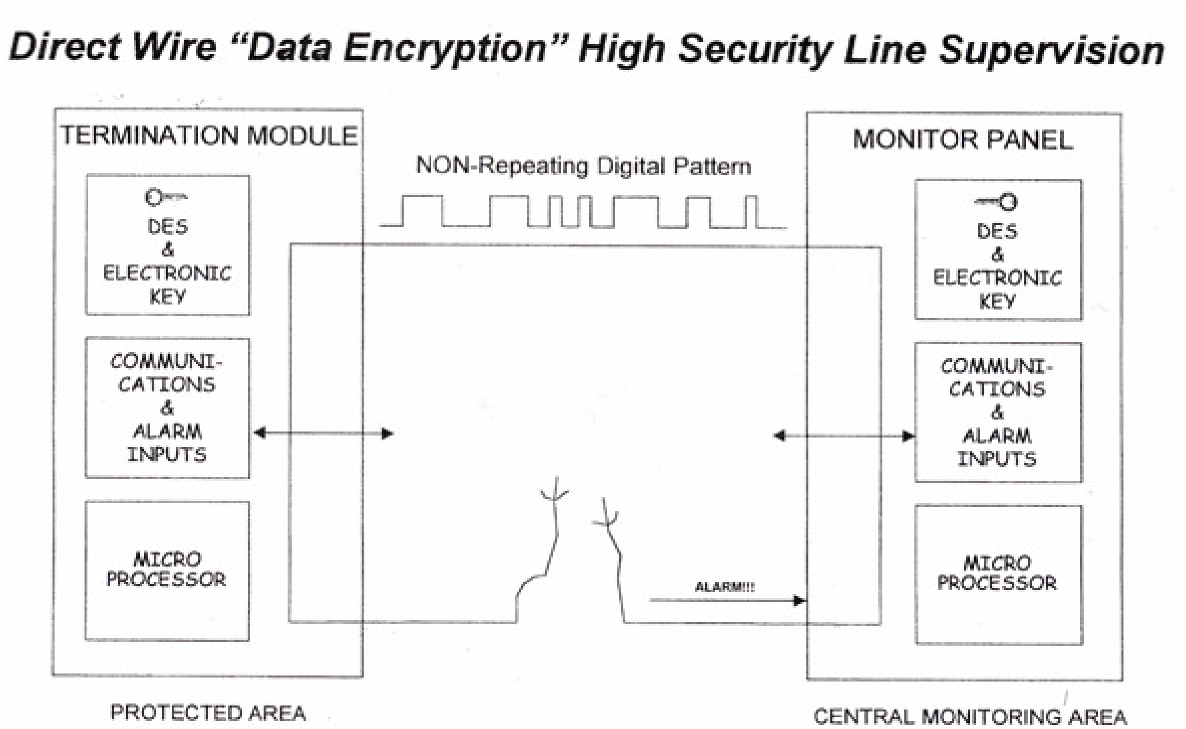

Figure LSS+4075 Data encryption high security line supervision provides the greatest protection for transmission links against interception. Encrypted data makes it extremely difficult to spoof, even if sniffer devices can be inserted along the transmission path.

Today, encrypted data is employed between the alarm processor and central station to insure security. Spoofing and denial of service attacks can be made more difficult but still occur.

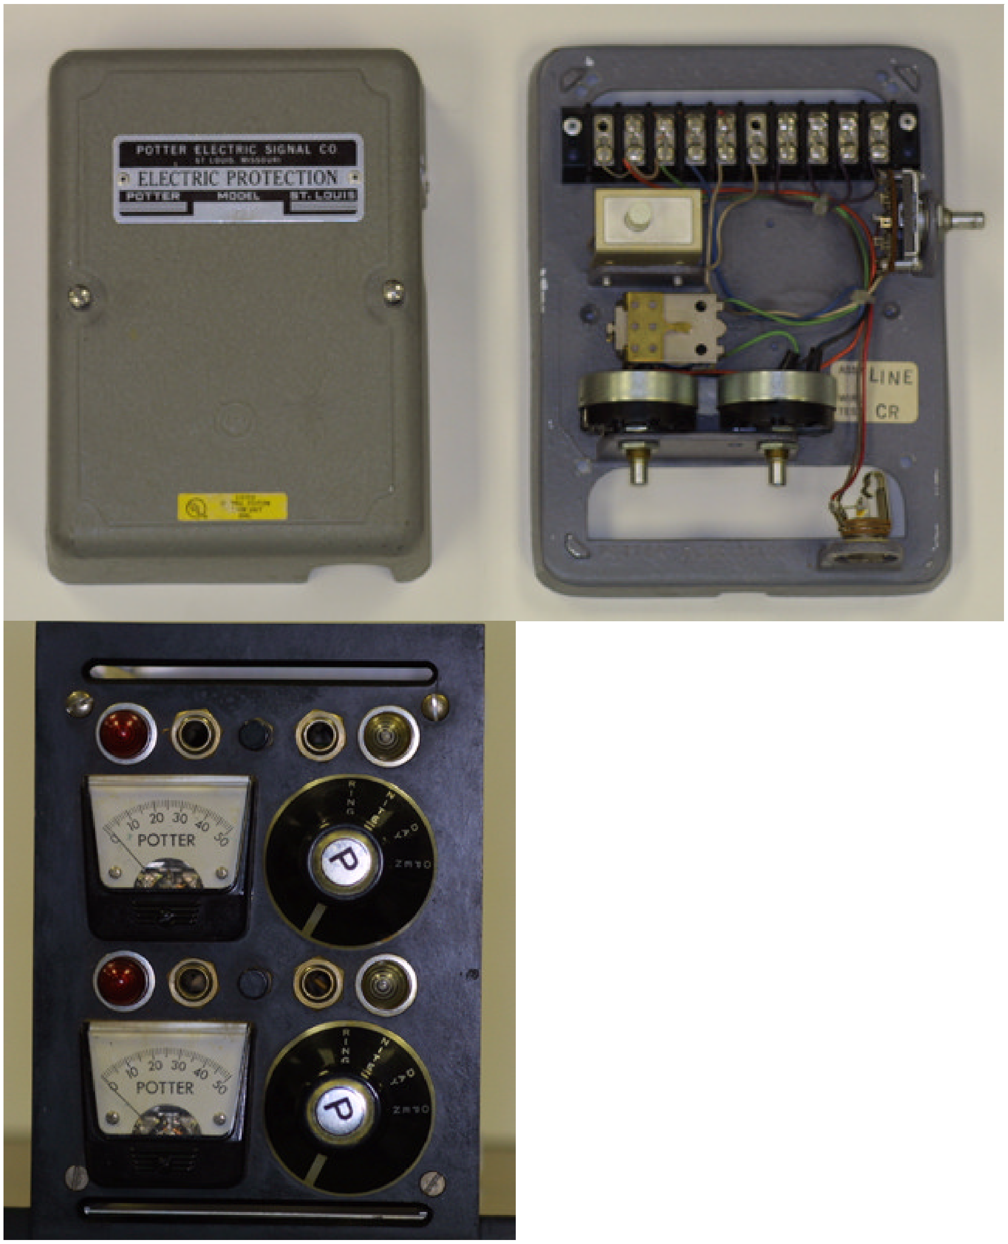

Figure LSS+4042 An early alarm transmission unit for central station application. The direct wire circuit had to be balanced both at the transmitter located on premises and the receiver at the central station.

40_2.1.5.2.1.2 Dial-Up Telephone Circuit

The normal dial-up (digital dialer) circuit using the public switched telephone network is the most common form used in the

alarm industry, and can be easily circumvented. For this reason, such systems are not utilized for banks and other high security installations. Although UL does certify a dial-up arrangement, it requires two independent paths to the receiving station, one of which may be wireless. Unfortunately, this level of supervision can be defeated by cutting all telephone lines that terminate in the local facility, unless wireless links are also employed.

Dial-up systems are not electrically supervised. This means that they can be circumvented without the receiving site being aware of the bypass. Although some dial-up arrangements do require periodic reporting, this may not provide adequate security.

Dial-up systems can be defeated in a number of ways, including:

- **Access the alarm panel through the use of a remote programming code. Then, change the telephone number for the alarm center. The panel may also be reprogrammed not to report any alarm condition, or a change in zone designation can be made;**

- **Inject a high voltage surge on the telephone line to damage the interface circuitry on the panel;**

- **Bridge the phone circuit at the demarcation point outside of the premises, preventing the panel from seizing dial tone;**

- **Physically cut or disconnect the telephone circuit from the subscriber premises;**

- **Call the number that is assigned to the alarm panel, thereby making it impossible for the system to obtain a dial tone;**
- **Cut a trunk line that feeds the central telephone office, thereby preventing the completion of a communications path from the alarm panel.**

40_2.1.5.2.1.3 Wireless Transmission Paths

Wireless transmission paths between protected premises and monitoring facilities are utilized to an ever increasing degree. The integration of cellular or spread spectrum links has provided path reliability and redundancy for alarm reporting and can make bypass of these systems extremely difficult.

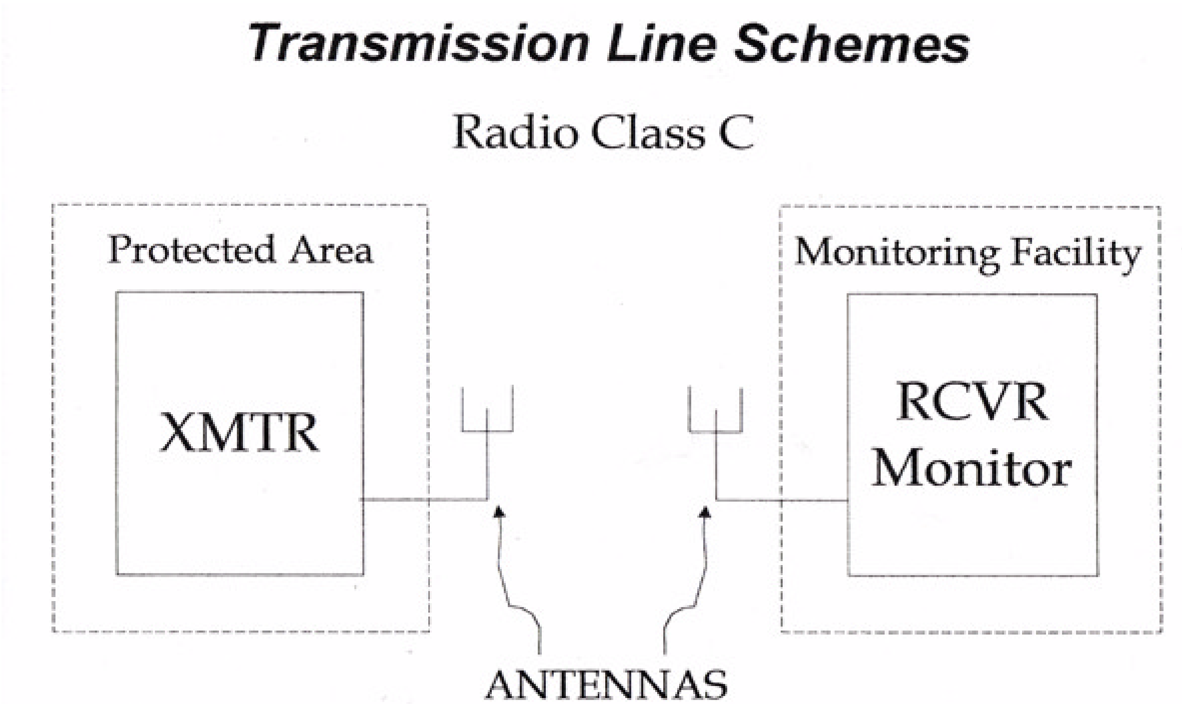

Figure LSS+4076 A basic wireless link consists of a transmitter and receiver.

40_2.1.6 Power Supply

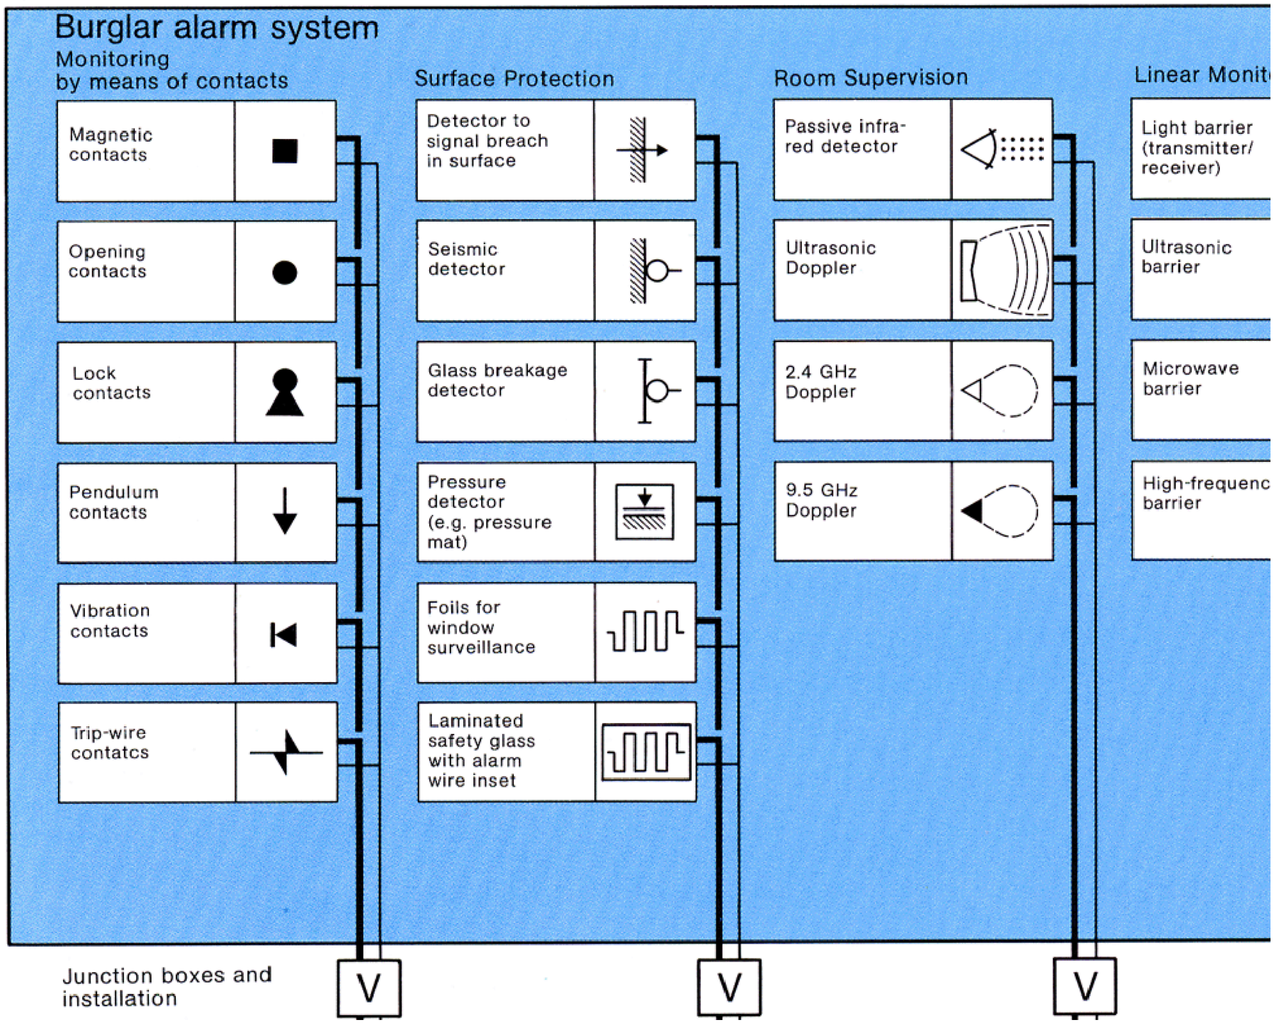
Most alarm systems are backed up by battery for enhanced reliability. Critical consideration should be given to the power supply for any monitoring system because of the vulnerability in case of failure. The system design must integrate power backup for all components, including sensors, reporting, assessment and response. See the discussion below.

40_3.0 Specific Types of Sensors

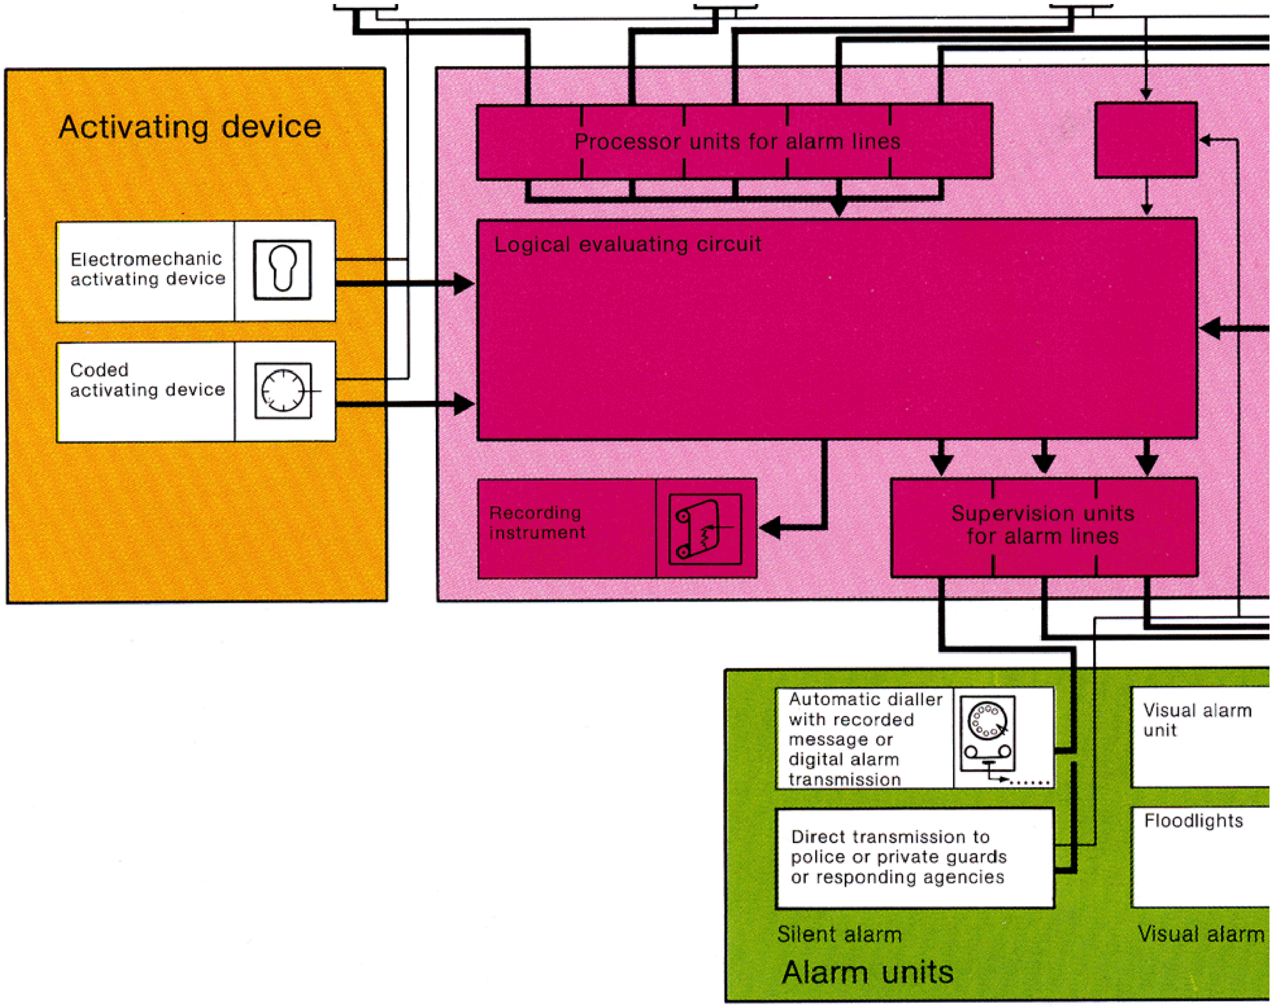
This section will describe the different classification of sensors and their individual characteristics, including operating principles, application considerations, and typical defense measures. They are categorized by their function and sensing technology, although all sensors can be divided into volumetric and non-volumetric classifications:

CLASSIFICATION OF SENSORS

CONTACT and CONTINUITY DEVICES	Magnetic contacts Balanced magnetic switch Mechanical switch Photoelectric Taut-wire Pressure mats Switches Foil
CAPACITANCE and PROXIMITY	Electric field Capacitance Strain sensitive cable Magnetic point detection
VOLUMETRIC PROTECTION	Microwave Dual-technology IR/Microwave Radar Ultrasonic
HEAT SENSING	Passive infrared Interior active infrared Exterior active infrared Thermal imaging and sensing
RESPONSE TO PRESSURE CHANGES	Audio sensors Acoustic detection (air turbulence) Passive ultrasonic Active ultrasonic Shock Wall vibration Fence vibration Fiber-optic wall and fence In-ground Fiber-optic Ported coax buried line Balanced buried pressure Glass break detection
LIGHT ACTIVATED	Photoelectric Light level sensing
VIDEO SYSTEMS	Video motion detection



SENSOR TECHNOLOGIES



- **Active ultrasonic**
- **Acoustic detection (air turbulence)**
- **Audio sensors**
- **Balanced buried pressure**

- **Balanced magnetic switch**
- **Buried Geophone**
- **Capacitance and proximity**
- **Contact devices**
- **Continuity devices**
- **Dual technology passive IR/microwave**
- **Electric field**
- **Exterior active infrared**
- **Fence vibration**

40_3.0A Electronic Security Methodology

Electronic security is an intrusion detection system (IDS) installed to adequately protect valuable assets against adversaries who pose a threat to these assets. Electronic security systems (ESS) are used to alert responsible personnel, such as security guards, to intrusions at protected facilities. In some cases, the system may cause actuation of physical barriers to prohibit access. Electronic security systems can be placed into two categories: perimeter detection and interior detection.

Burglar alarm system
Monitoring
by means of contacts
Magnetic contacts
Opening contacts
Lock contacts
Pendulum contacts
Vibration contacts
Trip-wire contatcs
Surface Protection
Detector to signal breach in surface
Seismic detector
Glass breakage detector
Pressure detector (e.g. pressure mat)
Foils for window surveillance
Laminated safety glass with alarm wire inset
Room Supervision
Passive infra-red detector
Ultrasonic Doppler
2.4 GHz Doppler
9.5 GHz Doppler
Light barrier (transmitter/ receiver)
Ultrasonic barrier
Microwave barrier
barrier
Junction boxes and installation

V
V

Regardless of the type of sensor and its technology, three criteria must always be met:

- **The sensor must be capable of sensing and discriminating between an occurrence coming within the scope and purpose of the device and one that is irrelevant;**
- **The device must be reliable and impervious to artifacts that fall outside of preprogrammed parameters;**
- **The central processor must be capable of evaluating the information from the detector and initiating the proper response based upon the data.**

40_3.0A.1 Exterior Sensors

LSS403: DOE on layers exterior protection

Perimeter detection is used to prevent entry into a restricted area; the devices are usually located so as to protect the exterior premises.

- **Microwave detection** links are devices mounted on posts inside the fence line. Transmitters radiate amplitude modulated X-band energy, and receivers detect and process the received energy. Thus, an invisible RF energy envelope is produced that will detect an intruder.

- **Infrared detection** links are devices that are post-like and mounted inside the fence line. Transmitters radiate multiple beams of modulated infrared energy, and the receivers detect and process the energy. Penetration of the invisible infrared shield will cause an alarm.

- **E-field links** are transmitter and receiver wires that are strung horizontally from mounting posts located inside the fence or mounted on the fence. A radio-frequency energy field is generated around the wires. The intrusion by a person into the invisible field will "short" energy, creating an alarm.

- **Buried sensor links** are devices that sense seismic pressure or electromagnetic (EM) disturbances. A combination of theses sensors are buried inside the fence line.

- **Other systems** are available that can be used in combination with the previously mentioned sensors. The probability of detection by these outdoor devices depends on their application. Perimeter detection equipment must be applied with consideration of the environmental limitations of the device's technology.

There are many types of sensors specifically designed for exterior protection. The choice of modes of detection will determine the intruder's ability to define his method of attack. The generic categories of sensors that may be employed to protect perimeter and external areas are:

- **Active or passive;**

- **Overt or covert;**
- **Line of sight or terrain following;**
- **Volumetric or linear;**
- **Free standing, fence related or buried.**

Exterior sensors are employed to provide assurance that an intruder that crosses an established perimeter or boundary or enters a protected area will he detected. This, regardless of the type of movement and at any point in the detection zone under specified weight and speed criteria. The system must be capable of detecting:

- **Walking;**
- **Running;**
- **Jumping;**
- **Crawling;**
- **Rolling;**
- **Climbing.**

Exterior sensor zones must meet the following primary operational criteria:

- **Adequate coverage in all weather and light conditions**
- **Overlap to eliminate dead areas**
- **Wide enough to deter bridging**
- **Detection zones must not contain:**
    - **dips**
    - **high ground**
    - **obstructions that could provide a pathway for an individual to avoid detection.**

Sensors can be placed anywhere within their zone of protection. These devices are designed to withstand changes in environmental conditions including temperature, humidity, and dust, and will continue to function in harsh environments. Typically, exterior sensors will be less likely to detect a target, and can exhibit a higher false alarm rate than the more protected interior units, mainly due to factors that cannot be controlled that involve the environment, debris, animals, unanticipated human activity, as well as electrical and electronic interference. Multiple sensor technology is often utilized to minimize the problem.

In planning for the use of exterior sensors, there must be a

well-defined and isolated area of surveillance for an individual zone and corresponding sensor. This will result in a lower FAR. For example, a fence, wall, or other marker can be effective in dividing a perimeter into unique localized segments.

Sensor Technologies Handbook.

40_3.0A.2 Interior Sensors

Interior intrusion detection systems are normally designed to protect specific security areas such as vaults, or vault-type rooms, or to detect intrusion into a building or facility. These systems employ various technologies (for example, the detection of physical movement, heat, movement related to time, cable tension, vibration, pressure, and capacitance). Many of these sensors are designed for indoor use only, and should not be exposed to weather elements.

If the intruder penetrates the perimeter detection, the protected area has been breached. The interior sensor then must be in place to prevent further entry into controlled or protected buildings.

- **Visual or closed-circuit television** surveillance may detect the intrude;

- **Entry into a building** is provided by the application of a balanced magnetic switch on doors and openings. This device uses an internal bias magnet to balance a delicate reed switch in the field of the external magnet attached to the door. Should the door be opened or should another magnet be introduced in an attempt to defeat it, the switch will change state and alarm;

- **Other devices** for detection of an intruder may be utilized inside the building, including microwave and infrared motion detection, photoelectric or laser beams, seismic, sound detection, and passive infrared.

Interior sensors perform specific functions:

- **Detection of an intruder approaching or penetrating a secured boundary, such as a door, wall, roof, floor, vent or window;**
- **Detection of a target that is moving within a secured area, such as a room or hallway;**
- **Detection of an intruder moving, lifting, or touching a particular object.**

INTERIOR SENSORS APPLICATIONS MODEL

The following example is a typical secured room employing various detection sensors. This illustration demonstrates how sensors operate in conjunction with each other, and where sensors can be installed to enhance security.

Interior sensors are also susceptible to false and nuisance alarms, however not to the extent of their exterior counterparts. This is due to the more controlled nature of the environment in which the sensors are employed. However, they can also be affected by external factors including:

- **Machinery noise and/or vibrations;**
- **Air movement from fans or air conditioning/heating units;**
- **Changes in temperature.**

Interior Intrusion Sensors

Applications Index

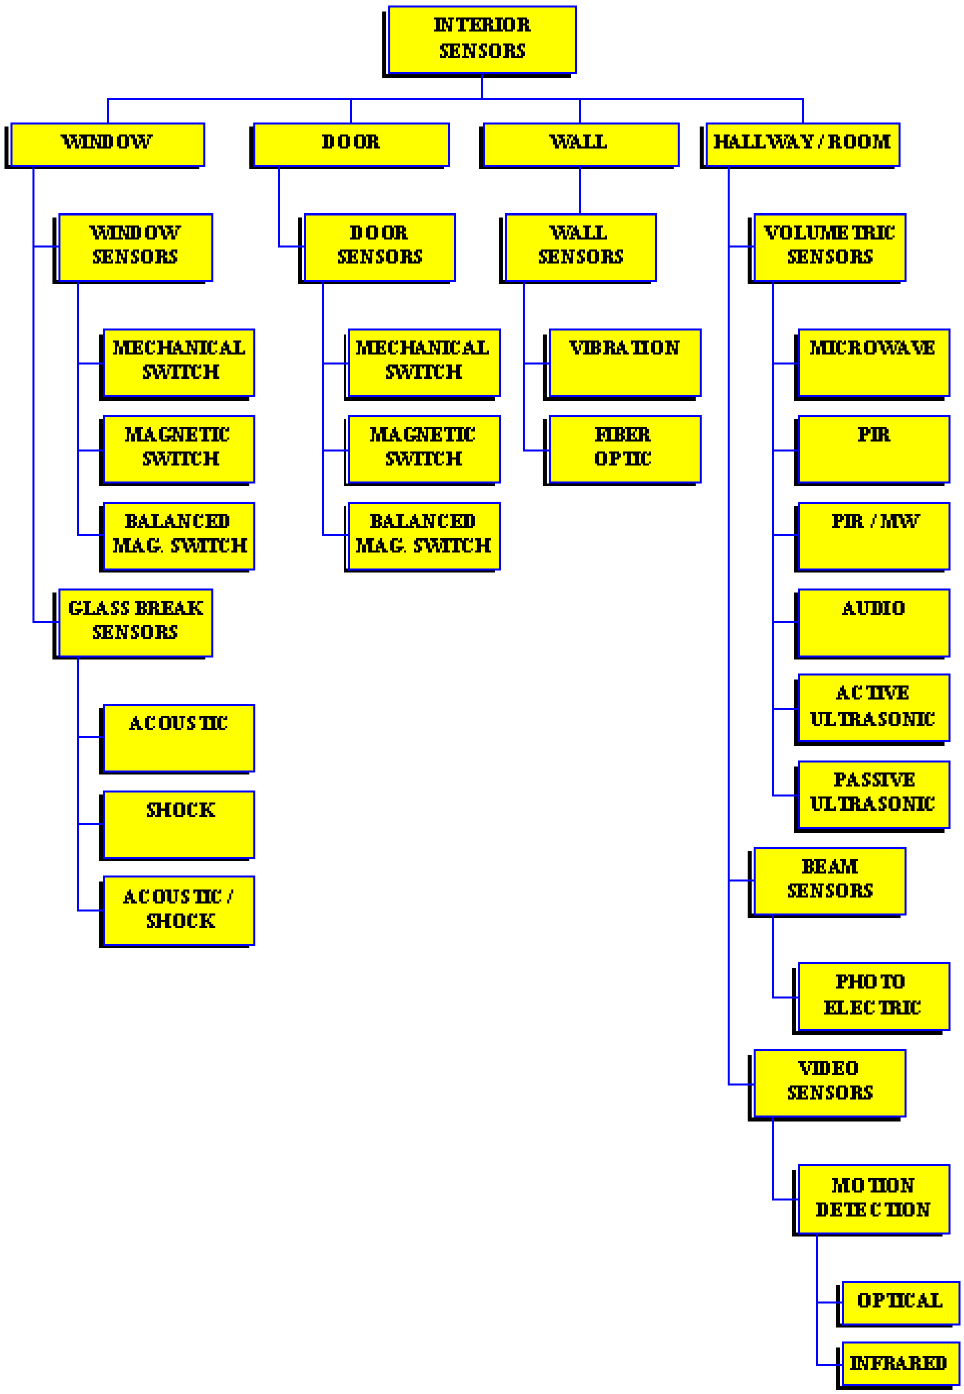

Figure LSS+4041 Interior intrusion sensor application

40_3.0A.3 Definitions

Certain definitions must be established in order to properly develop a Physical Security Plan, and to evaluate its implementation:

- **Alarm Zone.** A critical area alarm zone is a predesignated volume of space which is under surveillance of one or more sensors;

- **Detection Zone.** A detection zone is the volume of space under surveillance of a sensor that will create an alarm when the space is penetrated;

- **Self-Checkinq.** A feature to ensure secure operation. The system may periodically monitor the sensor transducer and signal processing circuits. Many systems require self-excitation of the sensor transducer (e.g., vibration, strain, pressure) while others monitor the signal level at the receiving transducer (e.g., microwave, infrared).

- **Standard Work Clothinq.** For evaluating CCTV motion detectors, standard work clothing is the equivalent of washed denim jeans and jacket. Such clothing should be a measure of intruder-to-background contrast.

- **Surface Protection Sensors.** Surface protection sensors are devices that detect penetration of the boundary of a secured volume rather than the presence or motion of an intruder within the secured volume. Surface protection devices are commonly used to detect the opening of doors and security cabinet drawers (portal-type detectors) or the attempted penetration of walls. Surface protection devices generally do not offer as high a degree of security as do volumetric intrusion detectors and therefore are often used to complement other sensors.

- **Tamper-Indicatinq.** A feature to detect tampering with or unauthorized manipulation of equipment components. The term includes line supervisory circuitry on data transmission lines, and switches used to sense the removal of equipment cover plates.

- **Volumetric Intrusion Sensors.** Volumetric intrusion sensor

systems are sensitive to the motion or presence of individuals within a specified volume. For the protection of rooms and large volumes, volumetric detection systems generally offer a higher degree of security than do surface protection systems. Various physical phenomena are employed in order to provide volumetric detection. These units offer a high degree of security if they are installed and operated in such a manner that they can detect movement by a small individual into the secured area at all rates between 6 and 180 meters (20 and 600 feet) per minute and in various crawling and walking postures within 1.5 meters (5 feet) from any direction.

40_3.0.1 Performance Characteristics and Criteria

In planning a comprehensive security system, individual sensor technology that is to be deployed must be analyzed in terms of three performance characteristics: **Probability of Detection (PD)**, **False Alarm Rate (FAR)**, and **Vulnerability to Defeat** (i.e. typical measures used to defeat or circumvent the sensor). The goal of any integrated Intrusion Detection System (IDS) design is to insure a low FAR and a high PD. Equally important: it is not subject to bypass or compromise.

Probability of Detection (PD): This criteria allows measurement of sensor performance in detecting a valid alarm condition in the area it is designed to protect. The characteristics of the sensor, environment, installation and adjustment, and the behavior of the target all must be taken into account. The sensitivity of a sensor is reduced due to numerous and/or excessive FAR or NAR. Pulse count and environmental adjustment circuitry, as well as automatic gain controls (AGC) can impact a sensors ability to increase PD. The industry emphasis is to reduce FAR and NAR and not to increase PD. The adversary takes advantage of this vulnerability.

False Alarm Rate (FAR) and Nuisance Alarm Rate (NAR): This measurement provides a projection as to the occurrence of false indication of activity within the protected area. Although false alarms and nuisance alarms are thought to be the same, they technically are not. A nuisance alarm may be a valid trip from an invalid target. For example, an animal, fan motor, or air turbulence may have activated the sensor. The problem is one of system design or unexpected occurrence rather than a true false alarm. In contrast, a real false alarm may indicate a possible intrusion attempt that cannot be verified, or an electronic failure. In either instance, the alarm must be responded to as if

valid. During the evaluation or inspection process, a review of all alarm logs and records should be made to determine false and nuisance alarm rates for a defined period of time. Any abnormally high alarm rate should be identified. The process should also insure that false alarms are correctly logged and reported, and that a correct definition has been established for false and nuisance alarm status, and that such definition is understood by alarm system operators. Obviously, the ability of operators to consistently make judgments as to whether alarms are considered false or nuisance will greatly affect false and nuisance alarm rate calculations.

Vulnerability to Defeat: This is yet another measure of the effectiveness of a sensor. Unfortunately, there are many classifications of sensors that can be used to protect a specific type of area; one type of technology may be optimum for a given environment. No sensor will reliably operate in all conditions; there is no universal detector. Each sensor is designed for low FAR for certain applications. Utilization of the proper sensor for a given task will insure that the potential for its defeat is low. Security can be enhanced by the use of multiple sensors and differing complementary technologies that overlap each other.

40_3.0.1.A System Performance Objectives

A facility can be protected in three ways: alarm systems, random patrols, and visual surveillance. Alarm and detection devices are fundamental components of any physical security system. To be effective, alarms must be clearly audible, and capable of immediate identification of the location and type of alarm by the operator.

To achieve an acceptable degree of assurance that the electronic monitoring and detection components of a security systems work properly, it is incumbent on facility management to provide adequate equipment, an effective testing and maintenance program, and a sufficient number of trained personnel to operate the alarm and assessment equipment.

Specific performance objectives should be established for an intrusion alarm systems:

- Detects attempts to gain unauthorized access to critical areas in conformance with the physical security plan (PSP);

- Whether critical area intrusion sensors meet the general

performance objectives, and are adequate and appropriate for their intended function;

- Whether the intrusion sensors are designed with sufficient redundancy and diversity to assure maintenance of their capability to meet the general performance objectives;

- Whether there is a system to detect unauthorized placement, movement, or removal of critical materials in conformance with the physical security plan and any regulatory requirements.

40_3.0.1.B Inspection Requirements

Each system must be carefully inspected to verify that each sensor is performing as required to insure proper intrustion detection, and detection system capability. The process must verify that:

- The location has intrusion detection systems capable of detecting attempts to gain unauthorized access to critical areas;

- That the system will detect the opening of all doors and emergency exits in all critical areas;

- That the location has detection systems and procedures to discover unauthorized activities and conditions, as defined by the PSP;

- That intrusion detection systems have sufficient redundancy and diversity to assure maintenance of their capability to meet the general performance objectives;

- That sensor detection systems are segmented into a sufficient number of overlapping alarm zones to provide adequate coverage of the areas under surveillance by the detection systems;

- For extremely critical areas, verify that the system protects unoccupied areas with intrusion detection systems that will alarm in all alarm stations upon entry of an individual into the areas, movement of an individual within the areas, and exit of an individual from the areas;

- For extremely critical areas, verify that the system has

detection capability and procedures to discover unauthorized placement and movement of materials within protected areas;

- For extremely critical areas, verify that the system protects designated locations with intrusion detection systems that will alarm upon entry of an individual into the location, movement of an individual within the location, and exit of an individual from the location;

- Verify that emergency exits from critical areas are alarmed to provide local alarm annunciation that is both visible and audible;

40_3.0.1.C Detection System Security and Performance

It is critical that detailed examinations be conducted to insure the integrity of all alarm sensors and associated systems. Verify that:

- Critical area sensors and associated systems, including transmission lines to their respective annunciators, are tamper-indicating and self-checking;

- Controls and switches that affect the sensitivity of any intrusion detection system are located within a tamper-alarmed container or housing;

- For extremely critical areas, verify that all intrusion detection systems and emergency exit alarms are provided with tamper-indicating alarms and line supervision;

- Alarms that annunciate in both the primary and secondary alarm centers indicate the type and location of the alarm source;

- All critical area intrusion detection systems are self-checking and annunciate equipment or component failure in all alarm centers, indicating the type and location of the alarm source;

Each sensor and zone must be evaluated to insure that they provide the requisite protection that is specified in the PSP. For maximum efficiency, the following performance tests of critical area sensors should be observed by at least two inspectors. The inspectors should be provided with handheld

radios that operate independently of the facility's radio frequencies. One inspector should be stationed in the alarm center to relay alarm response to the inspector that is observing the tests in the alarm zones. This inspector should verify that the alarms are annunciated audibly and visibly, and that there is an indication of the type and location of alarm.

Review the Physical Security Plan to determine that the system conforms with the goals of the PSP for detection parameters such as distance from detector, speed of approach, and height and weight of intruder for each type of sensor. Determine the type and locations of sensors that are used, the level of redundancy, the number and location of alarm zones, and the number and location of critical area doors and emergency exits.

To prevent the initiation of electrical fires, all components of detection sensors should meet the fire safety requirements of nationally recognized testing laboratories. Attachment of a label from Underwriters Laboratories (UL) or Factory Mutual (FM) to the equipment is acceptable as proof of meeting fire safety requirements.

Each sensor in each alarm zone should be tested in at least one sector of the alarm zone for its ability to detect penetration of, or activities within, the zone.

- **Volumetric Sensors.**

Ultrasonic and microwave sensors are most sensitive to movement directly toward or directly away from the detector, and are least sensitive to movement along an arc of equal radius from the detector. Conversely, passive infrared detectors are most sensitive to movement along an arc of equal radius from the detector, and are least sensitive to movement directly toward or directly away from the detector. These sensitivities to direction of movement must be considered when evaluating each type of volumetric sensors;

Volumetric sensors can be tested by crawling, walking, or running in several directions in each alarm zone under surveillance;

Verify through crawl, walk, or run tests near selected objects within sample alarm zones, that objects within the alarm zones do not prevent detection of movement or provide detection-free paths;

Verify through crawl, walk, or run tests through the intersections of adjacent alarm zones, that there is sufficient overlap of alarm zones to detect motion in any direction;

- **Surface Protection Sensors**

Infrared break-beam detection sensors can be tested by crawling, walking, or running through each detection zone;

Capacitance detectors can be tested by moving to within 15 cm (6 inches) of the protected object, or by touching the object while wearing a heavy insulated glove;

- **Critical area gates, doors, and turnstiles**

Open each critical area emergency exit door and gate, and rotate each emergency exit turnstile, verify that an alarm annunciates the opening or rotating (locally) by both visible and audible means and also annunciates in all alarm centers. The alarm should annunciate when the latch edge of the door is opened one inch and more;

Open each normally locked door and gate in a critical area and verify that an alarm annunciates the opening in all alarm centers;

- **Balanced Magnetic Switches**

Place one or more test magnets on selected samples of balanced magnetic switches so that the system alarms when the switch is subjected to additional magnetism;

- **Detector Tamper Alarms and Line Supervision**

Open the covers of selected samples of equipment cases, junction boxes, and conduit elbows to verify that the system will detect attempted tampering in both secure and access modes, and will annunciate the alarm type and location in all alarm centers. While the covers of the equipment cases and junction boxes are still open, disconnect a sample of alarm transmission wires at the terminal strips. The system should detect this form of tampering in both the secure and access modes;

- **False Alarm Rate**

Each critical area detection system should average not more than one false alarm and one nuisance alarm per alarm zone per week while maintaining design-performance detection capabilities. Assure that there has not been a reduction in sensor sensitivity levels to an unacceptable degree to reduce false alarms.

40_3.0.1.D Technical Considerations for Evaluating Sensors

Redundancy and diversity of critical area intrusion detection sensors is essential. This generally requires two or more independent intrusion sensors in each alarm zone that use different means to accomplish detection. Redundancy and diversity are good design concepts that should be considered. Any combination of the following commonly used intrusion sensors should be acceptable if properly implemented.

- **Acceptable Volumetric Intrusion Sensor Combinations for Redundancy:**

Ultrasonic motion detectors
Microwave motion detectors
Passive infrared detectors
CCTV motion detectors

- **Acceptable surface protection sensor combinations for redundancy include:**

Balanced magnetic switches
Infrared break-beam detectors
Capacitance detectors
Electric-field (E-field) sensors
Breakwire sensors

- **Unacceptable sensor redundancy includes the following:**

A guard or watchman monitoring critical areas using CCTV that is not the motion-detecting type is unacceptable as either the only detector or as a redundant detector of unauthorized access, activities, or conditions. Because the observation of seldom-varying scenes on CCTV monitors is monotonous, the probability of detecting unauthorized access, activities, or conditions using common CCTV and the human eye is unacceptably low.

- **Observation of Intrusion Detector Testing**

Test each critical area alarm zone. By appropriate sampling techniques, observe a sufficient number of tests to conclude that the tests are conducted properly, and that the equipment is performing as designed. Tests should include crawling, walking, and running in each alarm zone, unless problems are encountered. Simple go/no-go tests are sufficient to evaluate intrusion detectors.

- **Tamper Alarminq Conduit Elbows**

Although it is widely accepted that the physical protection standards require tamper alarming of all equipment housings and junction boxes in detection systems, many overlook the fact that the removable covers of conduit elbows must also be tamper alarmed. Specifications should require that all alarm devices, including transmission lines to annunciators, should be tamper indicating. The covers of all conduit elbows that house alarm-related wiring must either be tamper alarmed or they must be welded shut.

- **Test Magnets for Balanced Maqnetic Switch Detectors**

A test magnet kit consisting of two small bar magnets (such as Permag Sierra 22U17B, 3/8" x 3/8" x 7/8", Alnico 2) and two small horseshoe magnets (such as Little Giant #1022) can be used to verify that balanced magnetic switches will alarm when subjected to additional magnetism. The amount of additional magnetism needed to cause an alarm will vary among different manufacturers. However, a pair of either kind of magnets placed on opposite sides of the switch must cause an alarm.

40_3.0.1.E Lighting

Lighting is of primary importance in the operation of an effective alarm and detection system. Effective lighting provides a deterrent to adversary intrusion, assists the protective force in locating and assessing alarm initiations, and provides for effective use of CCTV as a surveillance and assessment tool. Lights are required to have a minimum specified luminescence at ground level for specific areas, a regular power source, and an emergency backup lighting capability.

In conjunction with alarm and video capture systems, lighting levels, reliability of lighting systems, and susceptibility to sabotage must be evaluated. Performance tests should be conducted to assess and verify:

- **Lighting levels at:**
  - Portals;
  - Security area perimeters;
  - Exterior and interior areas that rely upon CCTV;
  - Normal and emergency auxiliary supplies for lighting systems;
  - Procedures that are implemented in case of lighting failure;
  - Methods of monitoring lighting systems for failed equipment;
- **Observe lighting conditions and their adequacy during night time on both primary and backup power. Light meters may be utilized to check levels and contrast. Observe levels from different locations:**
  - Key visual assessment posts, such as towers;
  - Monitors in alarm centers;
  - Adequacy of lighting by observing individuals dressed in various clothing with different color contrasts;
  - Stand in different areas to check lighting via monitors;
  - Check lighting levels for low and high contrast ratios and glare or bright spots in images;
  - Look for blind spots;
  - Can animals and humans be distinguished for any location;
  - Lighting levels;
  - Light-dark contrast;
  - Glare;
  - Shadows;
  - Inoperative light bulbs;
- **Observe lighting for a variety of conditions:**
  - Clear weather;
  - Rain;

    - Fog;

- **Sabotage, vulnerability of:**

- Lighting circuits;
- Power supplies and critical components:

    - Switch yards;
    - Transformers;
    - Circuit breakers;
    - Power transmissions lines;
    - Generators and fuel supply;
    - Uninterruptible power supplies;
    - Lighting circuits and redundancy;

- **Vulnerability of power supplies to single point failure;**
- **Access control to critical areas that control power;**
- **Self-testing of all critical components;**
- **Backup systems for alarm assessment if power fails.**

40_3.0.1.F Power Systems

Auxiliary power sources, consisting of batteries and/or generators, must be be available with automatic and immediate transfer if the primary power supply fails. Generators should not be relied upon as the sole source of backup power; batteries should provide the initial energy until the generator can come on-line.

40_3.0.1.F.1 Tamper Protection for Power Sources

Often overlooked during planning and installation, the primary and backup power sources for intrusion detection systems are susceptible to tampering. Power switches, inverters, and generators must be protected. Exterior fuel tanks and filler points are especially vulnerable. An inoperable filler point or contaminated fuel tank, for example, may nullify all backup power sources.

40_3.0.1.G Improper Installation, Calibration

or Alignment

Improper installation, calibration, or alignment of sensors and other system components can degrade the effectiveness and reliability of an alarm system, generate false alarms, and potentially allow undetected intrusion. For example, if a microwave detector is not installed and aligned to system specifications, then an intruder may be able to take advantages of imprecise coverage and jump over or crawl under a beam at the crossover point where adjacent zones overlap.

40_3.0.1.G.1 Video Systems

Video motion and capture systems require continuous technical oversight to insure proper operation. This means maintenance, calibration, and verification of image quality. Specifically:

- Verify correct installation and alignment;
- Determine that there are no "holes" in coverage;
- Verify that the field of view is matched to the lens to insure that an intruder can be observed everywhere that the camera sees, and that motion detection technology properly responds to images to initiate an alarm or capture for instant playback.

40_3.0.1.H Testing and Maintenance

To ensure effective operation of alarms and detection devices, managers must provide for a regular test and maintenance protocol for both alarm devices and entry-control systems. Such a program must include the periodic testing and inspection of equipment and circuits. Most alarm system failures are the direct cause of an inadequate testing and maintenance program. The lack of maintenance and operation (testing) usually results in equipment failure. For this reason, the testing and maintenance program is one of the most important features of any protection system. An effective program will normally include provisions that require facility technicians, augmented by service representatives, to perform all tests, maintenance, calibrations, and repairs necessary to keep the detection and assessment systems operational. The surest way to incur a breach of security is to provide for inadequate testing and maintenance. Key indicators of such a condition include:

- **Frequent system failure;**
- **Cursory testing procedures;**

- **Inordinate number of items of equipment awaiting repair**

All test protocols should be well planned and the results documented. Such documentation must include:

- **Date of the test;**
- **Identification of access-control or entry-control system that was tested;**
- **Identification of alarm sensor and zone that was tested;**
- **Test type or protocol that was employed;**
- **Circuit number of other identifying characteristic, and type of test;**
- **Name of the person conducting the test;**
- **Results.**

40_3.0.2 Environmental Considerations

Each zone of protection has a unique environment that must be taken into account during system planning for sensor technology and installation. If the specific environment in which every trip will be operating is not taken into account, excessive false alarms and potential for bypass will be the result. Factors that must be considered will include:

- **Climate;**
- **Daily and hourly fluctuations in weather and environmental conditions;**
- **Random animal activity;**
- **Activity patterns;**
- **Electrical fields;**
- **Radio transmissions;**
- **Vehicle, truck, rail or air movement.**

40_3.0.3 Defeating Alarm Systems

Intrusion-detection systems consist of both an alarm and an assessment system, and are usually layered for both interior and exterior applications. Exterior systems are designed to provide the earliest possible detection of an unauthorized intrusion, as far away from the security interests as possible. The interior intrusion detection system may be even further divided into layers according to the configuration of security areas and the

required levels of protection.

**Figure LSS+4058 High security locations are protected by layers or concentric rings of perimeter sensors,
including fences, microwave, infrareds and buried detectors. Courtesy of DOE Office of Security and Safety Performance Assurance.**

LSS402 Defeat techniques for different sensor technologies

At critical facilities, various layers of protection are employed. The outermost layer of the exterior system is usually the **perimeter intrusion-detection and assessment system** (PIDAS). Exterior systems must he capable of withstanding the environmental conditions in which they are deployed.

Depending upon the operating environment and design parameters, systems will typically consist of multiple and complementary electronic sensors. Typically, the PIDAS also includes fixed-position CCTV coverage for timely assessment of alarms. PIDAS alarms normally annunciate in a monitoring station where the operator can acknowledge the alarm, assess its cause, and direct a response as necessary.

Exterior systems will often integrate the following technology, which are discussed in detail throughout this chapter:

- Microwave;
- Infrared;
- Electric field sensors;
- Fence disturbance detectors;
- Seismic sensors.

40_3.0.3A Physical Barriers

At most facilities, three barriers are utilized to form lines of defense to physically protect valuable assets. Perimeter barriers are normally found at the edge of the protected property and are considered to be the first line of defense. This may be a fence, wall, or a natural barrier, such as a river, lake, cliff, ravine, or other terrain that is difficult to traverse. The second line of defense is building exterior walls and roof. Interior building rooms, safes, and vaults make up the third line of defense. These physical barriers are mentioned because they establish areas where intrusion detection may be warranted.

Depending on the type, configuration, location, and other conditions of the protected area, applicable ESSs are selected from several different types. At property lines and large building walls, intrusion detectors covering large areas are required as opposed to a room within a building or a vault. Also, exterior applications require weatherproof enclosures and are sometimes subjected to a wide temperature range.

40_3.0.3B Detection Systems

There are many types of electronic security systems in use at military and other high security installations. All require frequent tests and checks, in some instances as often as once a day. The emphasis is on operational tests to ensure the continued functionality of the designed system, rather than on routine maintenance of component parts.

Before the advent of low-cost computer multiplexed hardware, security systems were simple hardwired alarm systems, providing a minimum level of intrusion detection. Today, the system may be a fully redundant computer-based system interfaced with a redundant looped time-division-multiplexed communication network for gathering alarm data from sensors and for sending commands to

release locked doors under the card-access control subsystem. The remote multiplexes may be microprocessor-based units, capable of data collection, communication with the host computer, and performing limited-access control functions.

The security system provides location information as well as delay time for the guards. By successive detections, the security force can track the intruder and relay location information to the responding guards. In turn, the guards can constantly inform the security force on the progress of their work or the need for additional assistance. The cameras, using various means of target intensification, can "see" better than the human eye. Guard patrols are also used to detect unusual activity.

Alarm systems provide another layer of protection in securing a facility or location. Throughout this chapter, defeat techniques or countermeasures are explored for various sensor technologies. In this section, general information is presented regarding adversary strategies, as well as defeat issues with regard to two-wire circuits, wireless equipment, and card access systems. A comparison between computer networks and physical intrusion detection is also examined because of the similarities in attack methodology. Transmission security, physical security of alarm panels, and closed circuit television systems are covered elsewhere in the chapter.

Regardless of the sensor type, there are three primary means for avoiding detection through a system's normal operation:

- **Deceit or Diversion:** Create false alarms to divert attention from an actual intrusion, or use false pretenses to incapacitate or bypass the sensor;

- **Employ force in combination with a rapid attack to avoid intervention:** This mode assumes that the response time to an alarm would exceed the ability of an intruder to reach its target. This technique presumes that detection and response is imminent;

- **Stealth and evasion methods:** There are several techniques that can be employed, including denial of service, alarm stacking, spoofing, camouflage, speed, and brute force. Exploit other pathways that may exist, such as over, under, through or around sensor detection patterns. Use sensor walk-test lights to determine a detection path. Alarm stacking takes advantage of the conditioning of the responder or monitoring personnel, and

assumes that the alarms are false and are being caused by environment factors or a defective sensor. Alarm stacking requires that several sensors be triggered simultaneously, or that one or more sensors report multiple detections. Both of these conditions will be seen as irregular by monitoring staff and may create a delay or a total disregard of the report. Intruders may also attempt to bypass sensors by extremely slow and stealthy movements into the detection path which would not materially change the threshold trigger levels of sensors. Bypass of passive infrared devices is an excellent example. Walking at an extremely slow pace toward a sensor will generally not be detected.

40_3.0.3C Comparison Between Computer Networks and Physical Alarm Systems

Network intrusion detection systems offer many parallels to physical intrusion detection alarm systems and sensors. NIDS are becoming quite prevalent in safeguarding computer systems and supplementing their security. Such systems provide security in the digital world, just as the burglar alarm does in the physical environment. Digital systems have vulnerabilities that can be exploited by an attacker, much the same as does a physical intrusion detection system. The author believes that lessons can be learned by comparing attacks on computer systems with attacks on physical facilities. Although the domains are different, the attack methodology can be quite similar in concept.

An intruder will try to evade detection by determining the weaknesses or design deficiencies in a system and attempt to exploit them. Each security system has different components, and thus, potential for bypass. Computer networks and alarm systems look for intruders in two ways: signature matching or abnormality detection. Each alarm sensor is looking for certain parameters that are considered normal for its environment. An IR detector, for example, is evaluating a range of temperature within its zone of coverage. Any deviation from what it expects to see will create a signature that it recognizes as an alarm condition.

The detection of an abnormality would include a sensor failure, tamper detection, failure to detect the expected signature, multiple hits, or the detection of an out of range parameter. Abnormality may also indicate that there is a problem with the system, in terms of transmission links, central processors, visual or audible indicators, or the normal baseline response of

a system, indicating a problem with overall integrity. The role of alarm assessment and the guidelines that have been established to define what is "normal" in terms of system performance, is critical to the determination of what constitutes an abnormality. It is therefore essential that those responsible for system design and evaluation carefully consider the range of events that are defined as normal with respect to a given facility. If the tolerance for events is too high, then the system may be easily exploited. If the tolerance is set too low, then a high number of false alarms may result.

False Positive and False Alarm

An alarm is received that is not valid and does not denote an intruder. It is the result of a faulty signature that the sensor is looking for.

False Negative

Failure to alert when a valid detection of intrusion is received.

Obfuscation

In the computer world, this concept relates to the manipulation of data to change its content without being detected. With regard to alarms, it means that signals may be interrupted from a detection device to the central processor, or from the processor to the alarm center, but such interruption or tampering would not be detected as an anomaly. This procedure may also be known as spoofing. In its simplest form, obfuscation might mean the jumping of contacts on a trip, the insertion of an end-of-line resistor near the circuit termination point, or the blinding of a video camera with an infrared laser. In the more complicated form, it might require the flooding of a photoelectric receiver with light that is modulated at the same frequency as that which is transmitted by the system. Likewise, in an ultrasonic motion detection system, it might require the generation of the transmitted frequency at high energy levels, thus minimizing the Doppler shift detection by the receiver. This method of attack can take many forms and is perhaps the most dangerous.

Fragmentation

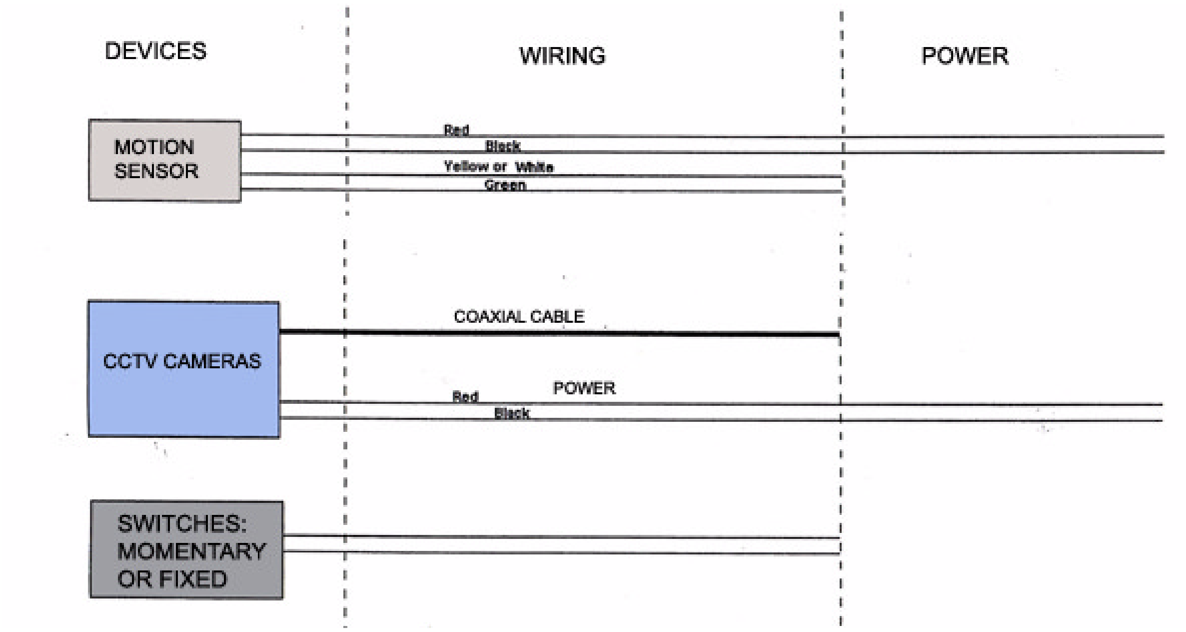
Within the digital environment, this attack refers to breaking a system by sending multiple fragmented packets that cannot be properly processed. It can be roughly approximated to alarm

stacking, where multiple signals from individual devices are received, causing an alarm condition to occur that may be improperly interpreted as a system failure, or due to causes that do not constitute a condition of intrusion (such as adverse weather conditions).

Encryption

Transmission links should always be encrypted between a central processor and alarm monitoring center. However, much like the computer world, the use of encrypted virtual private networks (VPN) can also cause problems, because the networks may not detect encrypted traffic that is not authorized, but is intended to directly access host servers.

Denial of Service (DoS)



A denial of service attack can be compared to alarm stacking, and is a method to overload processing capability. This form of attack can take many forms, ranging from multiple alarms from one or more devices within a specific facility, to causing the receipt of thousands of alarms from different premises throughout a community. Such attacks have been employed in major cities to mask burglaries of drug stores, jewelry outlets, and banks. In one particular attack, a major feeder trunk was cut outside of a telephone central office, taking thousands of telephones and alarm reporting circuits out of service for an extended period. The overflow of alarms into all monitoring centers made it impossible to assess the validity of any particular alarm, and allowed the burglars to proceed without detection.

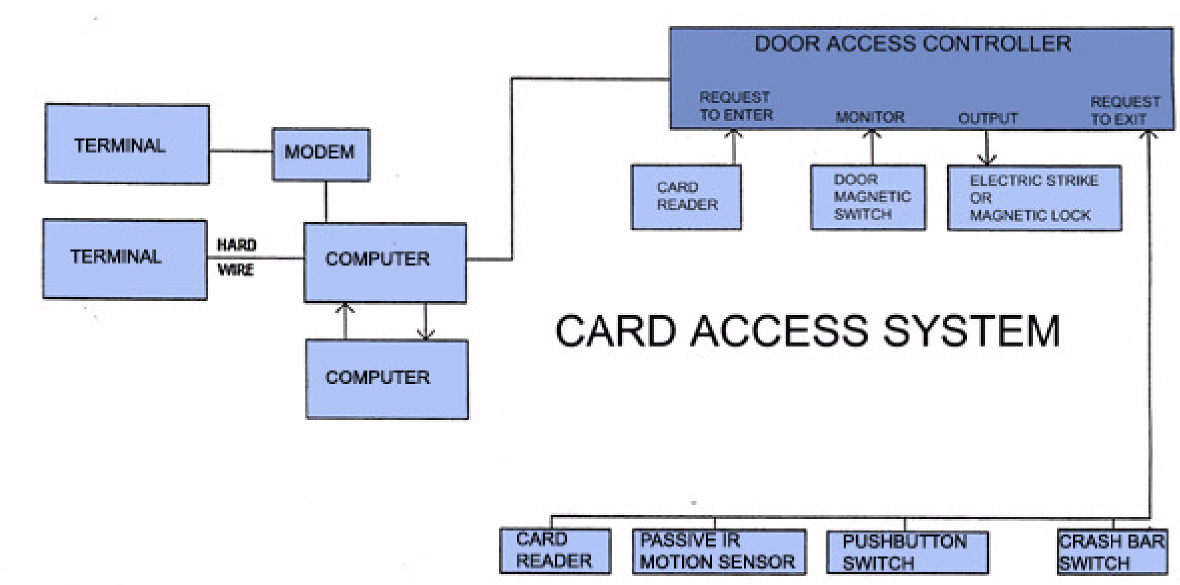
Application Hijacking

This method of attack involves the interception of a session between the alarm monitoring center and local facility central processor. The hijacker is able to assume the legitimate credentials from the local facility. Once this occurs, the local system is taken off line, so that there is no reporting to the monitoring center. There are variants of this method. One allows the attacker to steal the client's session token that permits it to communicate with the host. In another, the "man in the middle" attack is involves the hijacker pretending to be the legitimate user to the server and pretends to the server to be the legitimate user.

40_3.0.3.1 Two-wire devices

Switches, continuity devices, and sensors that utilize a single pair of wires to signal continuity or a normal condition are all subject to bypass.

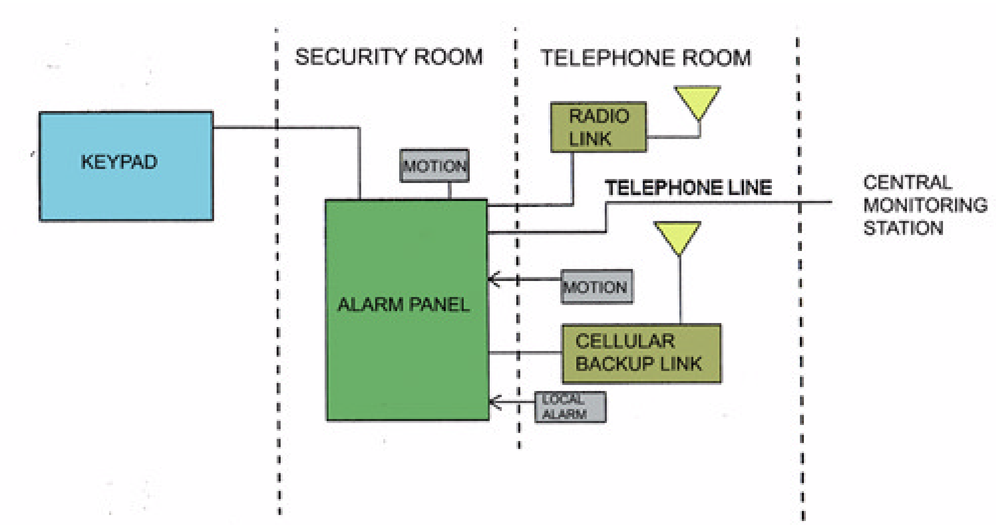
Vulnerabilities that exist with regard to sensors, wiring, and power include:



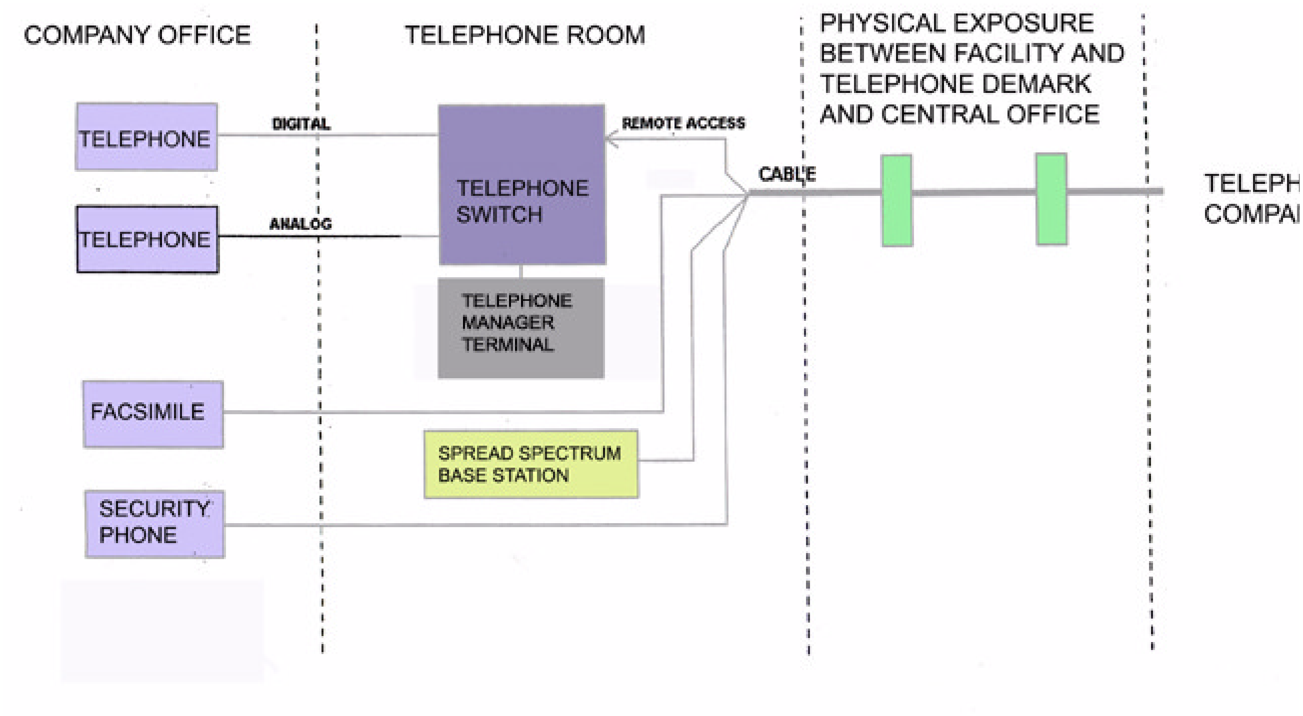
- **Walk test lights that are not disabled;**
- **Shielding of sensor before the intrusion occurs;**
- **Shielding during the intrusion;**
- **Mounting boxes that are accesible from the rear of the sensor;**
- **Two-wire trips are either opened or shorted to bypass;**
- **Wiring may be compromised when it is accesible and recognizable as to color coding or function;**
- **Bypass of wiring to control electric strikes;**
- **Power loss may cause a system to fail or go into alarm.**

40_3.0.3.2 Card Access Systems

There are a number of vulnerabilities that can be exploited with regard to card access system components. Such systems can be compromised in the following manner:



- **Computer terminals unattended while the user is logged onto the system;**



- Inadequate or not enforced security procedures;
- Shared passwords;
- Failure to change default password;
- Failure to monitor and implement a password procedure for selection and changing;
- Failure of physical security measures, such as a compromise of the master key system that allows access to secured areas;
- Stolen or borrowed cards from users;
- Failure to delete inoperative, lost, stolen, or former employee cards;
- Failure to implement a card technology that cannot be hacked or copied;
- Failure to implement proper controls on card programming access or information within the database of cardholders;
- Failure to adequately encrypt the cardholder database;
- Failure to restrict use of cards by time of day and day of week, as well as access only to areas within the employee's authority;
- Failure to properly vet janitorial or maintenance staff;
- Compromise of computer control system;
- Failure to monitor the system for access violations, or invalid attempts at access;
- Failure to implement independent card inventory control;

40_3.0.3.3 Hardware Room and Telephone Room Security

It is essential that security be maintained in the area designated for the location of the alarm central processing equipment to insure its uninterrupted and secure operation. Likewise, the location of telephone and wireless link equipment that ties the alarm system to a central station, remote monitoring facility, or response agency be secure against all forms of attack. Note that this area should not be on the top level master key. See **chapter 31**.

Each component of the security system input, output, and control hardware has specific vulnerabilities. These are summarized below.

Keypad

- Codes may be easily viewed by others as they are input;
- Failure to maintain a log of all entry and access attempts;
- Failure to review access logs;
- Sharing pass codes, thereby preventing individual accountability;
- Insufficient pass codes, requiring that they be shared among employees;
- No duress code;

Alarm Panel

- Keys left in the panel door or near the panel. This can allow unauthorized access to reprogram or defeat the alarm panel;
- Original lock has not been replaced with a high security cylinder, such as Medeco cam lock;
- Factory original keys will open the alarm panel. These keys are available to virtually anyone;
- Alarm identification is visible to an intruder;

- Security room is unlocked;
- Security room is unprotected with alarm sensors. There should be a magnetic trip on the door, and motion sensor to protect the area around the alarm panel;
- The room that contains the alarm panel is a shared use area, allowing janitorial, maintenance, other staff, or unauthorized individuals to access the panel;
- The security room is on the top level master key, allowing potential compromise;
- Individuals that have access to the alarm panel are unsupervised;
- Inadequate fire walls and protection for the security room;
- Alarm panel serial numbers are visible. This may provide information with regard to passwords or encryption keys;

Transmission Lines

- Transmission lines can be cut, if a dial-up circuit is utilized;
- Leased lines to a central station can be compromised if they are not supervised properly;
- Telephone room is kept unlocked;
- Telephone room is on the top level master key;
- A lock box is utilized to store the key to the telephone room. Unless proper security is maintained over the lock box, this is also easily compromised;
- The telephone room is not properly alarmed;
- No security clearance is required for individuals to access the telephone room;
- No covert CCTV camera is installed in the telephone room;
- There are inadequate fire walls in the telephone room;
- No written records are maintained with regard to all circuits that terminate in the phone room;
- Telephone circuits are not tagged and properly identified;

Central Monitoring Station

- Doors left open or unlocked for convenience or ventilation;
- Design of central station structure is not compliant with UL standards. There is no outer building shell;
- Owner/operators of central station facility do not follow proper procedures in order to accommodate clients;
- Improper response upon receipt of an alarm;

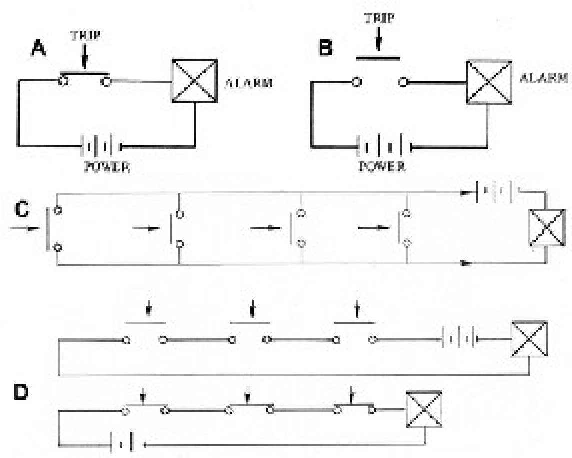
Telephone Rooms and Circuits

- Telephone circuits easily accesible and subject to intercept;
- Cordless telephone does not utilize spread spectrum and can be intercepted;
- Telephone wiring is accesible;
- Telecomm manager terminal is not protected from unauthorized programming or access;
- Remote access ports into telephone switch;
- Analog outputs from digital ports;
- Telephone room easily accesible;
- Punch blocks within telephone rooms are not properly documented and secured;

Exposure Between Facility and Telephone Company

- Surface pedestal with underground cable is subject to compromise. The buried cable pedestals are not under the user's physical control or supervision;
- Aerial splice containers with above ground cables are subject to compromise;

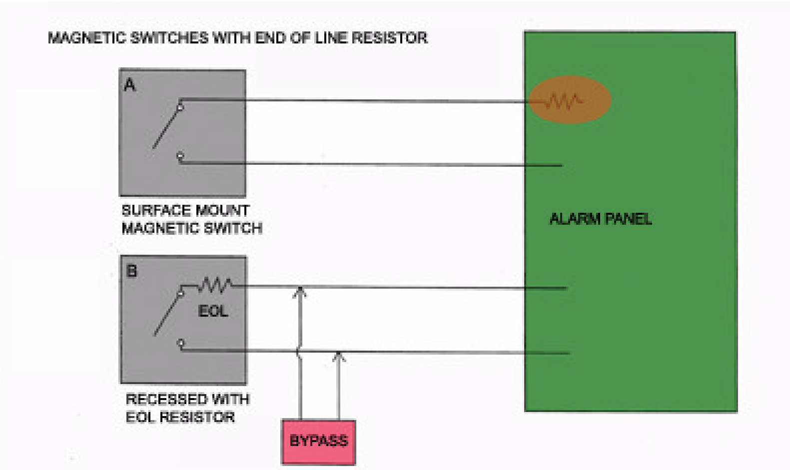
Telephone Central Office



- Legal wiretaps are non-detectable;
- Illegal wiretaps;
- Lack of security in central office;
- Failure to protect trunks that feed the central office.

40_3.1 Contact and Continuity Devices

Mechanical switches are used to detect the opening of a protected door or window. Contact switches depend on direct physical operation/disturbance of the sensor to generate an alarm. They are the simplest in theory and operation, and perhaps in a limited sense, the most stable and reliable. When an intrusion or other defined action occurs, the contact trip will make or break an electrical circuit.



The most common types of contact sensors are the magnetic trip, window foil, pressure floor mat, foot switch, holdup buttons, micro switch, level-switch, and taut-wire trips. All of these devices function on the same basic principle: circuit continuity is completed or broken upon activation. These mechanical switches are usually spring-loaded or plunger operated; they are activated when the contacts are moved to an open or closed position.

Contacts can be series wired within a loop if every device is in a “normally closed” condition. Otherwise, trips may be wired in parallel using one pair of wires, so long as all devices are “normally open” until an activation occurs.

Sensors can be mounted in almost any configuration: on doors, windows, drawers, cabinets, trap doors and any other item that must be moved. They are generally complemented by other protection technologies such as microwave or infrared. In order to operate reliably, trips must be properly mounted on secure and stable fixtures that are not loose fitting or subject to random movement.

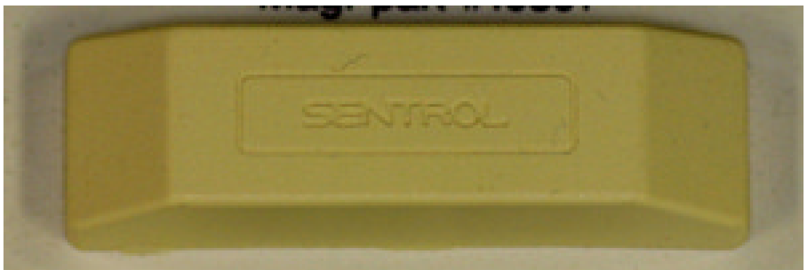
End-of-line resistors are utilized to protect sensors from bypass, as shown in the diagram below. If the resistors are not placed at the trip, then they can be easily circumvented. Magnetic (and other types) switches can be defeated by presenting a short circuit to the switch contacts or anywhere along the circuit, unless protected by a properly placed EOL resistor. The use of a magnet to simulate a normal condition will also defeat standard magnetic reed switches. Note that if the EOL is improperly placed within the circuit, then a simulation of the correct resistance can be inserted between the trip and the alarm panel. If the tamper device is later removed, there will be no evidence of such bypass. The switch (A) is a standard magnetic contact device. The end-of-line resistor is placed at the alarm panel, rather than at the switch and can easily be circumvented. The recessed switch (B) has the EOL properly placed, but can still be bypassed, as shown.

Nuisance alarms can be caused by:

- **Poor fitting or improperly mounted doors or windows;**
- **Extreme weather conditions (wind and storms);**
- **Seasonal fluctuations in the external and/or internal environment (heating versus air conditioning).**

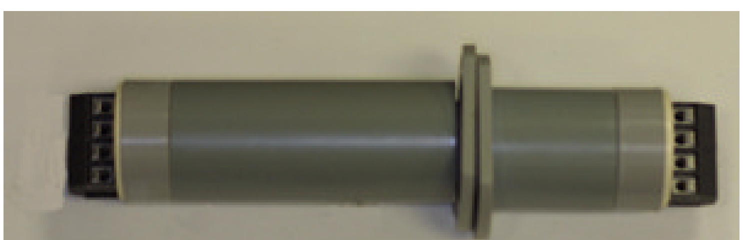
40_3.1.0 Defeat of Mechanical Contacts

Switch type sensors are subject to simple bypass in a variety of ways. These include:

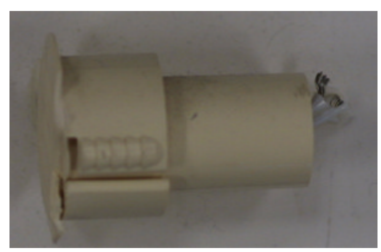


- **Holding the switch in the "normally closed" position while opening the door or windows;**
- **Use of a small piece of metal that prevents the switch from triggering;**
- **Taping the switch in the "closed" position during daytime operations;**
- **Placing a short-circuit across the terminals of the switch so that it shows its normal state in any condition;**
- **Cutting a circuit that is normally open;**
- **Bypassing end-of-line resistors;**
- **Release of a switch from an external location through the use of a stiff wire or other mechanical bypass;**
- **Shimming by forcing a small thin piece of material (metal or plastic) between the switch and protected area (door edge or object) to hold the switch depressed;**
- **Wedging an object into the switch to hold it closed during a**

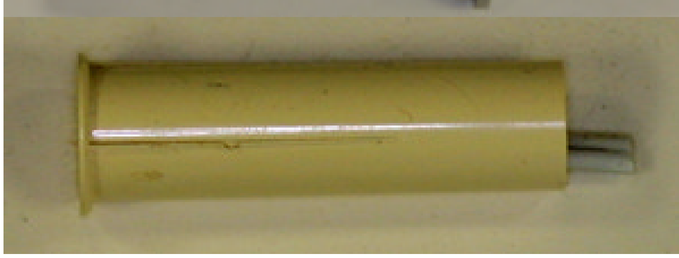
disarmed period. Use of a toothpick, super glue or other material is typical;



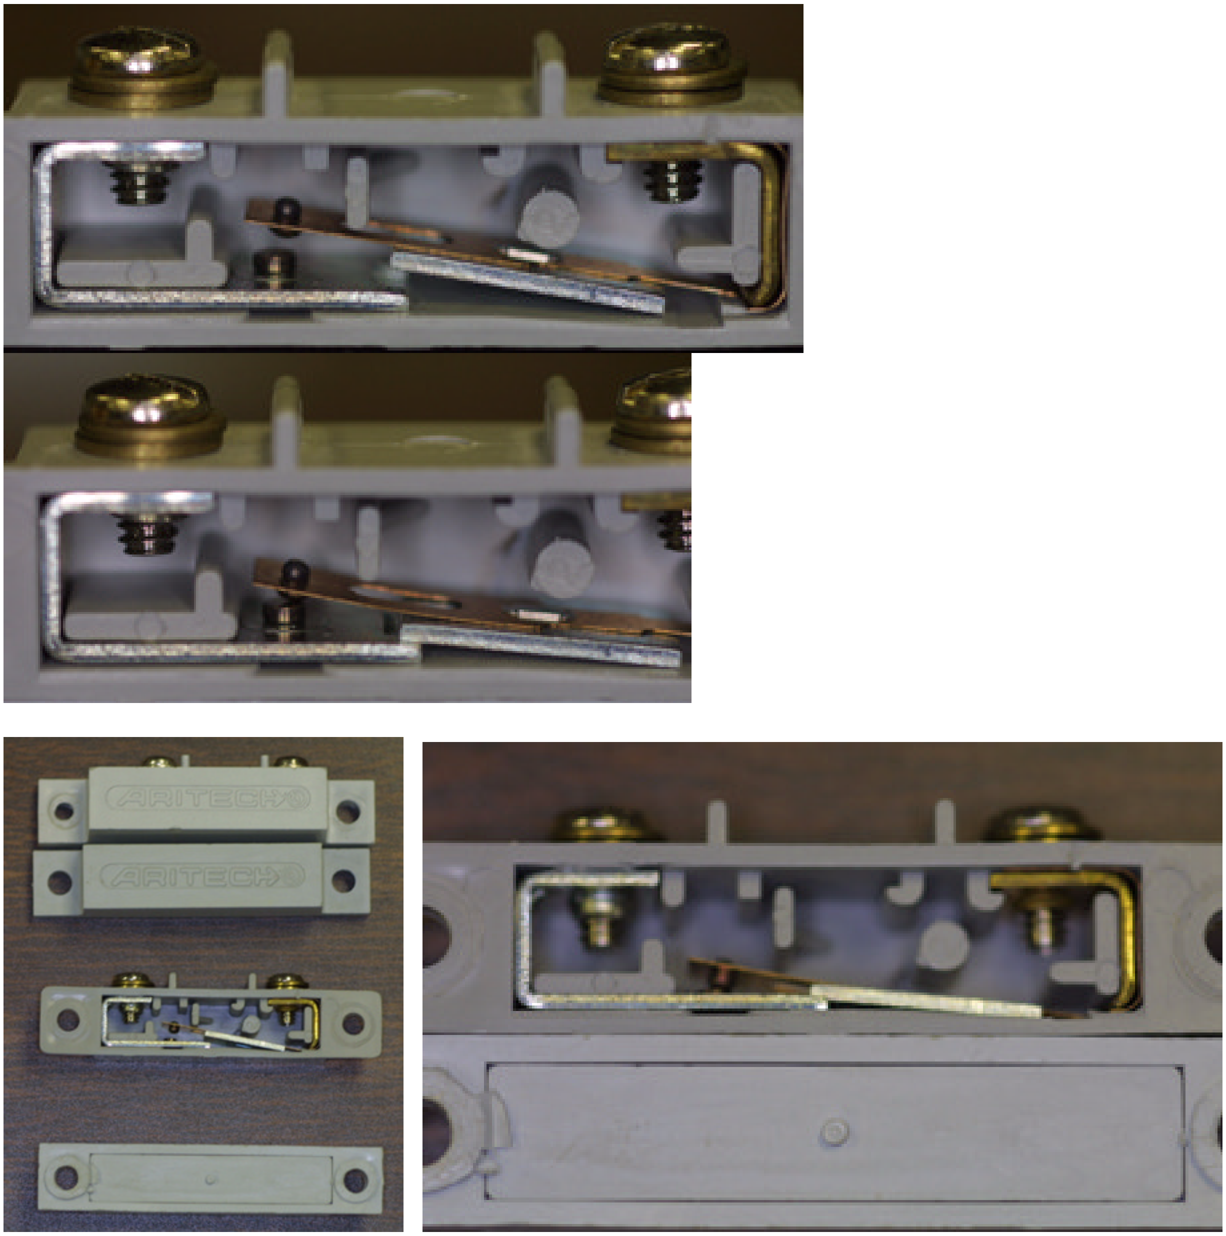
- **Bridging of exposed or internal switch contacts or at a splice point (jump-out).**



40_3.1.1 Magnetic Contact Sensors



LSS401: Alarm contact devices, including magnetic switches



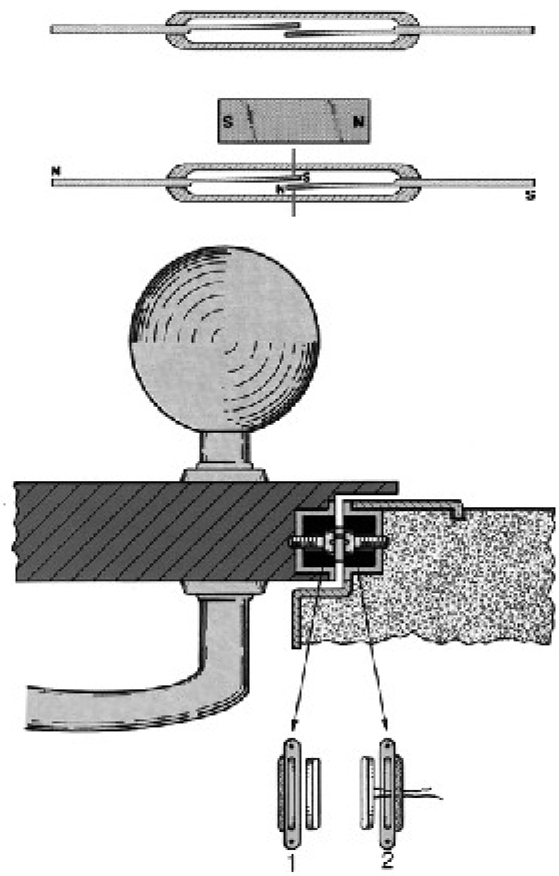


Figure LSS+4043 A variety of magnetic contact switches are available. The photographs show the switches in normal open and closed states. The magnet biases the contact, shown in the bottom photograph, so that the circuit is completed.

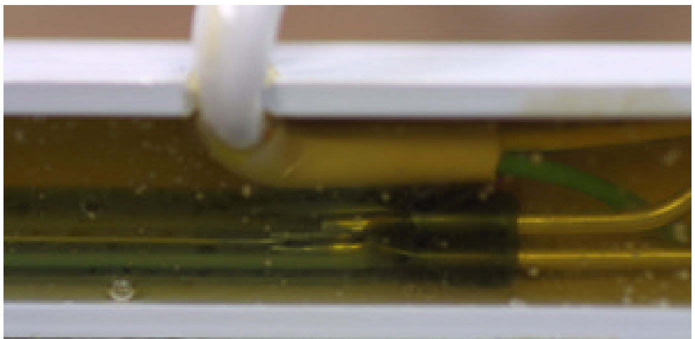
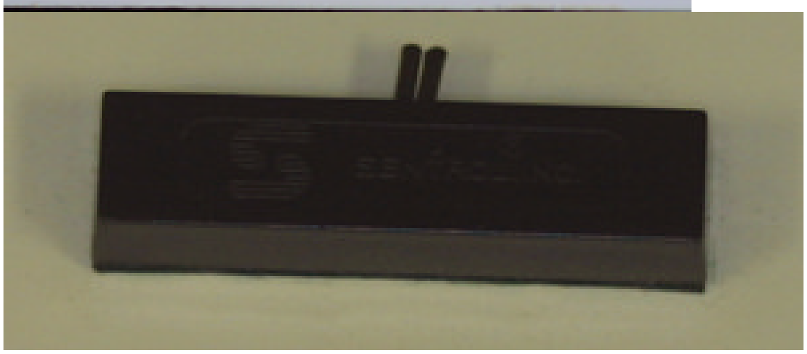
Magnetic contacts are utilized to protect doors, windows, drawers, paintings, statues, safes, and other objects that can be moved. They are produced in a variety of configurations and can be secreted in virtually any location. Their operation depends upon direct physical operation of the sensor by the target object. In high value items, other trips should be utilized to

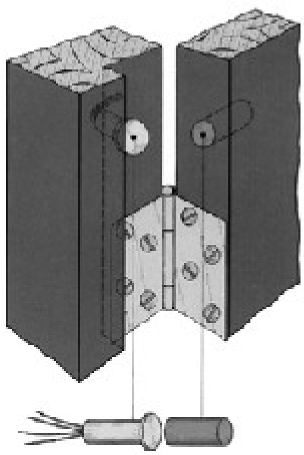
afford overlapping protection. Trips utilize a fixed magnet and some form of magnetically sensitive switch. When the field is in close proximity to the sensor, the switch closes (or opens). When the field is removed, the status of the contacts is reversed.



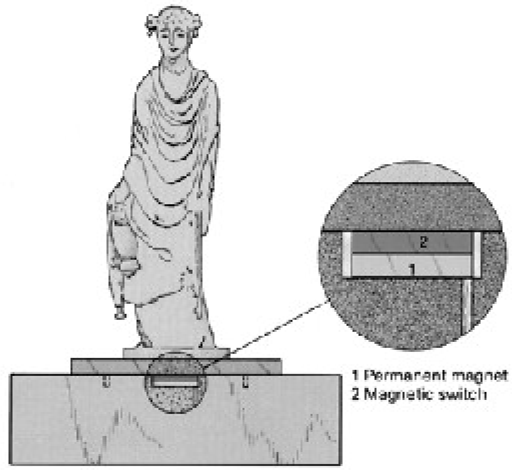


There are generally two parts: a magnetic switch that is mounted on the fixed object, and a magnet mounted on the moveable component. Most magnetic trips utilize sealed reed switches in plastic or glass tubes filled with an inert gas. A thin contact strip at each end of the vial is positioned so that the tips are parallel and overlap without touching. When a magnet is brought in close proximity to the reed, they are drawn together.

Reeds are constructed with ferromagnetic metal leads. This metal becomes magnetic in a magnetic field. When this happens, each lead assumes opposite magnetic polarity. The leads attract one another and when the field strength is sufficient to overcome mechanical lead stiffness, the leads make contact, thus making electrical continuity. This action happens in as little as



0.5ms.



Reed sensitivity is determined by the manufacturer, that specifies the gauss level of the magnetic field required to close the reed blades. Magnetic field strength is measured in Gauss and reed sensitivity is measured in Ampere-Turns. These units are not mathematically related, but can be matched empirically.

Unreliable operation will result if there is excessive movement of the mounting surface, such as poor-fitting doors, windows, access panels, or frames, as described in the preceding section. Extreme weather conditions can cause excessive movement of mounting surfaces.

40_3.1.1.1 Defeat Techniques for Mechanical Magnetic and Reed Switches

Traditional magnetic switches that do **not** employ reeds can often be easily bypassed through a variety of techniques. These include:

- Avoidance: cut through an opening;
- Capture with external magnets;
- Bridging of external or exposed switch contacts or at splice point (Jump out);
- Tape or glue a magnet to the switch during alarm-off mode;
- Alarm stacking with the application of shock from a non-secure side (use of a ball pene hammer);
- Liquid solder on exposed contacts.

During the past thirty years, the single element reed switch has been the primary magnetic switch component for perimeter protection of doors and windows. Almost all reed-based devices suffer from significant vulnerabilities in terms of bypass, mechanical reliability from external energy sources, and environmental issues. The traditional alternative to the single element reed switch is the balanced magnetic switch (BMS) which utilized multiple reed segments. Other technologies are available that can provide high security perimeter protection. These are discussed in later sections of this text, and in the accompanying video on magnetic switch defeat techniques.

Specific defeat techniques include:

• **Application of magnetic fields**

The traditional reed switch can be defeated with a strong magnetic field because of its inherent design characteristic that require that its active contact blades be equally magnetic in all planes. Any magnetic field that is within close proximity will temporarily magnetize the blades, causing them to be attracted to each other. This can result in a closed circuit condition. The remedy is to utilize a switch that has two sets of contacts, one of which will trigger upon the presence of a second field. Another method of bypass involves bridging of the contacts, resulting in permanent continuity. Access to the door or window without affecting the status of the trip will also allow bypass the alarm system. The position of the switch should not be easily observed or accessed.

• **Strong electrical fields**

Contacts can be permanently welded closed from a high voltage lightning or power surge, or through the use of a Taser gun. In addition, proper operation can be affected from the application or proximity to strong electro-magnetic interference (EMI) that is generated from nearby power lines and cables or large appliances. Remember that the wiring that connects such devices to the remote alarm panel can act as an antenna. Large voltage spikes will cause a permanent closed-circuit condition, rendering the sensor inoperative.

• **Physical reliability**

Sensors contain two parallel metallic blades that are encased in a glass envelope. The enclosure can be broken from shock or rough handling prior to or during installation. Sensors can also be damaged as the result of swelling of enclosures that can be caused by changes in temperature or humidity. Thermal expansion of materials can pose a serious problem.

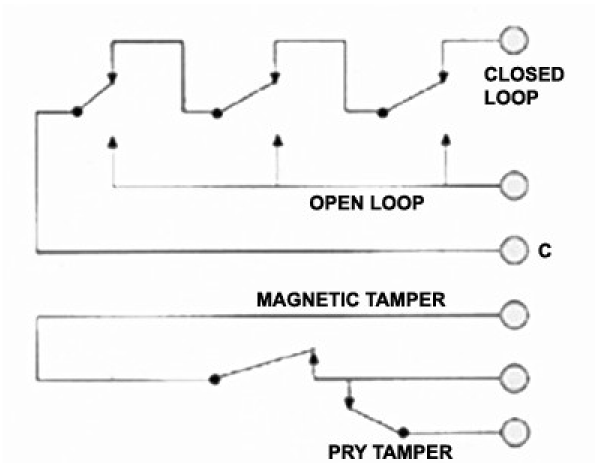
40_3.1.1.A Balanced Magnetic Switch (BMS)

LSS403: Defeat of magnetic switches, including BMS

A balanced magnetic switch consists of an assembly with an array of five internal magnet that is usually mounted on the door or window frame and a balancing (or external) magnet mounted on the

moveable door or window. The switch is usually balanced in one position between the biasing magnets and external magnetic fields. A disturbance of the fields caused by movement of the external magnet will cause the state to change. In the normally closed state, the biasing magnet interacts with the fields generated by the external switch magnets.

Generally, there are three reeds that respond to the external magnet array. These three magnets are set to north-south-north or south-north-south with regard to polarity. The bias magnets match the polarity of the external fields. Any attempt to introduce a magnetic field to bypass the normal operation of the switch will result in one or more reeds changing state, and an alarm. There is also a separate anti-magnetic tamper reed to sense the introduction of stray magnetic fields. A magnet in the base of the BMS provides anti-pry protection. Although certain manufacturers represent that actuating magnets are matched to specific sensors, they are in fact interchangeable. A magnetic array may also be placed on the front of the switch to defeat its operation.



These sensors offer a higher level of security than traditional magnetic switches. They are also available for hazardous areas where there is an explosion potential. Typical tolerance is a movement from about one-half to one inch from the door to frame. For added security, supplementary devices should be utilized. As with other switch sensors, erratic operation will result from excessive movement in the mounting surfaces caused by mechanical design, wear, extreme weather variances, or improper installation.

40_3.1.1A.0 Defeat Techniques for Balanced Magnetic Switch

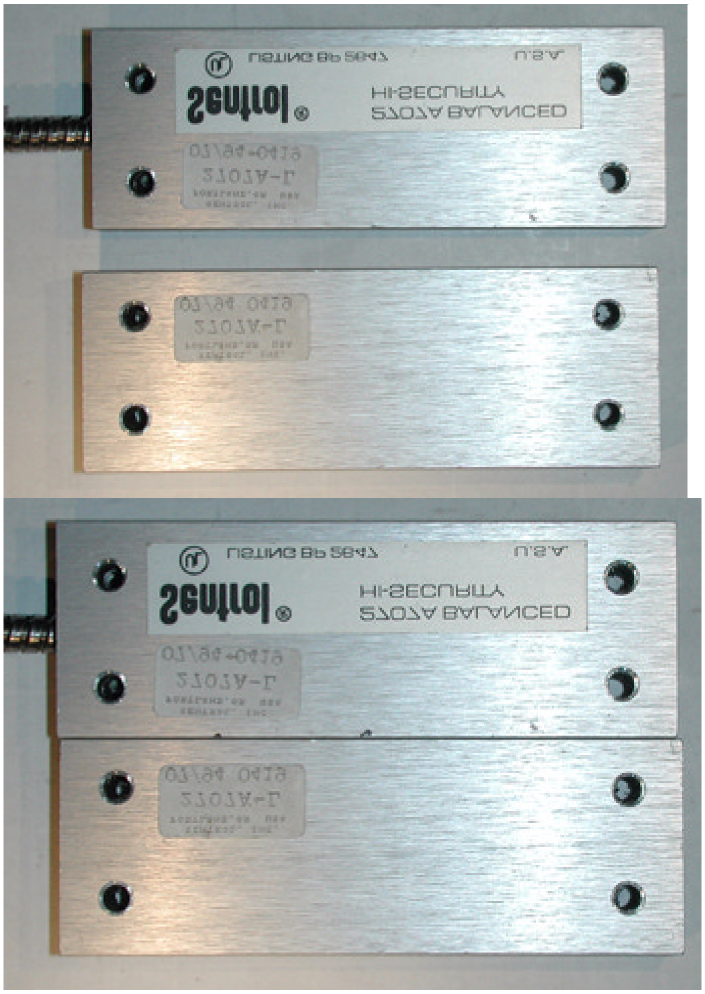
The BMS is a high security sensor that contains one or more internal biased magnets and reed switches. Unlike the conventional mechanical or reed switch, it is significantly more resistant to tampering or bypass through the application of an external magnetic field. Remember, the reed switch will react to the greater magnetic field. However, these switches are biased, so a precise field with the correct strength and polarity is required for activation.

In the photographs below, a triple balanced magnetic switch is shown. This device, manufactured by Sentrol (Model 2707) contains three reeds that are mounted at an angle, and another reed switch

to detect tampering through the use of an external magnet. A fifth reed provides an alarm in the event that the base is pryed loose. In normal operation, the switch must be mounted a specified distance from the actuating magnet, or it will not set up properly. A nominal gap of .4"-8" is recommended. The circuit is shown below for both normally open and normally closed loops.

This switch can be defeated, as shown in the photographs, by applying three magnets of the proper strength and polarity directly against the reed switches but separated by a metallic mounting plate. The author has utilized **Neodymium magnets** (NeFeB) consisting of neodymium, iron, and boron. A nominal strenth of 67 gauss is required at each of the reeds. As shown, the reeds can be located by reading the magnetic signature on the actuating magnet with a magnetic film, such as visimag, than transposing their position onto a piece of plastic, paper, or metal which is then affixed to the base of the switch. The location of the reeds can also be determined by applying material around each of the reeds to locate the bias magnets.

If done properly, the bypass magnets will not be visible during normal daytime operation. They will not affect how the switch works, but will maintain circuit continuity when the door is opened. Magnetized needles can also be utilized to pinpoint the center of each magnetic field, as shown.



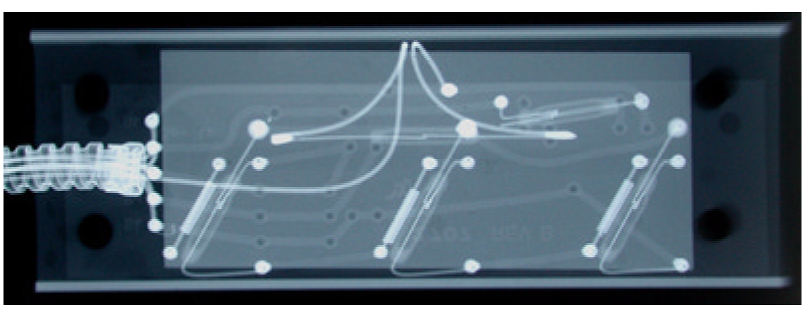


Figure LSS+4067. A Sentrol 2707A high security balanced magnetic switch (left) with the proper spacing between magnet and reed elements, and (right) the switch will go into alarm because the reqired gap is not present.

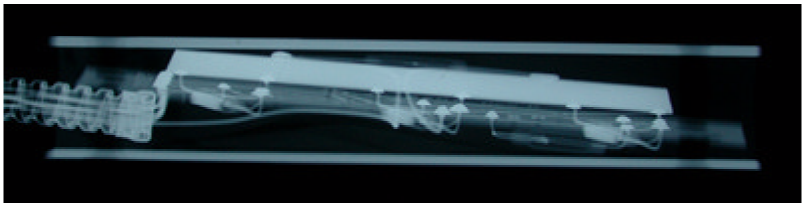

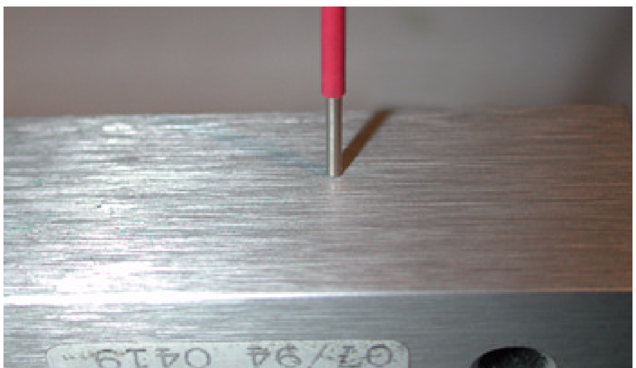

Figure LSS+4068. An x-ray view of the Sentrol 2707B BMS, shown above. Note the three reed switches that have been placed at an angle to the base of the switch. Note also the biasing magnets next to each reed. The reed switch that is parallel to the base detects the presence of the mounting plate and provides anti-pry indication. The reed that is located at an angle at the upper right corner detects magnetic tampering with an external field. The side view (right photo) shows the orientation of the switch to the magnetic array that would be located so as to create a .4" to .8" gap.

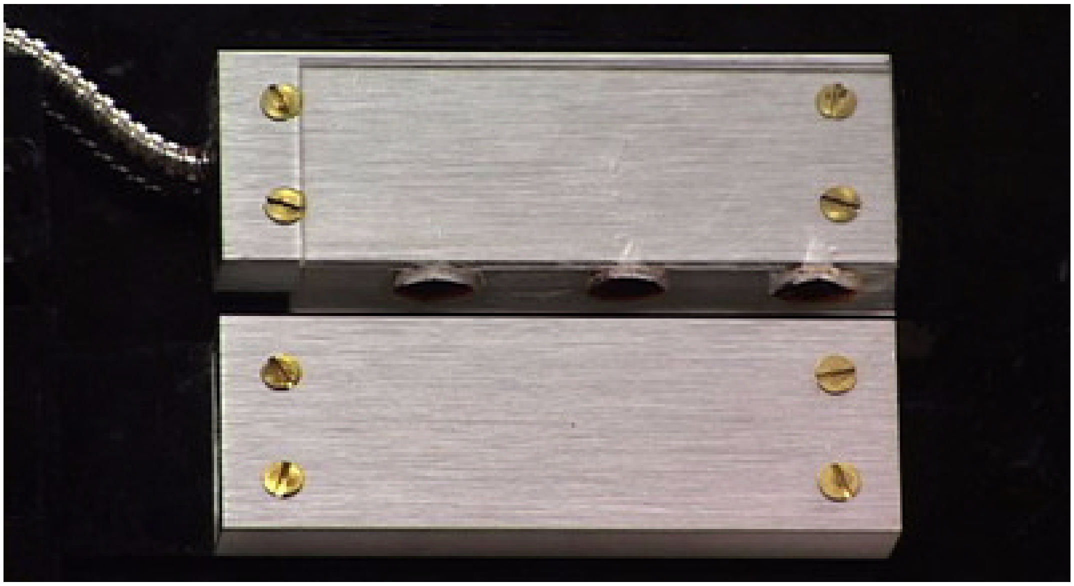

Figure LSS+4069. A balanced magnetic switch that contains three reeds can be bypassed with magnets attached as shown. Magnetized needles and visimag material can be utilized to determine the precise location of magnetic fields. Rare earth magnets can then be placed against the active portion of the switch. In the above photograph, a piece of plastic is utilized to support the magnets to demonstrate the principle. In a real bypass, the system shown below would be more likely to go undetected.

Another technique to defeat the BMS would be to embed three magnets within a plastic base upon which the sensor array is normally mounted (for anti-pry feature). If the magnets are oriented properly with reference to the three reed switches shown in the x-ray view above, then the device would always show a normally closed state, regardless of whether the door was opened or closed. Security staff should pay close attention to the base plate for the 2707 BMS because of the potential for substitution and subsequent defeat of the trip.

Generic methods to defeat this type of sensor include:

- Avoidance by cutting through or around the door or window;
- Alarm stacking with shock from the non-secure side;
- Jump-out the alarm circuit cables;
- Capture with external magnets of a single-bias BMS;
- Tape or glue one or more magnets to the switch during access to area.

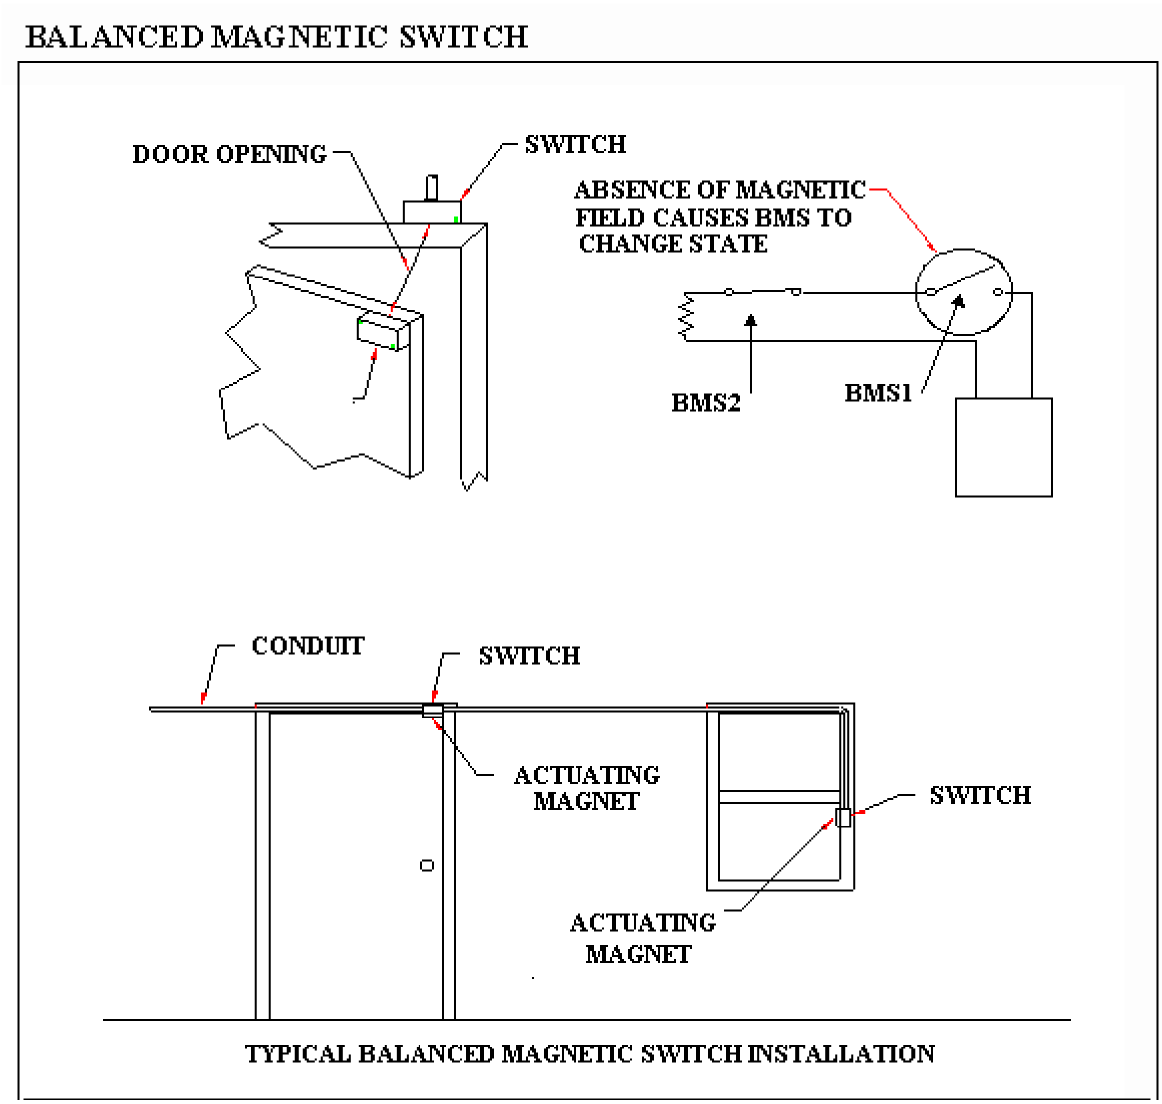

Figure LSS+4001 Typical balanced magnetic switch installation

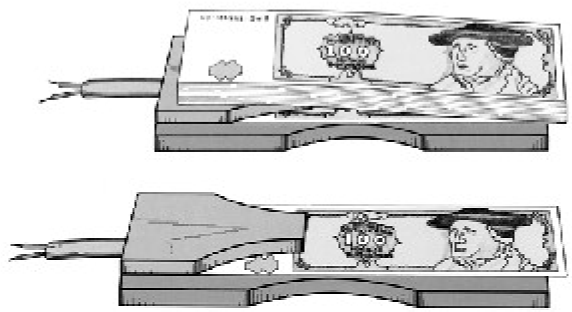
40_3.1.1A.1 Magnasphere Magnetic Switch

 **LSS403: Magnasphere technology**

The Magnasphere high security contact was designed specifically to eliminate certain vulnerabilities that are inherent in the reed switch. The design relies upon a tiny magnetic ball floating freely inside a small metal housing with two protruding wires. The switch remains closed only when a magnet is directly under the switch so it can pull the magnetic ball into electrical contact with the case and electrode, thereby completing the

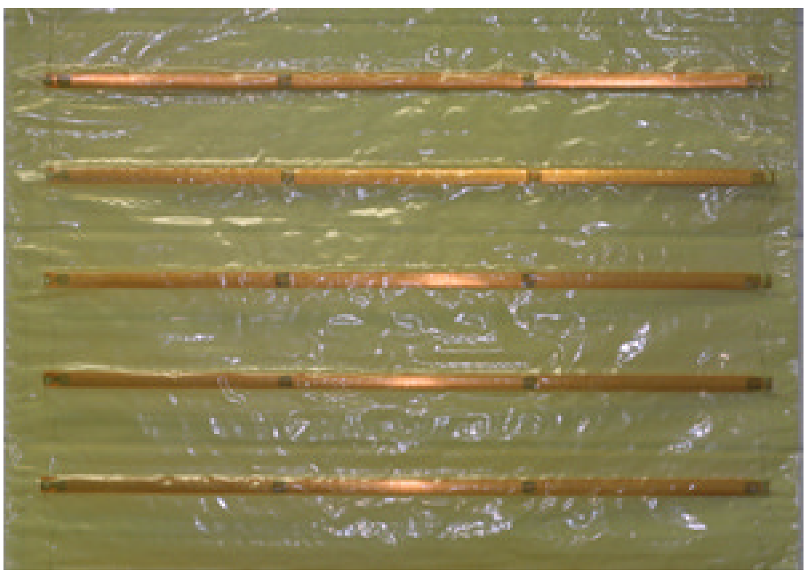
circuit. The presence of a strong magnetic field near the switch has the opposite effect of the reed switch; the magnetic force dislodges the ball and breaks the circuit. This design eliminates the possibility of magnetic bypass.



In contrast to the balanced magnetic switch, which is a 4" x 2" aluminum box containing three reed switches and armored cable. The Magnasphere high security switch can be packaged for surface mount in a 3/8" x 3/8" cube. The switch is suitable for installations where the sensors are less than ½" apart.

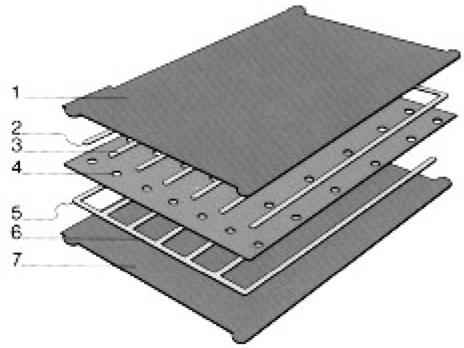
Exposure to high voltage will generally not result in contact welding, as can be experienced with traditional reed switches. False contact closure is virtually eliminated with the floating ball design. In the event that the ball contact sticks, normal door or window movement (with attached magnets) attracts the ball contact. This "torques" the contact to open the circuit. Other environmental issues, such as swelling and shifting of doors and windows and temperature extremes will not affect the switch. End-of-line resistors can also be incorporated directly into the switch wiring.

40_3.1.2 Bank Note Contacts



Special bundles of bank notes are provided to tellers for use in case of a robbery. When money is removed from the package or the entire group of bills is handed to the robber, a micro switch contact signals an alarm. Usually two spring-biased conductive surfaces are insulated from each other by several bills. When the currency is withdrawn, they are allowed to touch in order to complete the circuit. The contacts can be likened to a clothesline clip separated by an insulating material.

Such an alarm is automatic as long as the teller utilizes the bait money during a holdup. However, once the money is removed, it is obvious that an alarm device was attached to the bills and has been triggered. False alarms are also more likely with this arrangement.



40_3.1.3 Pressure Mats

LSS401: Discussion regarding pressure mats

Sensors utilized in pressure mats are usually quite simple in design and are often constructed as two thin metal strips that are electrically insulated. So long as a specified amount of pressure is not applied, the strips will not touch each other. Usually, the strips are configured as a "normally open" device; they will not complete the circuit in the absence of pressure.

Mats are available in various sizes or as rolls that are cut to the required shape. They are placed under carpets, carpet runners, pads and the like. When someone steps onto them and applies the requisite amount of force, a signal will be sent to the central processor, based upon circuit completion. The sensors should be placed in locations that are likely to be traversed by a burglar during the course of committing the crime. Such places might include:

- **In front of windows;**
- **In front of doors;**
- **In front of safes;**
- **At the top or the bottom of a flight of stairs;**
- **In front of valuable objects.**

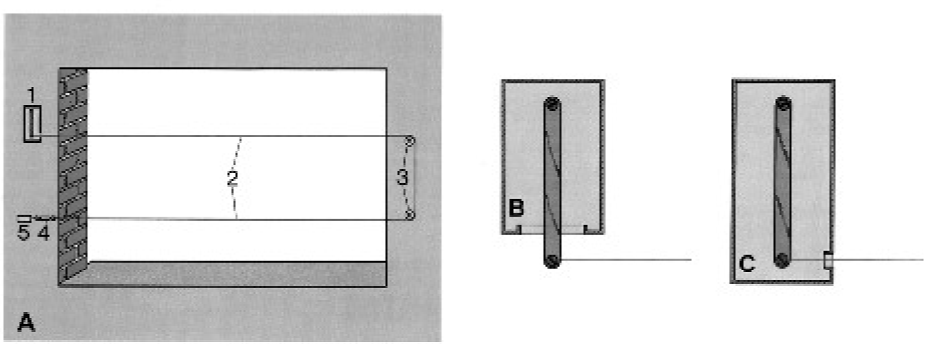
40_3.1.3.1 Guidelines for the Placement of Mats

Erratic operation and failures can result if certain precautions are not observed. The following guidelines apply to installation:

- **The protective layer of the mat should be watertight because a damp environment can alter the circuit impedance and lead to a false alarm;**
- **Small stones and other hard objects can become embedded into the surface layer of carpet and the pressure mat, causing a false alarm;**
- **The location of the mat should be evaluated in terms of visibility. Mats are generally between 5 - 10 mm thick. If they are observable under a carpet, then they can be easily bypassed.**

40_3.1.3.2 Defeat of Pressure Mat Sensors

Pressure mats can be bypassed easily, by:



- **Avoidance of mat, stepping over or around;**
- **Bridging the electronic detection circuit;**
- **Running a tack or staple through the mat, thereby causing a fault condition which will require it to be taken out of service.**

40_3.1.4 Trip Wire Contacts

LSS402: Trip wires in alarm systems

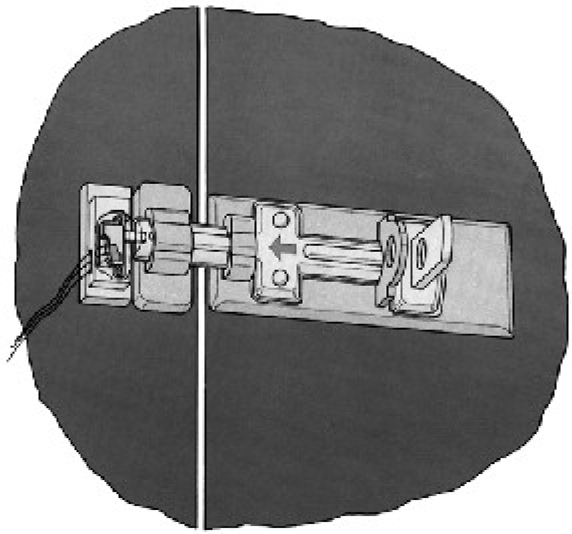
Trip wire or taut-wire sensors are another form of inexpensive contact device. They are comprised of a length of cord that is connected to the lever arm of a micro switch, together with a tightening device and deflection pulley. Sensors are used to monitor openings in walls, windows, doors, ventilation shafts, light domes, and skylights.

Typically, switch assemblies are designed to enclose the entire contact lever within a casing to protect it from tampering.

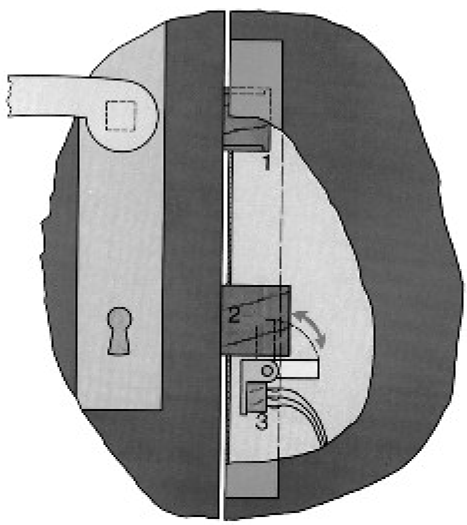
In operation, the wire maintains the contact lever in a neutral position. If there is any change in tension because of the cord being torn, cut, or pulled taut, the switch will be activated, causing an electrical change in the circuit.

40_3.1.4.1 Guidelines for the Installation of Trip Wires

- **Trip wires can monitor gross movement within an opening; they are not sensitive to small variations. Thus, when an intruder crawls through an air duct, the wire is sure to be disturbed. When the same intruder pushes a hand through the opening, there is much less likelihood of touching the wire. The sensor should be utilized to monitor spaces, based upon the likelihood of an intruder tripping the device;**
- **Suitable wires, threads, and cords should be utilized. These must not stretch when subjected to hot or humid conditions. The dimensions of long trip wires can change from extreme environmental factors;**
- **Deflection pulleys, terminal clamps and switches must be mounted so that they cannot be reached by an intruder. The entire switch and lid contacts should be incorporated within the housing to prevent bypass.**



40_3.1.4.2 Defeat of Trip Wire Systems



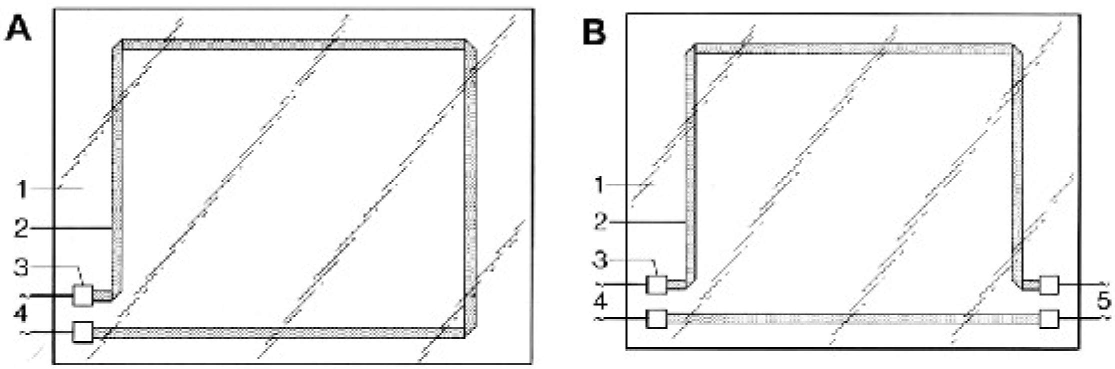
Trip wire detection systems can be easily defeated by:

- **Avoidance of the trip zone;**
- **Clamp and cut, thus bypassing the trip wire.**

40_3.1.5 Bolt Contacts

Bolt contacts supervise door and window latches to insure that they are fully extended or locked when an alarm is set. They consist of small switches that are activated by spring contact, lever, push button, or similar arrangement.

40_3.1.6 Foil and Embedded Wires in Glass or Screen



LSS401: Alarm foil

LSS401: Grid wires in alarm systems

LSS401: Ribbon switch material as a sensor

Electrically conductive lead foil or tape, ¼" to 3/8" wide, is used for the surveillance and monitoring of glass. Alarm foil is nothing more than a continuous wire through which an electric current is passed. Fine wires can also be embedded within a glass

panel or screens during manufacture.

Foil is affixed to the glass surface by self-adhesive bonding or with a thin coating of lacquer material. It is usually run completely around the pane or close to critical access points near the edge. Once it is bonded to the surface, any fracture of the pane will sever or tear the foil and interrupt circuit continuity.

Although foil has been utilized for at least seventy-five years, it is not particularly reliable. It is subject to fracture from expansion and contraction that is caused by changes in weather conditions. It can easily be sabotaged with a knife or sharp instrument and is prone to intermittent failure.

Foil is usually integrated with other trips within one loop. For example, foil and a magnetic door contact may be wired in series, so that a failure of either will result in loss of continuity.

The use of foil offers several advantages and disadvantages:

Advantages:

- **Visible deterrent;**
- **Low cost;**
- **Simple installation.**

Disadvantages:

- **Low rate of response: breakage or fracture of the glass may not necessarily tear the foil;**
- **High risk of sabotage, damage or bypass;**
- **Conspicuous and unattractive;**
- **Trips can be easily bridged.**

40_3.1.6.1 Defeat of Foil Glass-Break Material

Foil as a glass-break sensor is subject to compromise through a variety of techniques, including:

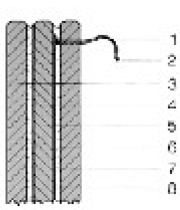
- **Avoidance;**
- **Cut and break. This technique requires that a circle be cut in the glass with a glass cutter. Use modelling clay to adhere to the glass prior to breaking it after being scribed by the diamond glass cutter. A wet newspaper can be used to hit the glass in order to dampen the sound;**
- **Use of an acid to physically remove glass within the internal perimeter of the foil protection;**
- **Use of adhesive material, such as duct tape, to protect the foil from fracture while the glass is broken;**
- **Bypass or jump-out of the circuit when the system is disarmed, or while the system is armed if the contacts that interconnect the foil can be accessed and bridged.**
- **Drill small lhole near take-offs and short circuit the contacts;**
- **Slice and break the foil during business hours to take the**

system out of service.

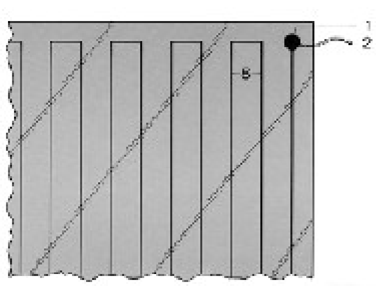
40_3.1.6.2 Defeat of Embedded Wires and Ribbon Switches

Wires embedded in screens and other materials are subject to bypass using a variety of techniques.

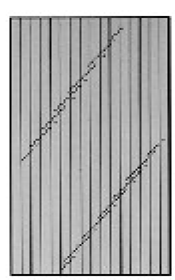
Grid Wires



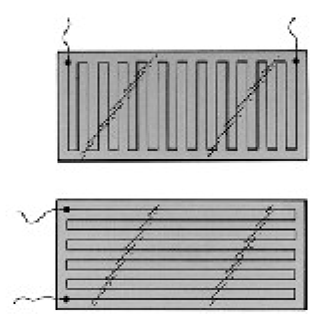
- Bypass or jump-out one or more of the grid wires while they are accessible;
- Avoidance of area that contains wires;
- Intentionally disable grid wire by damaging it;
- Folding back the grid wire mounting grill. This will only work if wire traps are not installed;



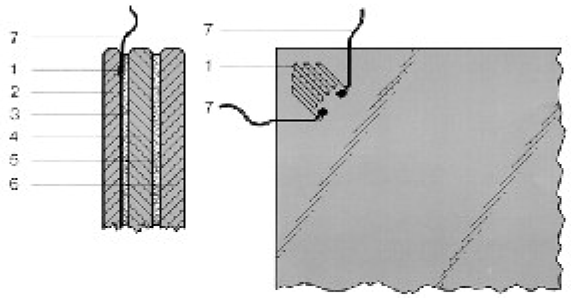
Screen



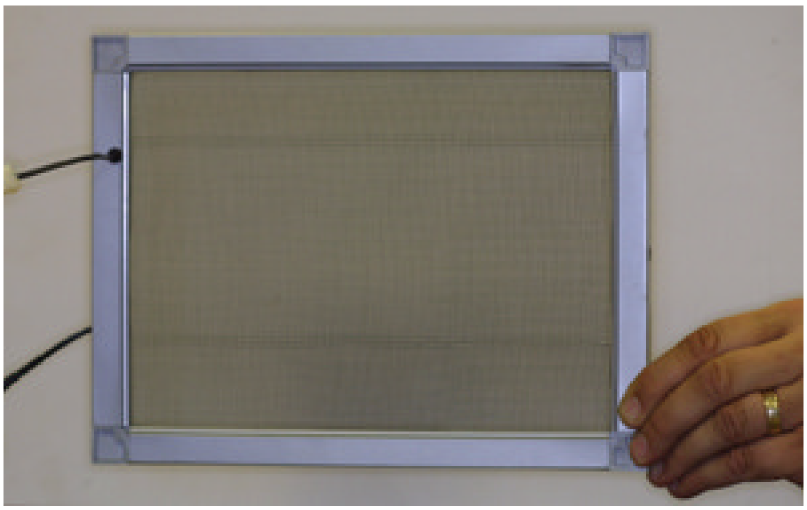
- Bypass or jump-out the alarm circuit while system is disarmed;
- Punch the screen and disable it, allowing intrusion during repair period or while the sensor is out of service;



Ribbon Switch



Avoidance, bridging over ribbon switch.



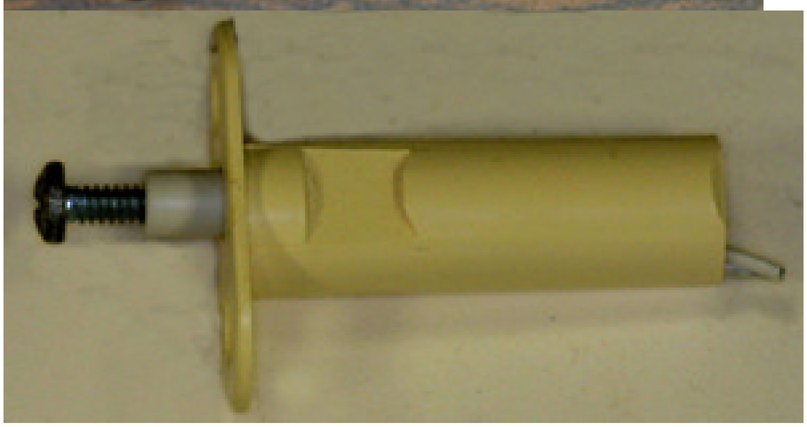


Figure LSS+4044 fine wires can be embedded in window screens during the manufacturing process. The photograph shows two individual wires that are interconnected to form a continuous circuit.

LSS401: Embedded screen wires

40_3.1.7 Foot Switches, Micro switches and Level-Switches

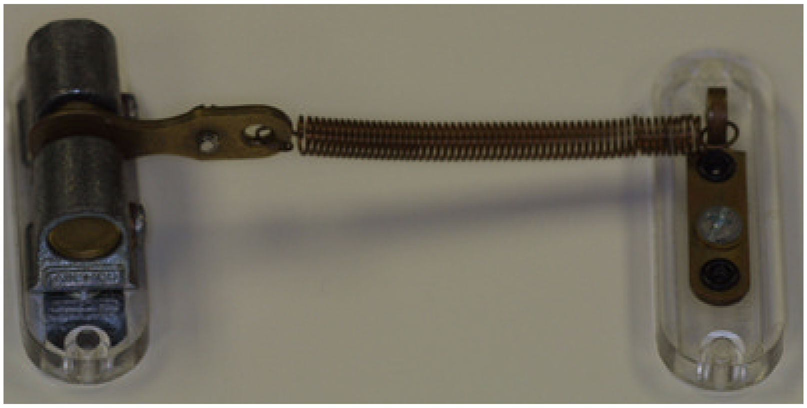

Figure LSS+4045 there are many different types of contact switches that depend upon a circuit being broken or completed.

Switches can be configured to sense a condition or status and change their electrical characteristics when a predefined event occurs. They can also be used for manual signaling of an event, such as a holdup. All switches are designed to complete (normally open) or break (normally closed) a circuit upon activation. Micro switches come in a variety of sizes, contact arrangements, and operating parameters. They can be installed in hard-to-reach areas and are quite effective as backup trip devices in drawers, on safes and safe locks, doors, cabinets and show cases.

Level-switches usually consist of a sealed glass tube that contains two metal contacts and a small amount of mercury. When tilted to a certain angle, the mercury will flow to or away from the contacts, completing or breaking the circuit. Mercury level-switches are well suited to specialized sensing applications. In one instance, the author placed a level-switch in a car that was supposed to be stripped in a salvage lot. When the auto was jacked up, the mercury flowed against the contacts to trigger a wireless alarm.

40_3.1.7.1 Defeat of Mercury Level Switches

Defeat of mercury level or tilt switches generally requires an avoidance of the device to which it is attached. Cutting and punching techniques will allow the circuit to be bypassed. Another popular method is to bypass the exposed contacts during a time when the system is disarmed. Spoofing will also defeat these switches.

40_3.1.8 Taut Wire

Figure LSS+4061 Taut wire systems can be defeated by spreading the wires, as shown, to create a gap for an intruder of up to fourteen inches.

Taut wire sensors, perhaps the most expensive fence sensing technology, are utilized with perimeter barbed wire fencing to detect changes in tension on the fence web through the integration of micro switches. Taut wire sensors do not detect vibration or stress; nor are they triggered by disturbance. The system is comprised of many micro switches that are a part of tensioned barbed wire placed at the top of a chain link fence, or actually installed as part of the fence. Installation is difficult and the system has a high maintenance requirement. The detectors are very reliable, provide a high probability of detection and very low false alarm rate. This type of sensor is employed at high security facilities.

The micro switch is constructed with a moveable center rod that is suspended within a metallic conductor. Normally, the rod stays within the center and does not make contact with the outer ring. The sensors are placed about six inches apart, vertically spaced and oriented inside of a tamper-proof enclosure that is mounted on a post near the middle of the zone to be protected. The enclosure runs the full height of the fence and protects the webbing and any outriggers. Individual strands of wire are tensioned and can be attached to the switch. Any change in tension caused by movement, climbing, spreading or cutting will cause the sensor rod to make contact with its outer ring. This will close the circuit and cause an alarm.

The switch housing is supported by a pliable, plastic support. The switch will always maintain a neutral position against gradual external force that is based upon settling movement or freeze-thaw cycles, thereby minimizing any affects upon sensitivity. Wind should not trip a sensor; a firm pull-force or exertion is required. Nor do small animals present a problem, because sensors are set for about a thirty-five pound force. Many sensors are placed on a fence line so that only one incident is required to trip the system. It is critical that regular tensioning maintenance be accomplished to insure the integrity of the system.

Sensors are mounted on top of a fence, or within the fence webbing itself. Outriggers may be added to protect top mounted sensors from climbers. Top mounted devices will not reliably detect cutting of the webbing in the lower fence. Thus, a vibration sensor should also be utilized to detect such cutting attempts or raising of the fence fabric to gain entry.

If the sensors are mounted as part of the fence fabric, strands of barbed wire within a single zone are supported at each fence post, (except the switch assembly post), by a supporting bar. The strands are loosely supported by the bars, allowing them to move freely, thereby activating the taut wire switches. If these two types of configurations are utilized, then an integrated barrier is presented to an intruder to detect cutting, climbing or raising of the fabric. High reliability, low FAR and low NAR will result.

A system can be enhanced by the installation of in-ground sensors within the protected fence line, thereby detecting tunneling or bridging. Volumetric motion detection such as microwave or infrared can be utilized along the perimeter. This, of course, depends upon the environment, terrain and length of the fence line. Video motion detection may also be utilized to increase the potential for detection.

The taut wire technology is extremely reliable and is less susceptible to environmental variables and small animals. It does have a high level of maintenance to insure proper functioning. If sensors are improperly tensioned, then unreliable detection will result. Medium to large animals that push the fence while grazing or nesting can be a problem and may result in false alarms.

Taut wire systems can be defeated by tunneling at mid-point between fence posts, or bridging the fence. Bridging can occur

anywhere along the fence line. Obviously, such an attempt would likely occur where there is a lack of observation.

40_3.1.8.1 Defeat of Taut Wire Systems

Taut wire systems can be defeated by:

- **Tunneling under the sensor. The optimum location is at the midpoint;**
- **Bridging, two-man or pole vaulting over the sensor coverage;**
- **Avoidance by attacking poor or non-existent sensor coverage at buildings and other obstructions. Look for gaps in coverage;**
- **Clamping the sensor wires to a stable frame, then cutting the sensor wires within the frame;**
- **Spreading the wires to create a gap through which an intruder can crawl;**
- **Alarm stacking.**

40_3.2 Sensors that Respond to Pressure Changes: Audio, Shock, and Vibration

An array of devices have been designed to respond to different forms of atmospheric pressure. These are employed to protect glass, walls, doors, floors, open ground, and enclosed spaces.

40_3.2.1 Noise Source

Audio sensors require some form of excitation at a threshold noise level to initiate an alarm. The units can be used in both large and small areas to signal the presence of intruders. They are particularly well suited for use in detecting break-ins and eliminating false alarms because most systems allow remote monitoring to validate the signal.

The sensor usually consists of a microphone, contact pickup, transducer, or some form of piezoelectric device to detect pressure changes. They can be designed to respond to a wide range of noise that has a broad frequency spectrum, or they can operate in a narrow frequency range to detect a very precise audio wave signature. Glass-break sensors, for example, are designed to respond to certain precise frequency bands.

Audio devices must be carefully placed and tested to insure immunity from false trips and for reliable operation. If they are set with a low threshold noise level or too broad of a response to a spectrum of frequencies, they can be triggered from heating and cooling equipment, cars, telephones, and other noises. If the threshold is too high, then an intruder may bypass the system. These sensors must be calibrated to avoid common background noises that can cause nuisance alarms.

40_3.2.2 Glass-Breakage Detectors

LSS402: Shock sensors for glass break detection

LSS402: Other types of shock detection sensors

LSS402: Glass break sensors and how they work

Glass windows constitute one of the weakest points of entry for any building and thus require constant surveillance. Panes can be monitored with conductive window foil or electronic breakage

sensors. There are three primary types of sensors: **acoustic**, **shock**, and **dual technology** (shock and acoustic). Coverage does not generally exceed one hundred square feet of glass surface. Newer devices are sensitive to the band of frequencies that are generated when glass is fractured or broken.

There are two versions of electronic detectors: **passive** and **active**. Although each of these are designed to function in a slightly different manner, they both can receive and interpret the wide spectrum of solid-body oscillations that are generated when the surface tension of the glass is altered. The sensors utilize a microphone to listen to specific frequency bands, with processor filters to reduce all unwanted frequencies and only allow certain ranges of sound to be received.

Older sensor technology relied upon the use of a form of mercury level-switch that was affixed to the glass. If oriented properly, any vibration or shock would cause the conductive liquid to touch a set of contacts to complete an electrical circuit. Modern sensors are located in a single unit that is mounted on an internal wall or ceiling, facing the glass surface to be protected.

Acoustic Sensors: These detect high frequencies that are typically created upon initial shattering impact of glass. Waves travel away from the point of impact to the outer edges of the glass.

Shock Sensors: This sensor "feels" the 5 KHz (nominal) shock wave that is generated upon the breaking of glass. There are two types of "shock" transducers: electric piezo, and non-electric piezo. In the non-electric design, the crystal substance bends when it is pressured by the shock wave, and has a very low false alarm rate.

Dual Technology Acoustic/Shock Sensors: This technology links acoustic and shock devices to operate in complementary fashion to provide for a low FAR. Generally, the two sensors are packaged together and are ANDED electronically. A microphone detects signature frequencies and if they match glass-breaking characteristics, then the output is fed to the AND gate which is also connected to the shock detector. If there is a coincidence of signals, then an alarm is sent to the central processor. The dual technology sensors have a very low incidence of false alarms caused by background noise, RFI, and ambient noise created by telephones and office machines.

Acoustic devices are often mounted on the window, window frame, wall or ceiling. If they are placed on the glass, it should be located in the corner, approximately two inches from the edge of the frame. Glass mounting is not recommended because of temperature variables that can affect adhesive materials. Such materials should be able to withstand long exposure to heat and cold, as well as condensation. Remember, glass can reach 150°F in the summer, and -30°F in the winter.

If mounted on the wall or ceiling, the sensor should be installed opposite the window. Supplementary devices such as magnetic trips and microwave should always be used with glass break technology to insure reliability of operation. If microwave or infrared is employed, it should be positioned so as to look toward the window.

There are several factors that can cause unreliable or erratic operation:

- **Mismatching of sensor range capacity to the window size;**
- **Poor location of sensor, causing it to be out of range;**
- **Failure to account for the acoustic characteristics of the room. This can include "soft" rooms with carpet or drapery that absorb vibration, or attempting to make a "hard" area softer by adding wooden shutters, blinds, draperies, or rugs after the sensor has been installed and optimized. All windows should be checked for cracks prior to installation to insure that a valid frequency is generated upon fracture.**
- **Improper calibration or installation;**
- **RF interference;**
- **Sharp impact noise;**
- **Improper application or placement of the sensor;**
- **Background noise.**

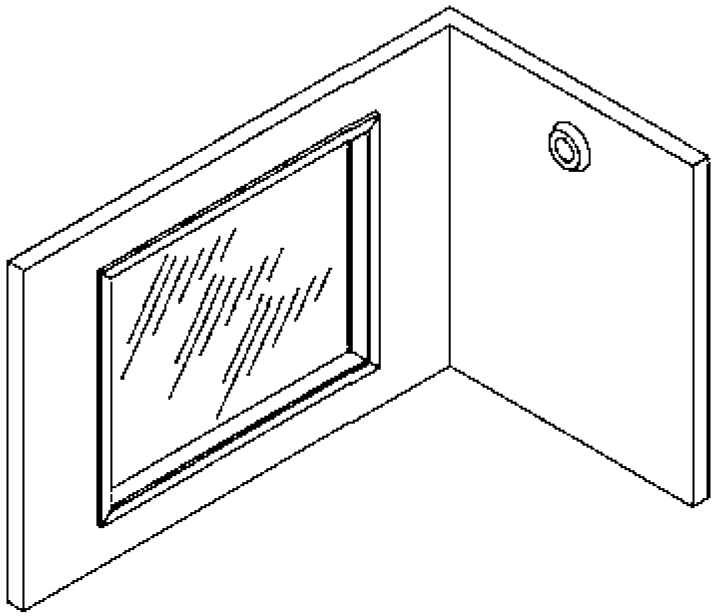

Figure LSS+4002 Typical glass-break sensor installation

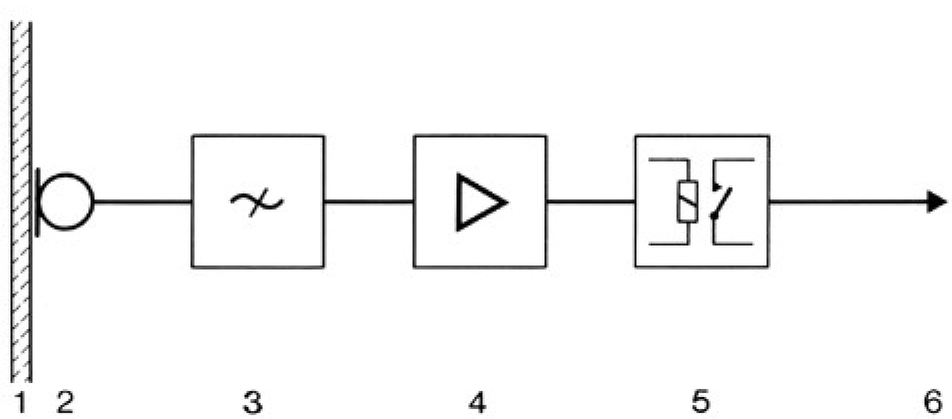
40_3.2.2.0 Defeat Techniques for Glass Break Sensors

Sensors can be defeated by a variety of measures:

- **Detaching or cutting of an opening in the window;**
- **Removal of the window pane with or without a sensor attached to it;**
- **Distortion of the break frequency by muffling or masking the sound of breaking glass.**



Generally, all glass break sensors can be bypassed by any entry means that does not involve the breaking of glass to which a detector is attached or that is within close proximity (audio sensors). In other words, avoidance of the detection systems or mode of attack that does not disturb the protected surface can bypass the sensor. These devices can also be circumvented by methodically cutting the glass without involving actual fracture. Passive audio systems can be defeated by the utilization of sound and shock absorbing materials that dampens the signature of breaking of the glass. Additionally, any blocking or muffling of the transducer or microphone will have the same affect.

Inertia sensors (Window Bug) that rely upon the detection of a

shock can be bypassed if the area to which they are attached is not disturbed. Sensors that rely upon pulse counts that correlate to shock, and which have high settings as their threshold can be circumvented by explosions, because such shock does not trigger threshold levels. Slow penetration, spoofing, and alarm stacking can also be utilized as techniques to bypass such devices.

40_3.2.2.1 Passive Glass-Breakage Sensors

A passive detector utilizes a piezoceramic converter (microphone) in conjunction with a frequency filter, amplifier, and evaluation switch or microprocessor. These components will translate information from the converter, selectively filter it, and evaluate the resulting data. Normal ambient noise is ignored, and only oscillations that are generated when glass is broken are fed to the processor. Glass-breakage sensors can monitor a radius of up to two meters (six feet) of glass.

As should be expected, the use of such detectors offers advantages and disadvantages.

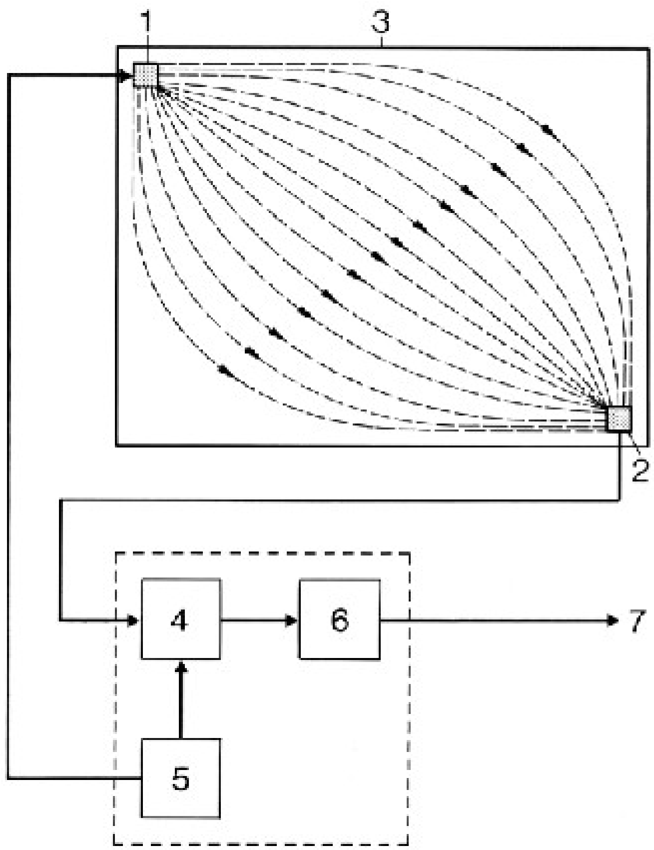
Advantages

- **Detectors are packaged in a small, inconspicuous shape;**
- **Relatively inexpensive;**
- **More reliable than vibration contacts.**

Disadvantages:

- **Detectors are not supervised: they only respond to**

oscillations and bands of frequencies that are generated when the glass is broken. Inoperative sensors cannot be detected;



- **There is no way of knowing if a detector will properly respond to a break;**
- **The propagation of frequencies is dependent upon at least three critical factors:**
  - **Type of glass;**
  - **Type of frame and mounting of glass;**
  - **Temperature.**
- **The sensitivity of the detector is proportional to the risk of false alarm;**
- **The sensor may receive validated information from external effects that do not result in breakage. Certain objects can generate solid-body oscillations within the valid band of frequencies that trigger a false alarm;**
- **There is a significant risk of sabotage from the outside surface of the glass;**
- **A detector can become loose if the adhesive surface fails. Such a detector is usually impossible to monitor;**
- **Detectors should only be affixed to insulation glass or second (interior) panes;**
- **Sensors should only be used on surfaces that are not directly linked to outside panes due to the potential for false alarms;**
- **Detectors cannot be used on multi-pane laminated glass or single-pane security glass;**
- **Detectors cannot be used on surfaces with posters, plastic, or anti-splinter foils because their operation is unreliable;**
- **Detectors should be used in conjunction with other monitoring devices that cover the same area;**
- **Detectors must be affixed to the glass surface and checked at periodic intervals.**

40_3.2.2.2 Active Glass-Breakage Sensors

These devices utilize a transmitter, receiver and processor to evaluate signals transmitted **across** the glass. The transmitter and receiver may be located in single or separate housings. The

purpose of the processor is to constantly evaluate the signal that is transmitted, using the glass as a medium.

A transducer that emits ultrasonic signals is attached to the glass. The band of frequencies is spread over the complete surface of the pane and is used to excite the piezoceramic converter within the receiver. Any fractures, cracks, or holes in the glass will alter or interrupt the transmission characteristics. These changes are sensed by the evaluation unit.

There are several advantages to the use of active devices. These include:

Advantages

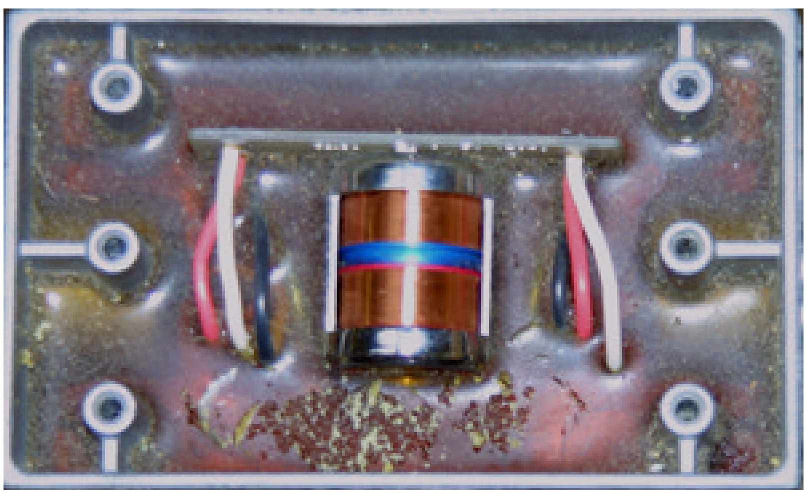
- **Active sensors are supervised, in that a failure in the transmitter or detachment of a sensor will result in an alarm;**

- **Sensors are very reliable in their response to fractures and breaks;**
- **Sensors are resistant to sabotage and exclusion of artifacts;**
- **Active sensors can monitor larger areas of glass than the passive sensors.**

Disadvantages

- **Although active detectors can be affixed to multi-pane laminated glass, the transmission characteristics of such materials may preclude reliable operation. It is necessary that measurements be made to determine attenuation of signals across the surface;**
- **Glass-breakage detectors, either active or passive, should not be used on plastic surfaces, due to the difference in propagation characteristics.**

40_3.2.3 Seismic Detectors



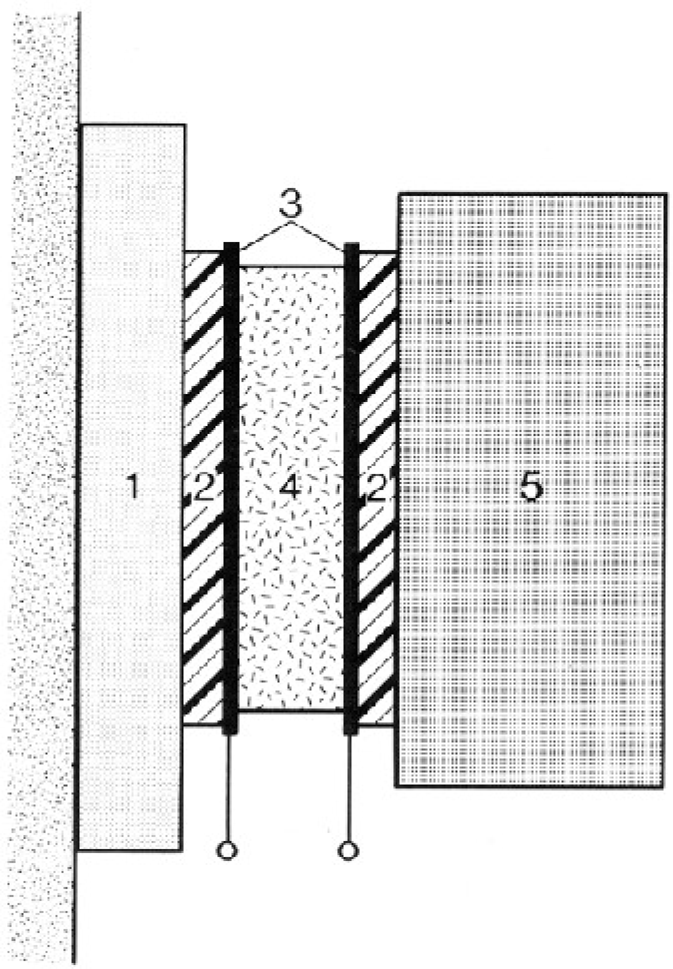


Figure LSS+4046 A seismic detector senses shock, vibration, or pressure in three planes. Generally, a cylinder, ball, or other object is suspended within a cylinder or enclosure. Any movement will cause it to make contact with its outer barrier.

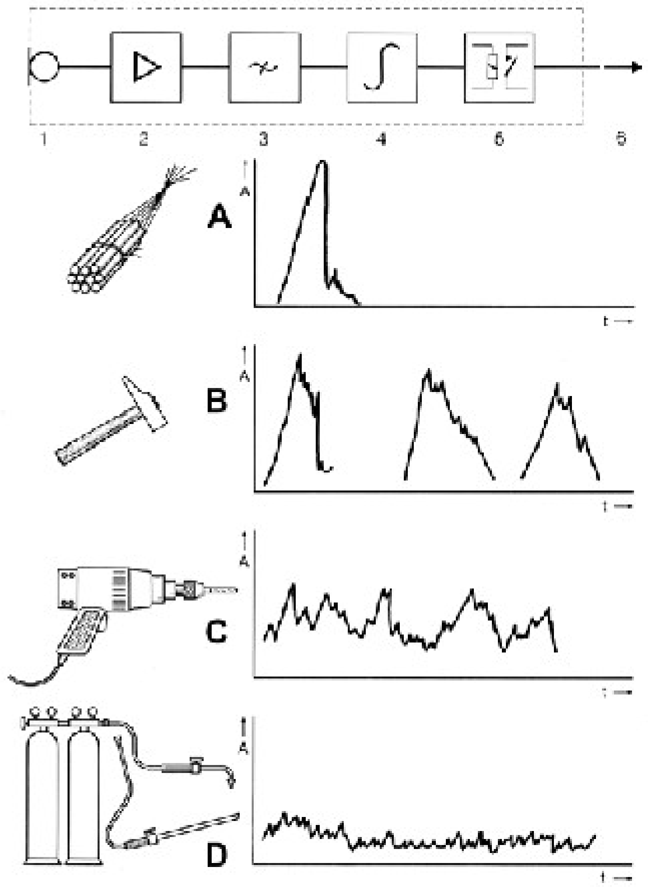
Seismic detectors are particularly effective for monitoring safes and strong rooms, because sensors can be permanently mounted on walls, floors, ceilings, and doors, or in the ground. They may

also be temporarily placed in certain locations to provide additional protection. A seismic detector is classified as a passive device. The range of a sensor is dependent upon many factors. These include:

- **Design, construction, and materials of the structure to be monitored;**
- **Joints and cracks can reduce the overall effectiveness of a sensor;**
- **Propagation characteristics of sound waves in the monitored materials will determine placement and number of sensors.**



Seismic detectors are sensitive to a broad range of events.

Sensors that are mounted internally are responsive to vibrations from power tools, mechanical striking, drilling, and forced-entry techniques that create shock waves. They are impervious to environmental interference. Internal detectors may be attached to night safes and cash dispensers, although normal noise and vibration may cause false alarms. They are better suited to large safes and vaults. Seismic sensors that are mounted in the ground may produce nuisance alarms if installed too near fences, power poles, guy wires, or roads where vehicles generate heavy ground vibration.

40_3.2.3.1 System Components

Detection systems are comprised of a piezoelectric microphone, amplifier, frequency filter, integrator, processor, and output interface. The use of sophisticated processors can reduce the likelihood of false alarms caused by ambient noise, shock, and vibration. A microphone is usually constructed with a ceramic element between two metal foils and mounted directly on a monitored object. Its function is to detect sound waves in solid bodies without being sensitive to ambient noise.

Seismic sensors are not supervised. Therefore, remote testing must be utilized to monitor system performance, components, and the mounting integrity of the detector. Sensors cannot send a signal in case of failure.

40_3.2.3.2 Guidelines for Installation

- **Detectors should be mounted on inside surfaces of rooms under surveillance. This will protect the system against sabotage;**
- **Placement of detectors must afford complete coverage without dead zones;**
- **Remove existing interior furnishings prior to installation;**
- **Individual sensors should be mounted on each door;**
- **Sensors should be placed close to or over the lock or keyhole in a strong room.**

40_3.2.3.3 Defeat of Vibration and Audio Discrimination Sensors: General Issues

Vibration sensors are subject to a number of defeat techniques. These include;

- **Avoidance by using an entry method which does nor require contact with the protected area;**
- **Muffling or dampening of the low frequency energy;**
- **Explosive penetration using limited force;**
- **Slow penetration to avoid meeting the threshhold of pulse count and accumulator circuits;**
- **Spoofing and alarm stacking.**

Audio discriminator sensors can be defeated by:

- **Avoidance, muffling the noises associated with forced entry;**
- **Substitution of taped normal background noise to spoof the sensor;**
- **Bypass the sensor circuit while the system is disarmed;**
- **Mask the sensor microphone.**

40_3.2.3A Fence Vibration Sensor

LSS401: Fence alarm system

LSS403: Shock sensors utilized to protect fences

Figure LSS+4047 There are several different sensor technologies that are utilizes to protect fences, including strain, vibration, and noise detection.

Higher frequency disturbances and greater amplitudes of events associated with sawing, cutting, climbing or lifting of the fence fabric generate mechanical vibrations or stress that can be differentiated from normal changes that occur from routine environmental activity. Fence vibration detectors are mounted directly on the fence webbing to detect these vibrations through electro-mechanical or piezoelectric transducers. The frequency characteristics for typical intrusion-type activity is filtered and processed and matched with known signatures.

Electro-mechanical sensors incorporate a signal processor that has a pulse accumulation circuit that recognizes momentary contact openings of electromechanical switches. Piezoelectric sensors have a signal processor that responds to the amplitude, duration, and frequency of the transmitted signal.

The Electromechanical Sensors use either **mechanical inertia switches** or **mercury switches** to detect fence vibration or stress. Mechanical-inertia switches consist of a vibration sensitive mass that rests on two or three electric contacts that create a closed-circuit. The mass is moveable and reacts to minute changes in the vibrations (frequencies) that are generated in the fence

during a penetration attempt. These vibrations disturb the mass, causing it to be moved or separated from one or more of the contact points, thereby momentarily opening the circuit and creating an alarm. In some sensor designs, the mass is intentionally constrained or restricted by an internal guide in order to ensure that only a significant vibration will cause movement, break the circuit and activate the alarm.

Mercury switches, as described elsewhere in this chapter, consist of a glass vial containing a small amount of mercury with a set of normally "open" electrical contacts that are located in close proximity, but not touching or immersed in the mercury. An impact or disturbance of the fence fabric causes the mercury to be displaced from its normal resting position. This will result in a momentary contact between the mercury (a conductor), and the electrical contacts.

A piezoelectric sensor is much like the old crystal microphone: it has the ability to convert the mechanical impact forces into an analog electrical output. Its output distinguishes it from the electro-mechanical sensor which can only generate an open or closed signal. The piezoelectric detector's output varies in proportion to the amplitude of the event. The signal is processed and filtered to match against known signatures.

For optimum performance, fence vibration sensors are mounted directly to the fence fabric. Each detector is connected in series along the fence with a common cable to form a single zone of protection. A zone length can have a recommended range of up to 300 feet. The vibration sensors are the most economical in their class and the easiest to install. They have a high probability of detecting intrusion and work well in protecting properly installed and maintained fence lines. Additional protection against tunneling and careful climbing can be achieved with the installation of in-ground vibration (seismic) sensors that are placed adjacent to the perimeter fence (in a controlled zone within the overall protected area).

Fine tuning of these systems is enhanced by adding information to the processor about current weather conditions to increase or decrease the detection sensitivity. A weather sensor station can be mounted on the fence line to feed information to a field processor, which then adjusts vibration alarm sensitivity, based upon weather data input.

Additional reliability can be obtained by placing the appropriate

volumetric motion detection devices (microwave, active infrared) along the perimeter of the fence. Which volumetric device to employ will depend upon the environment, terrain, and length of the fence line.

Vibration detectors are designed to sense many different variations and thus, can become confused and subject to false indication of an alarm status. In order to reduce the FAR, a pulse count accumulator may be added to the circuitry. This will require a threshold of pulses generated by individual trips in order to show a valid alarm status. A pulse is a measurable amount of activity (amplitude) based upon stress or vibration to the fence, caused by cutting or climbing.

Reliable operation of sensors is based upon their proper installation, and utilization on quality fencing material. Poor quality fencing with loose webbing can create "noise" from flexing, sagging or swaying that translates to false alarms and unreliable detection. Difficult weather conditions can add to the problem. Shrubbery, tree branches, and animals can also cause the fence to vibrate, thus triggering sensors. If fences are located in areas of high wind or numerous animal interactions, vibration sensors are not recommended. Remember, fence vibration detectors are designed for one specific function: to detect vibration. If they are located in areas with inherently high vibration, such as from railroad yards or tracks, construction sites, or heavy highway traffic, then they are not a suitable means of protection.

These detectors can be defeated by bridging the fence and thereby avoiding contact altogether. Use of overhanging trees and structures can assist in this regard, as can cars, trucks or other platforms. Deep tunneling is also a preferred method. Fence corners can be a particularly difficult problem because of the increased bracing of the fence posts and more solid foundations typically used at a corner or turn-point. Detectors will be less sensitive to input at these points because of the damping effect of the corner structures.

40_3.2.3A.1 Defeating Fence Vibration Sensors

Figure LSS+4056 A fence vibration sensor will trip from the use of hooks or a climber. Courtesy of DOE Office of Security and Safety Performance Assurance

Electromechanical/vibration fence sensors can be defeated in a number of ways. These include:

- **Tunneling under the fence or barrier;**
- **Bridging, two-man or pole vaulting over the detection zone;**
- **Use a vehicle that is positioned next to the fence as a platform for jumping or bridging over the barrier;**
- **Injection of a dampening material into the sensor;**
- **Removal of the sensor from the fence, thereby preventing contact with the barrier;**
- **Alarm stacking.**

VIBRATION FENCE SENSOR

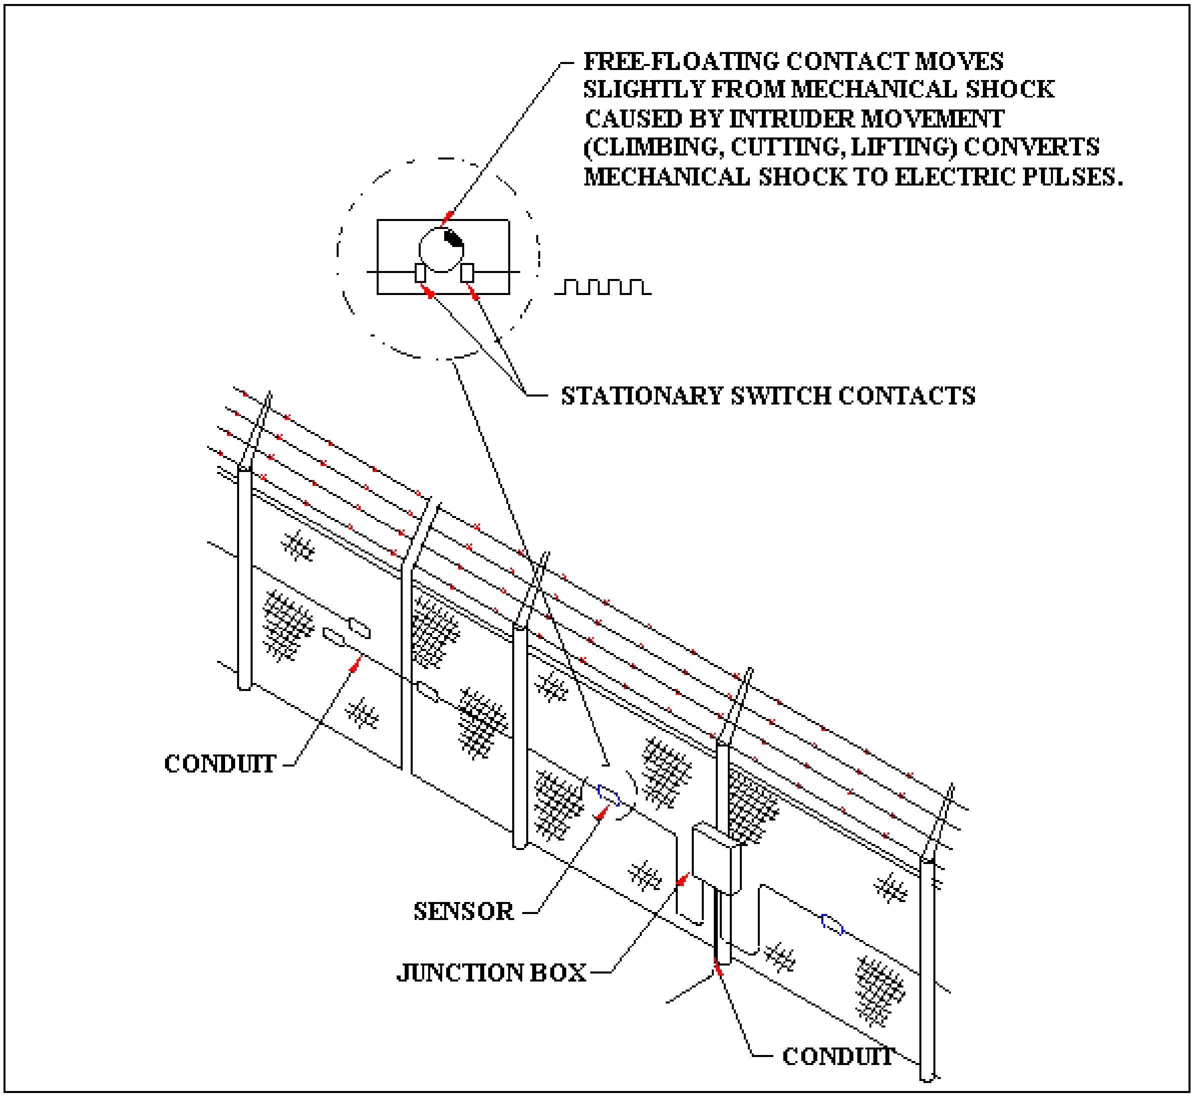


Figure LSS+4020 Vibration fence sensor

40_3.2.3B Strain Sensitive Cable

Strain sensitive cables are line sensors that use electric energy as both a transmission and detection medium. They maintain constant sensitivity across the entire length of the circuit. Supervision against cutting, short circuit or removal of wire is maintained along the cable from the processor to an end-of-line resistor.

In operation, the cable is mounted on the fence. When it is subjected to mechanical vibrations that are caused by attempts to cut, climb or raise the fence fabric, electrical signals will be induced that are proportional (analog) to the exerted force, from which a signature analysis can be performed by the processor. The cable acts like a microphone.

There are two basic categories of strain sensitive cables: **coaxial** and **magnetic polymer**. The coaxial cable is a specially sensitized conductor in which the center conductor carries a permanent electrostatic charge.

The "coaxial" cable that is sensitive to strain related stresses conducts a permanent electric charge along its center conductor, which is then insulated and covered with a braided shield. The cable is designed for outside use, being coated with a UV resistant material to withstand direct sunlight. In operation, the cable is constantly electrically biased. When stresses occur based upon vibration, electrical signals are produced in proportion to the force exerted, and analyzed for specific signatures. The cable can act as a contact microphone to allow human analysis to evaluate a processor decision on alarm status. These detectors are extremely sensitive to EMI (electro-magnetic interference) caused by power substations and to radio frequency interference (RFI). Care should thus be exercised in the location of such sensors.

The magnetic polymer utilizes two semicircular magnetic polymer conductors that are separated by an air gap containing two noninsulated wires, resembling the design of a capacitor. Strain sensitive sensors function as poles of a linear magnet; two semicircular magnetic polymer conductors are paired and separated by an air gap. Two insulated wires run between the polymers. Parallel to these wires are two noninsulated wires free to move in the air gap between the magnetic field created by the polymer conductors.

Vibration and stress can cause the noninsulated wires (active conductors) to move within the air gap, generating minute electric signals to the signal processor. Smart processors are available that "learn" from normal fence fluctuations and revise the data, thus minimizing false alarms and enhancing the performance of the system.

The "magnetic polymers" multiple conductors form a symmetrical and balanced pair configuration that makes this type of sensor

virtually impervious to both EMI and RFI. Its low impedance creates higher signal-to-noise ratios that can offer more finite signal processing. The sensor also functions as a transducer microphone that can provide a "listening" function for human override and analysis.

Cables should be installed using ties halfway between the bottom and the top of the fence. Also, stainless steel wire ties, as opposed to plastic ties, should be utilized to prevent silent removal by burning or ultraviolet decay. Sensor zone lengths can be extended to 1,000 feet, with the requirement of a quality fence and stable installation of both the sensors and fence line. Supplemental protection should be implemented. Volumetric motion detection devices, video motion detection, and electric field detectors can add reliability and redundancy to a system.

Nuisance and false alarms can be caused can be caused by severe weather conditions and animals. This problem can be minimized with proper calibration and installation, and the use of a listening device to analyze signals. Countermeasures for this type of sensor are the same as for other fence line protection systems discussed above.

40_3.2.3B.1 Defeat of Strain Sensitive Cables

Strain sensitive cable sensors can be defeated by a variety of methods, including:

- **Tunneling or trenching under the sensor. An alarm will not be initiated unless there is contact with the fence;**
- **Pole or two-man vaulting or bridging;**
Avoidance of protected area;
- **Bridging of protected area with board, ladder, or other structure;**
- **Bypass the sensor circuit while the system is disarmed;**
- **Creating small holes in the cable jacket (with pins or other sharp object) to allow water or moisture to enter and desensitize the cable. This is a long-term method of defeat and will require several days or months to accomplish;**
- **Remove the cable from the fence by gently severing or melting the wire ties, and then lowering the cable to the ground. This technique is accomplished over a period of time and takes advantage of poor fence inspections;**
- **Alarm stacking.**

40_3.2.3C Fiber Optic Fence Sensors

LSS403: Fiber optic fence sensors

Fiber optic sensors use light rather than electricity as a carrier for transmission and detection. Fiber optic cable can be easily incorporation into existing fences, or it can be used as stand alone fencing.

The construction of an optical fiber is a thin strong strand of glass or other optical medium, often referred to as a wave guide because the optical fiber guides light waves from a light source to a detector at the terminating end of the fiber. Pulses of light replace their equivalent electrical impulses in a wire. There are many advantages over other conductive medium, including:

- **Immunity to electrical interference and Electrical Magnetic Interference (EMI) disruption;**
- **Intrinsically safe;**
- **High reliability due to the stability of the electronics;**
- **Greater transmission distances as compared to metallic carriers. Light has a very low attenuation factor through glass. There is approximately a 3db light loss (absorption) per kilometer.**

Based upon the signal processor, there are two primary types of fiber optic sensors: **continuity** and **microbending.**

The fiber optic continuity sensor requires the glass strand to be broken in order to initiate an alarm, and can be compared to a closed loop device. The transmission of light is monitored from source to receiver; a break in energy is detected as an alarm. A composite strand sensor can be combined with a continuity sensor contained within a barbed steel tape. An installed system is similar to a taut wire installation; the difference being that it does not require the mechanical activation of switches. This makes preventive maintenance and repair of the system more affordable. The tape can be used as a free standing fence or can be applied to an existing fence, or attached to walls and buildings.

The fiber optic microbending detects alterations in the light

pattern caused by movement of the cable, generally as the result of bending or distorted to affect the wave guide characteristics of transmission. This correlates to stress on the fence webbing. The cable is actually the sensor when it is integrated into the fence fabric. An LED provides the light source. A threshold of change in the transmission of light will provide an alarm.

In order to insure maximum reliability, sensors should be mounted directly on, or woven into, the fence fabric. As with all other fence line detectors, a quality and stable installation of the fence is necessary for reliable detection. The fence should be free of rattles, clanks, knocking sounds, and vibration and stress activity. This will maximizes line sensor quality. If there is significant ambient noise on or around the fence, the lower the sensitivity setting will be for the system, with the correlation that it will be less likely to detect an intruder. Supplementary sensors, such as in-ground, can add another level of protection. Volumetric sensors and video motion detection can also increase redundancy and security.

Unreliable detection will result from poor fence quality (stability). Loose fence fabric and poor stability cause the sensitivity setting for the fence to be calibrated lower than preferred, making the system less likely to detect an intruder. When properly installed on a good quality, stable fence or installed in a taut wire-like configuration, the system is very stable and reliable.

Nuisance and false alarms can be caused by extreme weather turbulence that damages or disturbs the fiber, or by animals. The system will not respond or be affected by transient voltage or lightning strikes, but can be affected by RFI, EMI, and extreme changes in temperature and blowing debris.

40_3.2.3C.1 Defeating Fiber Optic In-Ground or Fence Mounted Systems

Fence protection systems that utilize fiber optic sensors, either mounted on the fence itself or in the ground, can be defeated. Techniques include:

- **Bridging;**
- **Tunneling under a barrier-mounted system;**
- **Careful and assisted climbing over a rigid turn or corner points in a coverage zone. In such cases, sensor coverage will**

generally not be as sensitive on a fence-mounted systems;
- **Alarm stacking.**

FIBER OPTIC CABLE

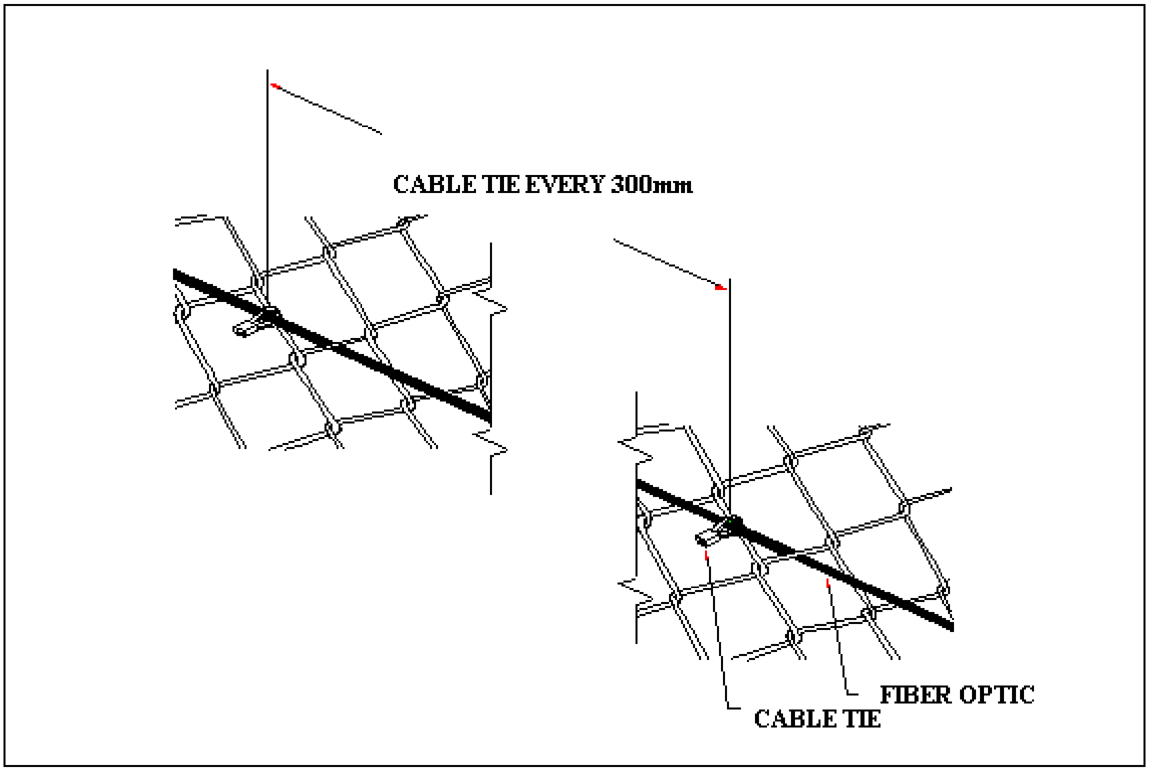

Figure LSS+4026 Fiber optic cable

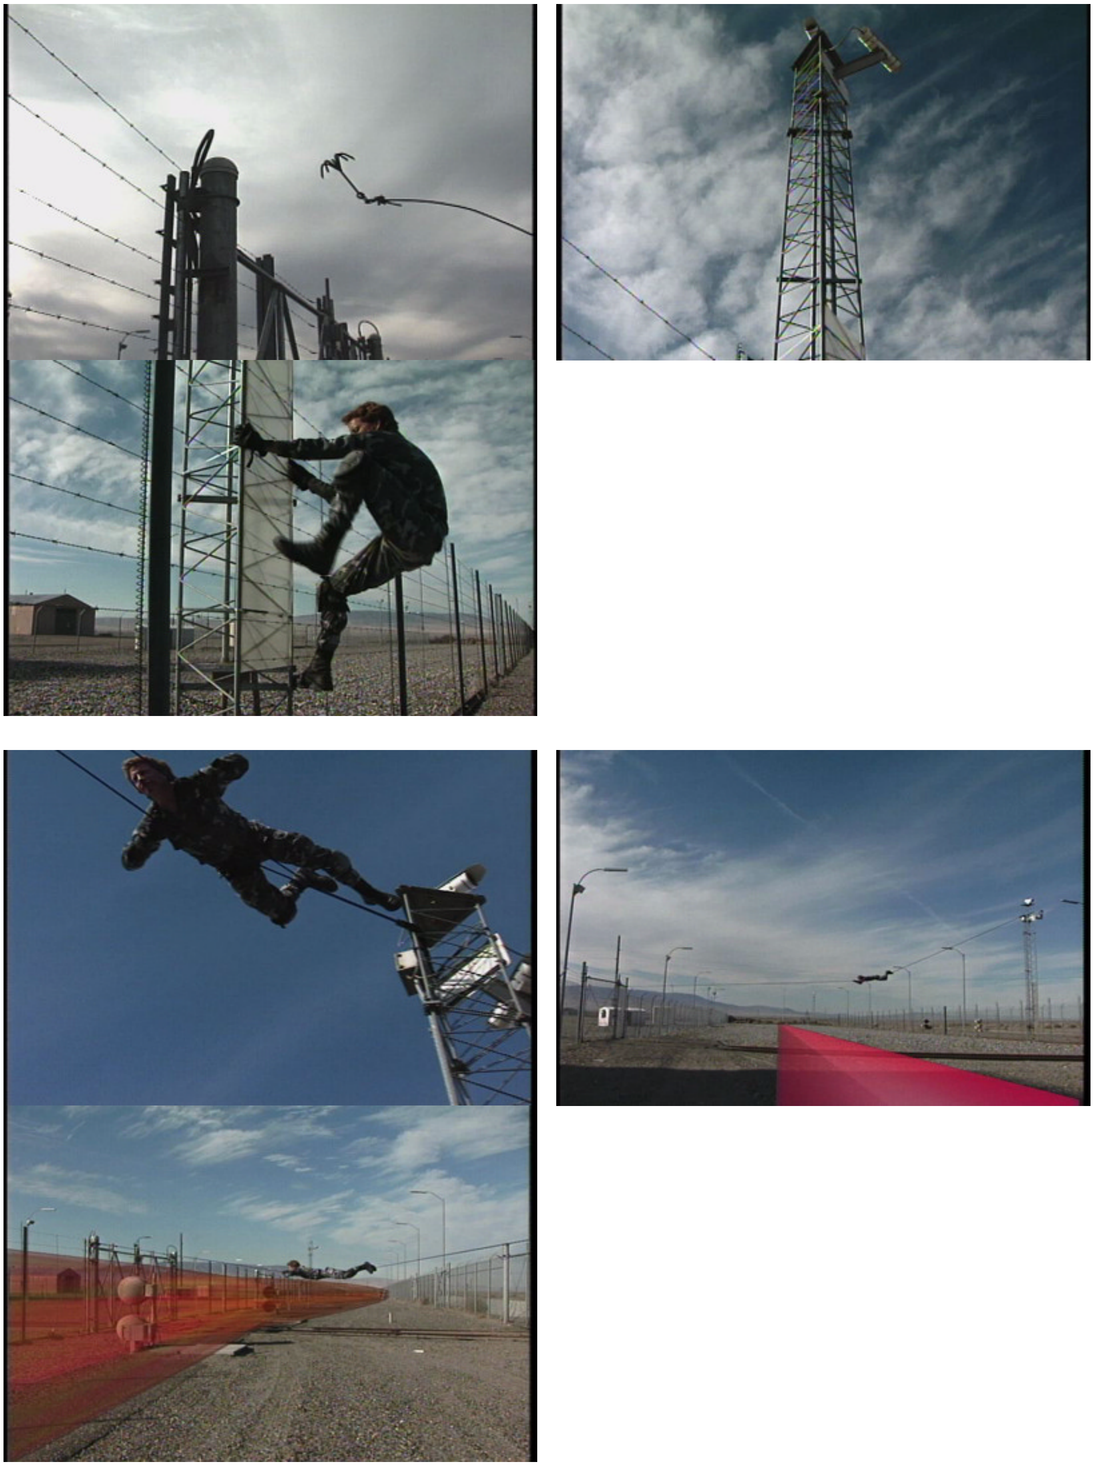
40_3.2.3D Defeat Techniques for Perimeter Fence Lines

LSS403: DOE on perimeter sensors and their defeat

Perimeter fence lines can provide the first barrier to entry by an intruder, although other sensors may detect a violation before the fence is reached. There are four recognized techniques for compromising fence lines and other perimeter sensors: **crawling, clinmbing, jumping, and bridging.**

40_3.2.3D.1 Bridging



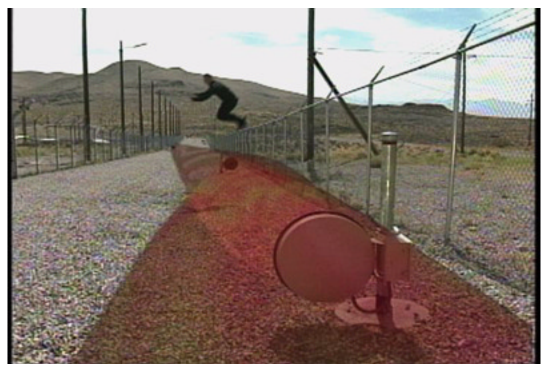


Figure LSS+4062 Bridging of the sensor is a popular method of bypass. In these photographs,
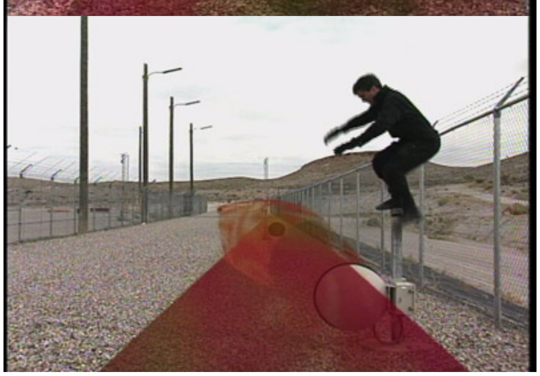
simulation of a microwave path is shown in rad. The intruder is able to bridge across and

over the RF pattern, avoiding detection. Courtesy of DOE Office of Security and Safety Performance Assurance

40_3.2.3D.2 Jumping



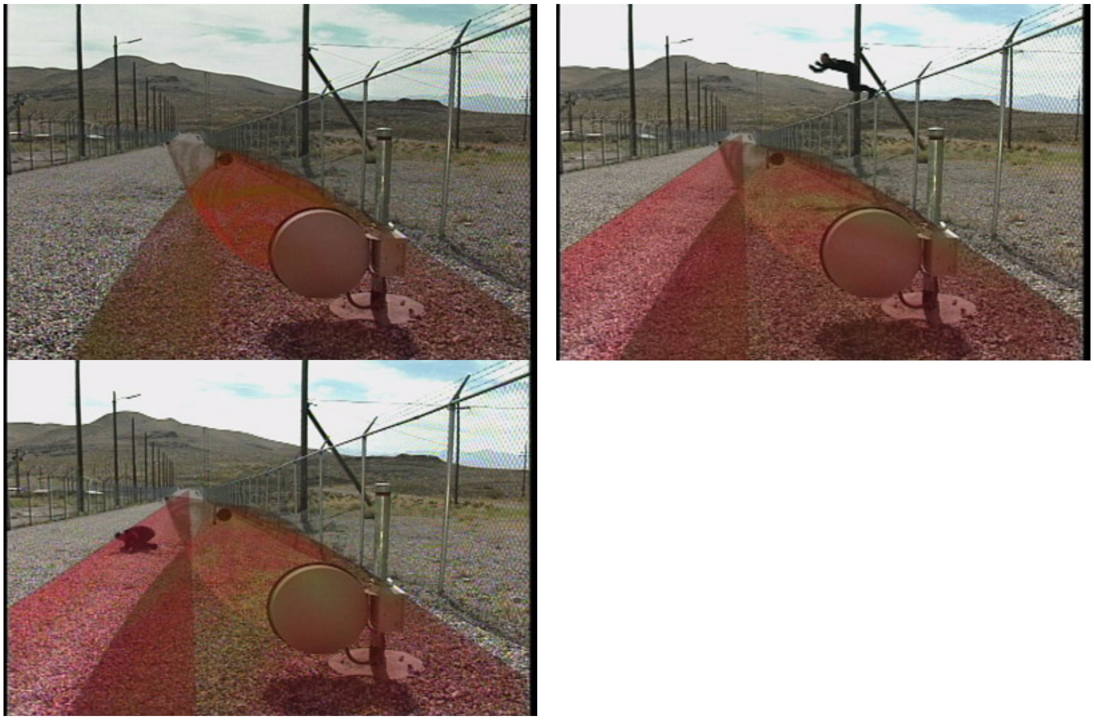


Figure LSS+4063 An intruder is able to successfully jump over a monostatic microwave pattern,
but not for a bistatic system. Note the overlapping coverage that catches the inruder. Courtesy of DOE
Office of Security and Safety Performance Assurance

40_3.2.3D.3 Climbing

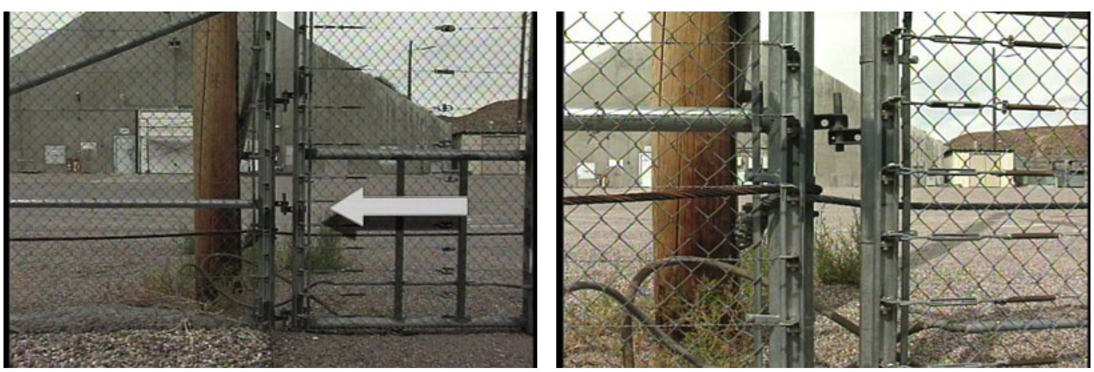

Figure LSS+4064 A climber is able to scale a fence by gaining a foothold. This is poor design.

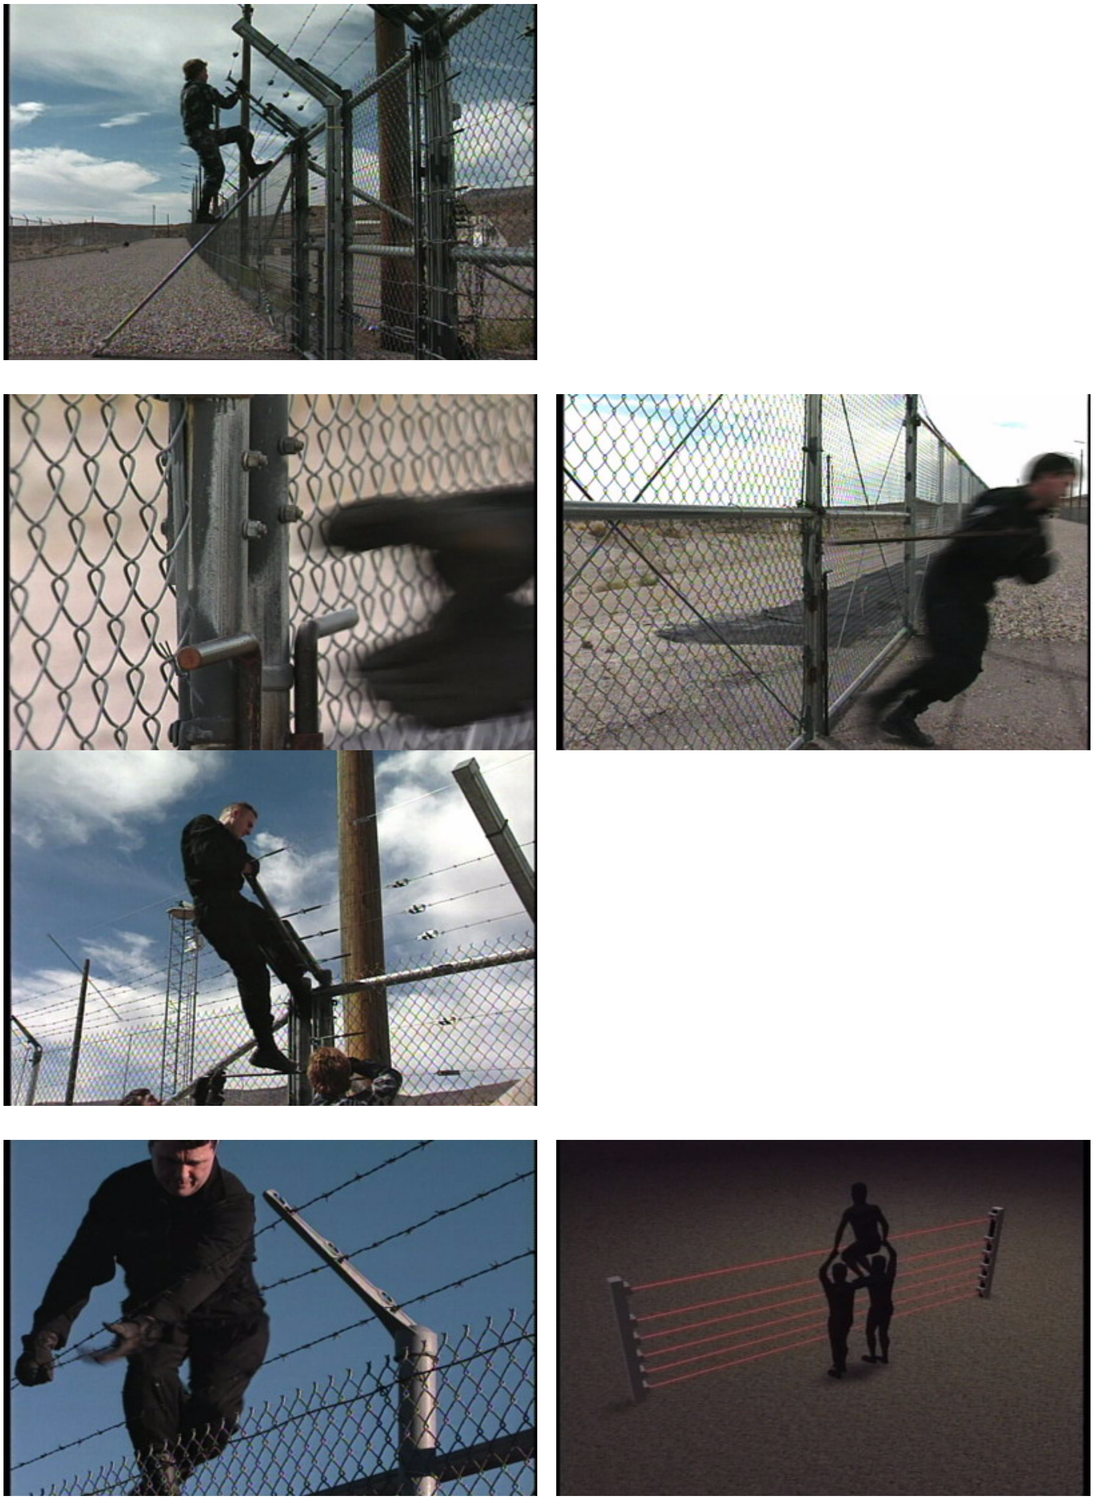

Figure LSS+4065 Intruders are able to penetrate a facility using a variety of techniques. Materials are removed from the fence and used as an aid to the climbing process. The top of the fence line can be used for support. A

three-man climb can be accomplished to jump over barriers, such as the photoelectric beams, as shown. Boards may also be used as ladders to scale the fence. Courtesy of DOE Office of Security and Safety Performance Assurance

40_3.2.3D.4 Crawling

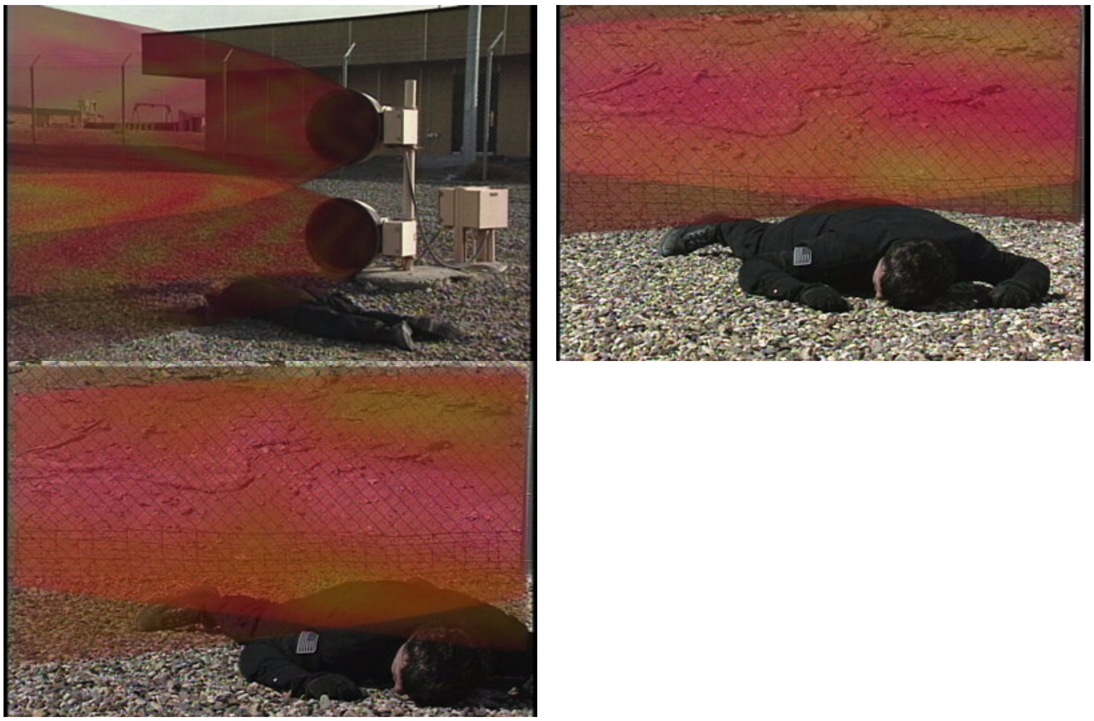

Figure LSS+4066 An intruder may crawl under or through sensor coverage. In the photograph, the intruder is able to circumvent a bistatic microwave system by passing under the RF field at an extremely slow pace. Courtesy of DOE Office of Security and Safety Performance Assurance

40_3.2.4 Wall Vibration

Vibration sensors are designed to be mounted on walls, ceilings and floors and intended to detect mechanical vibrations caused by chopping, sawing, drilling, ramming or any type of physical intrusion attempt that would penetrate the structure on which it is mounted. See the discussion in section 40_3.2.3 above.

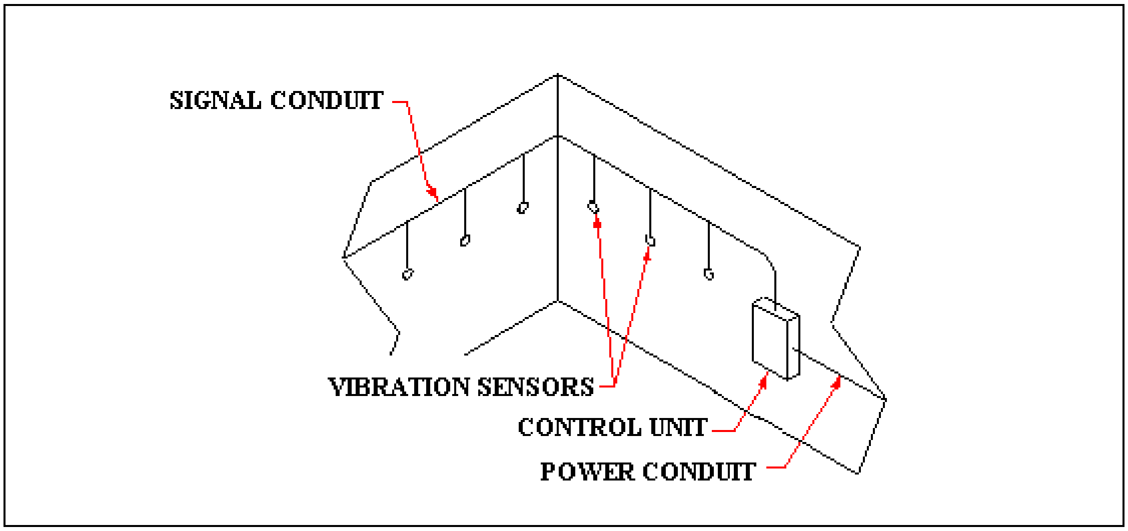
Transducers that are designed to detect the low frequency energy that is typically generated during a physical intrusion attempt and transmitted via the surrounding walls, roof or floor. The sensors are mounted directly to the inner walls of the protected zone, and will detect the change in the normal "vibration"

profile.

There are two basic types of transducers that are utilized to sense these changes: piezoelectric and mechanical transducers. Both devices convert the seismic shock waves into electrical signals that are proportional to the acquired energy. These are processed and analyzed against known signatures.

Reliable operation requires that sensors should be securely and firmly spaced from eight to ten feet apart on a wall or ceiling where intrusion is expected. Actual placement is dependent upon the transmission characteristics of the target wall. The use of sensors should be avoided on walls of limited structural integrity, such as sheet rock, plywood or thin metal, unless bolstered by main supports. These materials are subject to external vibrations other than caused by an intruder. Likewise, walls that adjoin or are exposed to vibration created by trains, planes, trucks, or vibrating machinery should be avoided.

Supplementary detectors are recommended for added reliability of detection. Volumetric or infrared sensors that focus on vulnerable areas will increase security.



Problems can result from the improper placement of sensors, or their application to inappropriate surfaces. Erratic operation can result from:

- **Unstable or improper installation of units;**
- **Improper spacing of units;**
- **Mounting of the sensors to materials (rugs, fabric, heavy wall coverings) that are not conducive to detecting vibrations;**
- **Poor placement of sensors;**

These sensors can be bypassed by:

- **Avoiding entrance through the protected area;**
- **Selection of a point and method of entry in a segment of a wall, roof or floor that will permit the suppression or diffusion of vibrations created by the entry;**
- **Generation of a persistent but random number of false alarms over a long period of time.**

WALL VIBRATION SENSOR

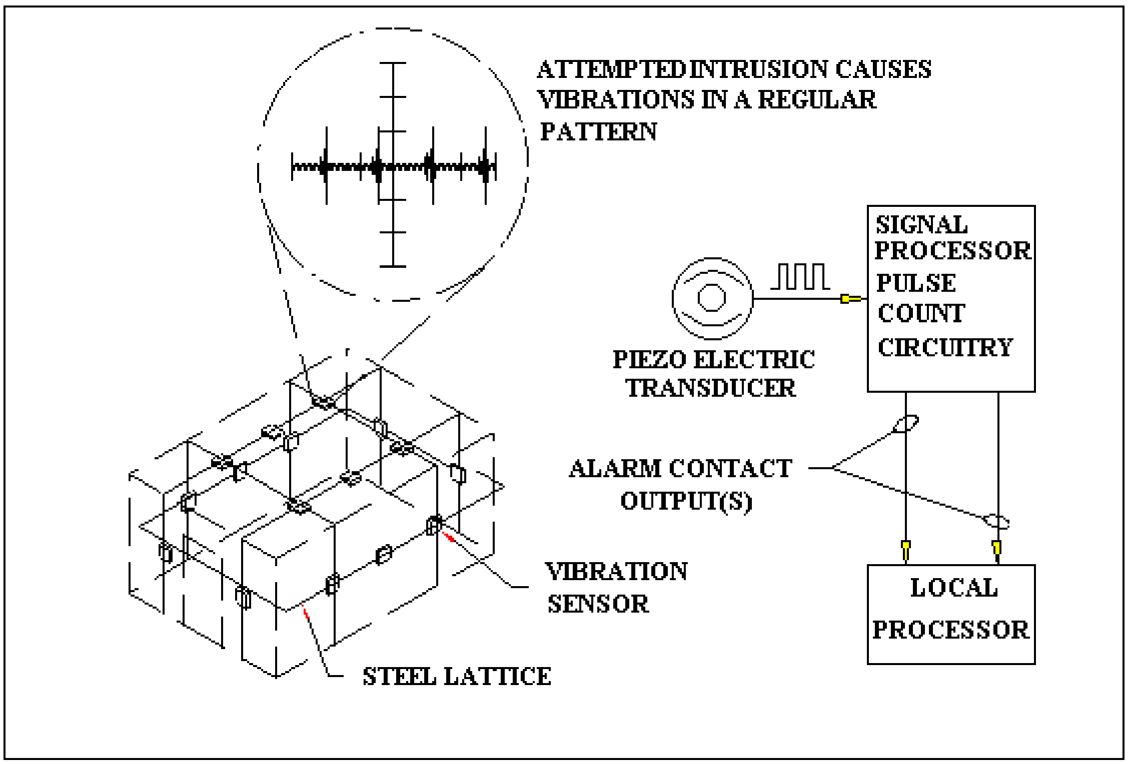


Figure LSS+4009 Wall vibration sensor

40_3.2.4.1 Defeat of Wall Sensors

Fiber optic wall sensors can be defeated by:

- **Avoidance;**
- **Targeting an insensitive or overlooked location as a point of entry;**
- **Bypass the sensor circuit while the system is disarmed.**

40_3.2.5 Fiber Optic Wall Sensor

This type of sensor is configured as an open mesh network (quilt) appliqué that can be applied directly to an existing wall or roof, or installed in a wall (or roof) during construction. The system is designed to sense vibrations at low frequency energy that are created by chopping, sawing, drilling, ramming or other physical attempt to penetrate the structure on which it is mounted. This detection is similar to other fiber optic devices described in this text. There is a source LED that generates light through the fiber, and received by a detector that is sensitive to changes in the transmitted energy. Signatures of various low frequency components are stored within the processor and matched to minute variations in transmitted energy.

Fiber optic wall detectors are extremely sensitive and are not suitable for every installation. They should not be installed on any wall or surface that is exposed to external vibrations, such as generated from aircraft, vehicles, trains, or machinery. They should not be used on walls of poor structural integrity, such as sheet rock, plywood or metal. Smart processors can be programmed for differing types of intrusion, but cannot distinguish between certain external stimulus.

As with other vibration detectors, unreliable operation will result if they are installed or calibrated improperly, or implemented on surfaces that are unsuitable. These systems can be compromised by an intruder avoiding entry through a protected area, or penetrating an insensitive location.

FIBER OPTIC STRUCTURAL VIBRATION SENSOR

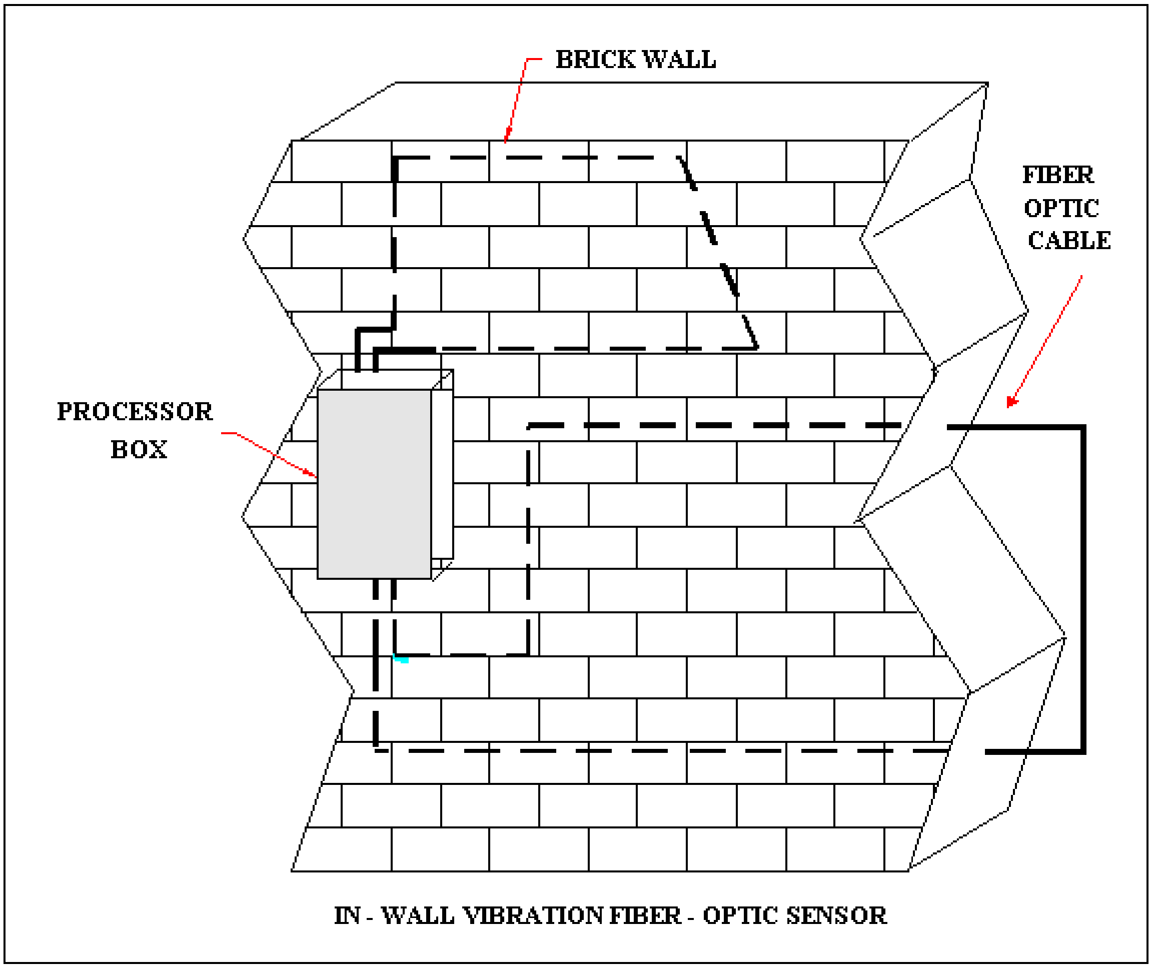

Figure LSS+4010 Fiber optic structural vibration sensor

40_3.2.6 In-Ground Fiber Optic Sensor

Fiber optics can also be used for an in-ground, pressure sensor. The theory of operation is similar to most other light emitting devices described in this text. A light source provides an emitter at one end of the glass network. The conductivity and reflectivity of the system is calculated, and the energy at the receiving sensor is constantly evaluated. Pressure on the cable can create changes in the characteristics of the received signal. Such pressure can be caused by vibrations from walking, running, crawling or jumping.

These systems should not be installed near poles, trees, in or under concrete or asphalt. If they must be located near a pole, then the protected zone should be at a distance equal to the height of the pole. The area of installation should have proper drainage in order to prevent water from collecting over the detection zone.

There are several conditions that will create false alarms when using in-ground fiber optic sensors:

- **Areas with erosion problems caused by heavy rain or lack of vegetation. This can result in the cable being exposed or buried deeper in the earth, causing any sensitivity settings to become ineffective;**
- **Tree roots can be affected by windy conditions above ground that can cause their movement underground and result in bending of the cable;**
- **Large animals passing over the zone of protection.**

These systems can be defeated by bridging over the sensor area. Because of this, supplementary sensors such as microwave are recommended.

IN-GROUND FIBER OPTIC SENSOR

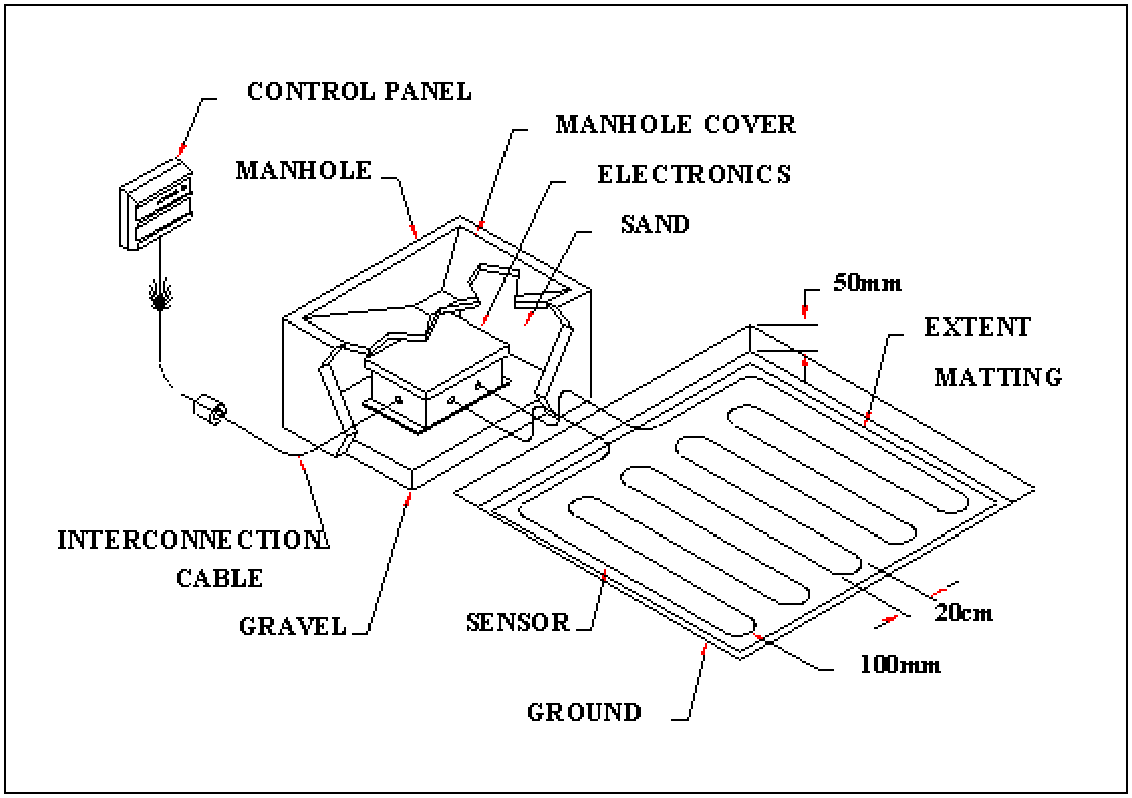

Figure LSS+4030 In-ground fiber optic sensor

40_3.2.7 Ported Coax Buried Line

LSS401: Buried Cable sensors

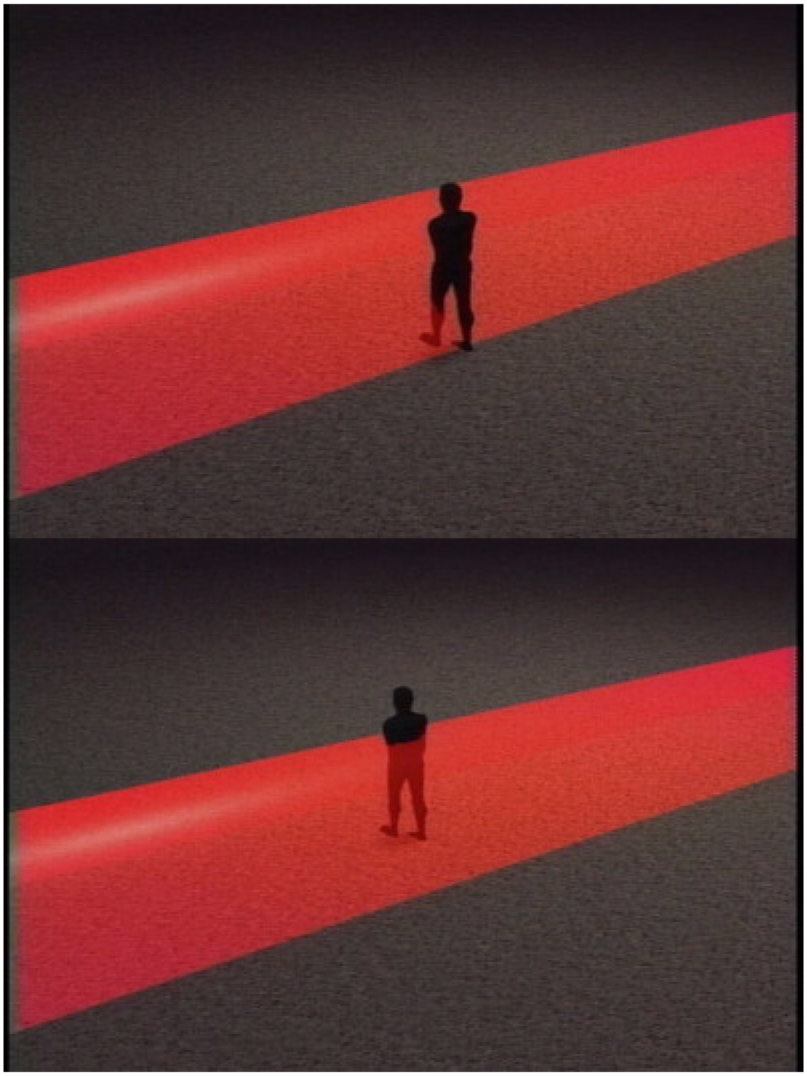

Figure LSS+4060 Ported coax emits an RF field above the cable that can detect an intruder as the beam of energy is crossed. Courtesy of DOE Office of Security and Safety Performance Assurance.

Ported coax buried line sensors are coaxial cables that have small, closely spaced holes in the outer shield that allow electromagnetic energy to escape and radiate a short distance. This emission creates an electric field that can be disturbed upon the presence of an intruder. The system requires that cables be installed in pairs spaced about five feet apart. Under the control of a central processor, a pulse of radio frequency energy is transmitted through one of the cables and received by the other. The pulse timing is constant and thus creates a signature that can be constantly evaluated by the processor. Any

interruption of the field will cause a change in this signature that can indicate an intrusion. The processor has the intelligence of updating its signature parameters to adjust for gradual changes in the environment and surrounding medium.

There are two basic types of sensors: **continuous wave**, and **pulsed**.

A constant emission of RF energy is transmitted simultaneously through the **continuous wave** sensor in both cables and received by the opposite number. This creates a detection zone above ground with a continuous surface. When an intruder enters this area, the electric field is disturbed.

Pulsed sensors emit a pulse of RF energy through one cable and receive it through its corresponding receive side. As the transmission speed is constant, this creates a standard amplitude signature that can be evaluated.

The cables are typically buried about nine inches below the surface of the ground, depending upon the soil density. This creates an electric field that is approximately three to four feet above the ground and extends nine to twelve feet in width. The variation in zone size depends upon cable separation and the characteristics of the burial medium. Using this sensor, zone length can extend up to five hundred feet.

Routing of cables underneath chain link fences, or running metallic pipes through the sensor field should be avoided. If this is impossible, they should be buried at least three feet below the ported coaxial cable. When installing the cables along or near fence lines, the cables must be installed between six and ten feet from the fence in order to avoid distortions and to reduce potential false alarms that can be caused by the motion of the fence fabric disrupting the detection field. Supplementary protection in the form of video motion detection can complement the cable sensor system.

Ported coaxial systems can suffer from false alarms and unreliable operation if installed incorrectly or in difficult environments, such as where there are nearby metallic fence fabric, vehicles, signs, and organic objects such as people, medium to large animals, and medium to large vegetation. Although individual small animals generally do not have the mass to affect these systems, a congregation of small animals can cause distortions.

Heavy snowfall can cause problems due to the limited height of the detection zone. In addition, burial mediums that have drain ducts located beneath the buried cables, and wind disturbance of standing water over the cables can pose a problem. In such cases, ducts must be constructed of metal. The burial zone should be graded to provide immediate runoff and good drainage. It should also be noted that ported coax sensors are affected by high EMI from sources such as large electrical equipment or electrical substations and should not be used in close proximity to these types of installations.

40_3.2.7.1 Defeating Ported (Leaky) Coax Cable Systems

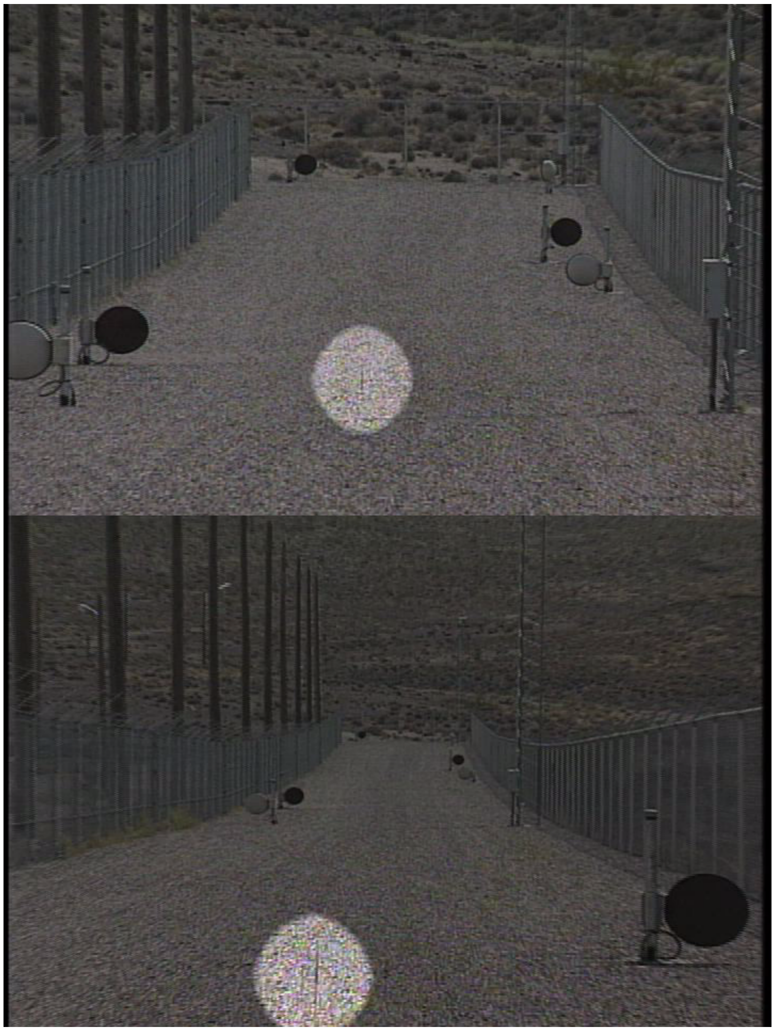

Figure LSS+4055 Marker points for buried coax systems should be removed because they provide an indication of coverage for an intruder. Courtesy of DOE Office of Security and Safety Performance Assurance.

Perimeter defense systems that utilize ported or leaky coaxial cable can be defeated through a variety of methods. These include:

- **Walking on wooden stilts;**
- **Bridging, two-man or pole vaulting over the detection zone;**
- **Alarm stacking;**
- **Leaching a salt water solution slowly through the cable in a specific zone over a period of time. This procedure will have the affect of desensitizing the sensor cable;**

- **Cut the cable from the fence to create an intrusion path;**
- **Bypassing the area of coverage;**
- **Using marker points as an indicator of coverage.**

BURIED PORTED CABLE SENSOR

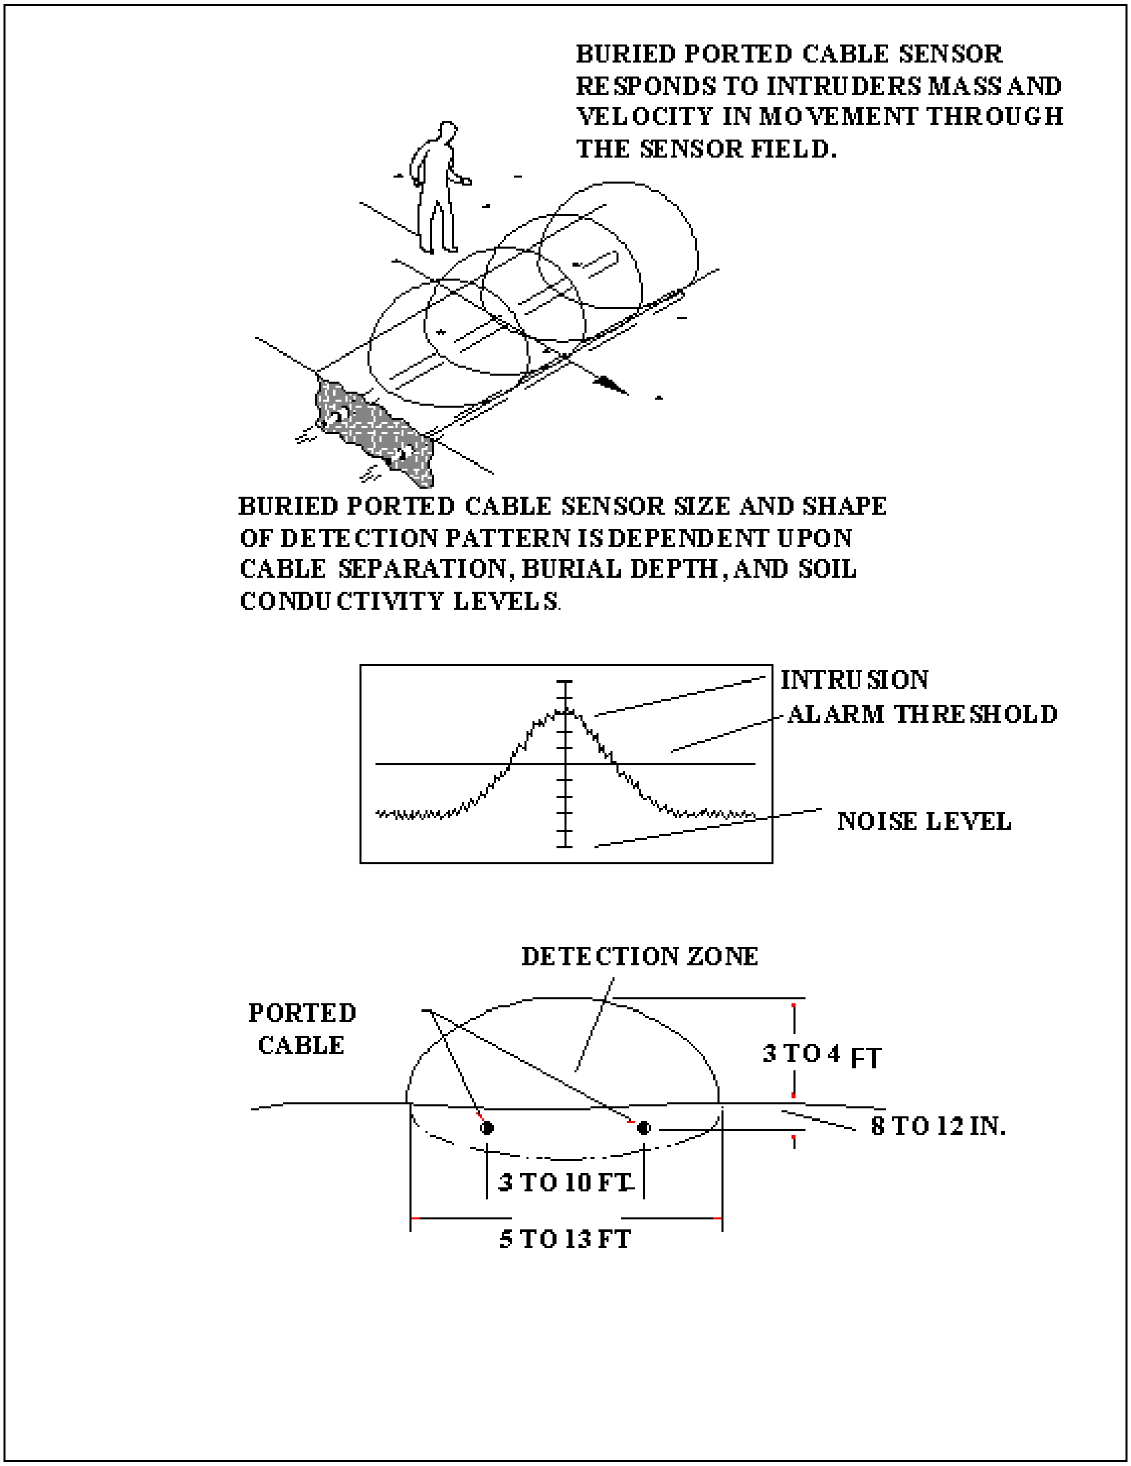

Figure LSS+4031 Buried ported cable sensor

40_3.2.8 Balanced Buried Pressure Sensor

A Balanced Buried Pressure line sensor is another type of in-ground system that detects vibrations and seismic energy that can be caused by personnel, animal or vehicular movement across the surface of the ground in which the sensors are installed. The tubes are extremely sensitive to pressure changes upon the medium in which they are located. Ground within a zone that is subjected to walking or running intruders, vehicles, or other forms of compression will cause proportional changes in pressure in the farthest tubes. This is processed and analyzed.

The amount of sensed pressure waves directly relates to the weight and movement impact that is created by objects contacting the earth. Each type of impact creates its own identifiable signature, much like sonar. Thus, a runner will create greater pressure than a person that is walking. Likewise, a heavy person that is walking upright will create more pressure than a smaller person moving on hands and knees.

Sensor zones (usually two sensor tubes) consist of pressurized, closed end, pliable tubes or hose segments filled with water or an antifreeze-like solution. The zone size will vary depending upon soil density and composition and the nature of any surface material. The tubes are very sensitive to changes in pressure and react to pressure exerted on the medium in which they are implanted or buried. A processor monitors and regulates the pressure inside the tubes and generates a signal if there is a deviation from a determined norm.

There is a self-compensating valve that is used to maintain pressure within the tubes, and to adjust to gradual or moderate (not rapid) changes that can be associated with the burial medium (not of personnel and vehicle movement and other man-made or sudden natural movements such as earthquakes and explosives). Such changes might include those caused by moisture content (rain) or temperature changes (frost or drought). The differential pressure system and the nature of the self-compensating valve provides a high degree of immunity to normal environmental noise and weather conditions.

A detection zone is created by burying the tubes approximately four feet apart, with the pressure-sensing unit linked and placed between the sensor tubes. Depending upon the nature of the soil,

this type of system can create a detection zone that measures up to a 350 feet radius. The depth at which the tubes are placed depend upon the composition of the medium in which the tubes are placed. Depth for different medium is as follows:

- **Earth and sand: ten inches is sufficient;**
- **Soil with an asphalt covering: four to eight inches;**
- **Concrete surface or area: bury just beneath the under-surface of the concrete, because this material is not a good conductor for waves created by personnel. It serves to dampen or insulate such waves, thereby reducing the probability of detection.**

Tree roots closer than ten feet to a sensor set can pose a false alarm problem, due to the potential for windy conditions above ground. Such movement can transfer pressure waves into the ground via the root system. So also, areas with heavy snowfall or shifting sand may create a problem for the system to properly sense seismic vibrations. In such cases, snow and sand look the same to detectors with respect to the shock waves created upon their movement. This would, of course, depend in part on the depth and composition of the snow or sand.

As with other systems discussed above, the improper installation or calibration of detectors can cause normal activity to be interpreted as an alarm condition. The location near heavy road or rail traffic or seismic activity from pulsating or shock machinery can generate nuisance alarms.

40_3.2.8.1 Defeat of Balanced Pressure Sensors

The ability to defeat these systems relies upon the avoidance of potential zone(s) of detection or of the following actions:

- **Cushioning movement vibrations;**
- **Dispersing or a lowering of impact energy;**
- **Attacking the sensor in extremely cold weather;**
- **Alarm stacking;**
- **Avoidance of sensor;**
- **Bridging or planking over or through the detection zone.**

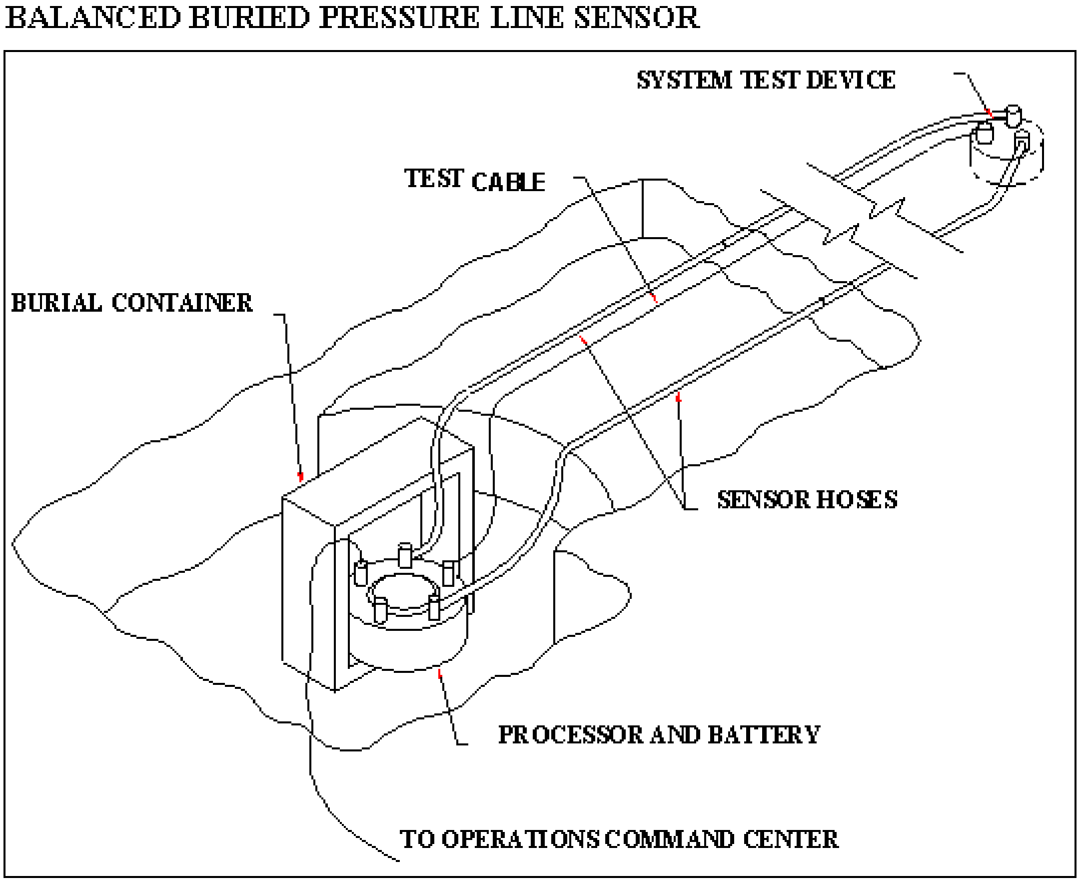

Figure LSS+4032 Balanced buried pressure line sensor

40_3.2.9 Buried Geophone

A buried geophone transducer is designed to detect the low frequency seismic energy created in the ground by someone or something crossing through the detection screen above the sensor by crawling, walking, or running.

The system consists of two elements, a processor and a series of geophone sensors. Signals are generated by the detectors that are then filtered and processed, based upon predefined signatures. In typical installations, twenty to fifty geophones are placed in a line of detection that can extend up to three hundred feet. They are buried between six and twelve feet apart to a depth of six to fourteen inches in soft to compact soil, and six inches in asphalt. Soil must be stable and relatively compact, with the geophones seated between layers of sand, due to its conductivity.

In many systems, direct audio monitoring is available to validate alarms by human operators. Much like Sonar in a submarine, a trained operator can usually differentiate between normal stimuli and that associated with intrusion attempts.

These systems are subject to unreliable detection and false alarms if the material in which the sensors are buried is inconsistent or loose. In such cases, the soil becomes a poor conductor of energy, resulting in little data being received by the geophone. On the other hand, the detectors are sensitive to low levels of seismic activity and thus, noise can be generated by animals, trees, fences, light poles and telephone poles. Each of these structures are anchored in the ground and are conduits for energy transfer. Because of this, a geophone should be located at least thirty feet from a tree, ten feet from any fence, and at a distance equal to the height of any nearby pole.

Geophones, as with all vibration detectors, can be defeated by bridging over the sensor.

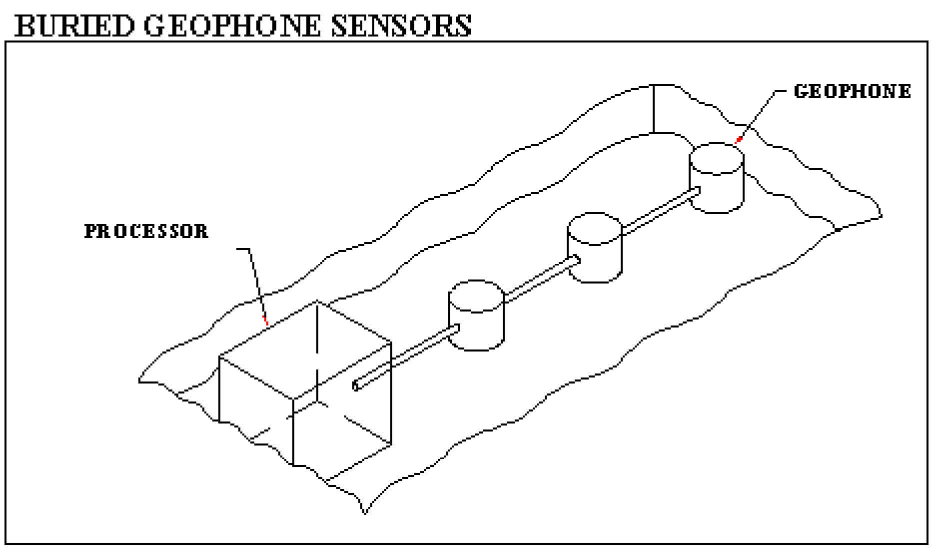

Figure LSS+4033 Buried geophone sensors

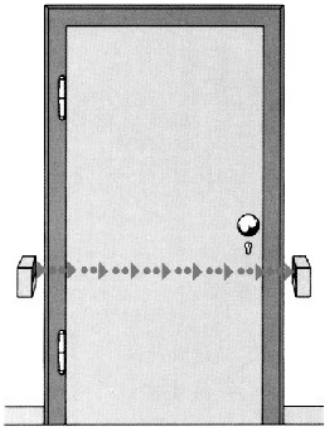
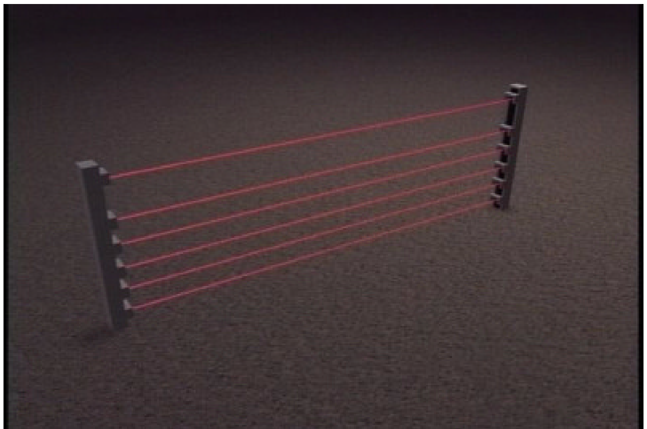
40_3.2.9.1   Defeat Techniques for Geophone

Sensors that detect vibration or seismic energy (geophones) can be defeated through a variety of techniques, including:

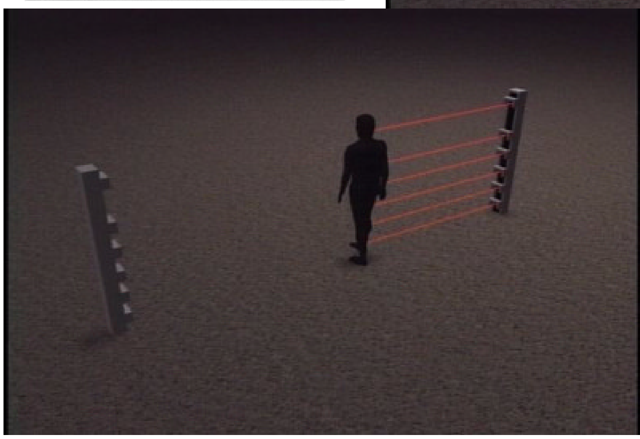
- **Bridging;**



- **Tunneling under the sensors, or use of a two-man pole vault over the fence-mounted version;**
- **Stacking of alarms;**
- **Avoidance;**
- **Explosive penetration if pulse count is set improperly;**
- **There is a high probability of alarms during storms or wind. This fact can be used to bypass a system by creating trips that may be ignored;**
- **Spoofing and alarm stacking.**



40_3.3 Light-Activated Sensors



LSS401: Photoelectric sensors

Light sensors are employed to provide an invisible electronic barrier against entry. They can be positioned within a building or outside along a perimeter to protect a path against intrusion. Photoelectric sensors transmit a beam of infrared light to a remote receiver and thereby create an "electronic fence". Such sensors can "cover" openings such as doorways, walls, or hallways; they act like a trip wire. Once the beam is broken or interrupted by an intruder, a contact closure or other signal is generated. Photon-sensitive devices rely upon the transmission and interruption of one or more light beams for their operation. When photoelectric systems are installed properly, they will provide a reliable measure of protection for small or large areas.

A system consists of a transmitter and receiver. The transmitter emits one or more narrow light beams in a straight or reflected path to the receiving unit for a range of up to 1,000 feet. So long as the rays are not interrupted, the receiver will maintain a continuous circuit.

Photoelectric sensors are comprised of two critical components: a **transmitter** and a **receiver**. The transmitter utilizes a Light Emitting Diode (LED) as its light source. It generates a consistent infrared beam to a receiver. The receiver is actually a photoelectric cell that detects the presence of IR at a specific modulated frequency. If the detector fails to receive at least 90% of the transmitted signal for as brief as 75 ms.(time of an intruder crossing the beam), an alarm condition is created.

In most systems, the IR carrier (one or more beams) is modulated at a very high frequency, and this frequency is further changed at a rate of up to 1,000 times per second in an algorithm that correlates with that programmed into the receiver. This prevents bypass attempts through the use of a substitute light source. The only way to bypass this system would be to replicate the angle of the beam and modulation frequency.

In practice, the transmitter and receiver can be separated up to 1,000 feet and still provide reliable coverage. A photoelectric sensor is not affected by changes in thermal radiation,

fluorescent lights or Radio Frequency Interference (RFI). These systems exhibit a high probability of detection and low false alarm rate. The path of the beam can be altered using mirrors to create a less predictable detection barrier, although the use of mirrors can reduce the signal strength of the beam and diminish its effective distance. If mirrors are utilized, caution must be exercised because they are often accidentally knocked out of alignment, generating a need to calibrate and realign them periodically. They are also prone to dust build-up and refraction or diffusion of the reflected beam.

The major failure in these systems is the introduction of anything that blocks or interrupts the path of light between transmitter and receiver. Such action can affect the detection reliability of the sensor. Fog, smoke, mist, dust, and reflective particles cause the light to be refracted or scattered. If there is more than 10% reduction in the signal strength, an alarm is normally generated. Extreme variations in background lighting or sunlight may also reduce sensitivity.

A nuisance or false alarm can be caused by any objects that interfere with beam transmission, such as birds, animals, blowing leaves, or paper. The improper alignment of the transmitter, receiver or mirrors can also generate an alarm.

40_3.3.1 Defeat of Light Sensing Systems

Light level detection systems are triggered by the presence or absence of ambient light. They differ from photoelectric sensors in that they sense lighting conditions, rather than a specific directed beam across an identified path. Light sensing systems can be neutralized by:

- **Entry without alteration of the ambient light level;**
- **Use of night vision devices in an optically controlled environment;**
- **Blinding of the light sensor to simulate a specific condition;**
- **Blocking of sensor to prevent the detection of light. The photograph shows the use of black electrical tape to defeat a light level sensor at the diamond exchange in Antwerp, Belgium during a large burglary.**

40_3.3.2 Defeat of Photoelectric Active Infrared Sensors

There are several techniques for defeating internal and perimeter photoelectric detection devices. These include:

Interior Sensors

- Avoidance, moving or stepping over or under the sensor light beam or projected laser plane, by determining the location of transmitter/receiver or reflective tape. Proper placement of mirrors can counteract this vulnerability by creating a "zig-zag" multiple beam barrier pattern;
- Extension of fiber optic cable material from transmitter to receiver in order to create a new light path;
- Capture of a beam by external light source. This will generally apply to non-pulsed units using visible light only, although modulated IR or lasers may also be utilized;
- Interposing reflectors or mirrors in a single-ended systems (Bounce back);
- Spoofing and alarm stacking;
- Using a black and white camera or IR goggles to determine light source;
- Stacking of alarms using birds;

Exterior Sensors

- Tunneling or trenching under the sensor beam pattern;
- Bridging, two-man or pole vaulting over the sensor beam pattern;
- Beam capture of unmodulated sensors only;
- Avoidance of the sensor, by stepping or sliding through improperly spaced beams;

- Utilize the ridged sensor sunshades or the sensor itself as a ladder. This is model dependant;
- IR beams can be observed by using a monochrome CCTV camera or IR goggles to determine transmitter path;
- Alarm stacking using another IR light source aimed at the receiver.

40_3.4 Proximity and Capacitance Sensors

LSS402: Proximity sensor technology

Proximity detectors can signal the presence of intruders near to or touching a certain object or area by a change in capacitance, inductance or other characteristics of the structure. They are used in driveways, office areas, schools, banks, strong rooms, safes, and other locations where specific structures or items are to be monitored.

Magnetic point detectors are utilized to sense large metal objects such as vehicles driving across concrete.

LSS403: Magnetic point sensors

Capacitance sensors are designed to detect changes in an electrostatic field that is created by an array of wires. The presence of an intruder can change the capacitance of the field by approaching or contacting the wires. The sensors consist of three closely-spaced wires that are arrayed and installed on the top of a fence. A low voltage signal is induced in the array that creates an electrical field, utilizing the fence as the system electrical ground. A processor continually measures and compares the differential capacitance between the sensing wires and ground.

Three strands of closely spaced 16 gauge wire form the sensor array. The wires are secured to a fence top fabric or wall by using high-dielectric brackets, which can be adapted to any barrier. They are most commonly utilized on outriggers atop chain link fences. The sensor segment can extend 1,000 ft. In order to trip the sensors, physical touching of the fence is usually required. If the sensitivity of the system is increased, then close proximity can often trip the system. Supplementary sensors should also be installed, because these systems are subject to bypass by cutting of the vertical fence fabric. The systems are

impervious to weather, EMI, and RFI; such conditions have no effect on detection capabilities, although there is a high level of maintenance required to assure that the capacitance characteristics of the fence are always adjusted.

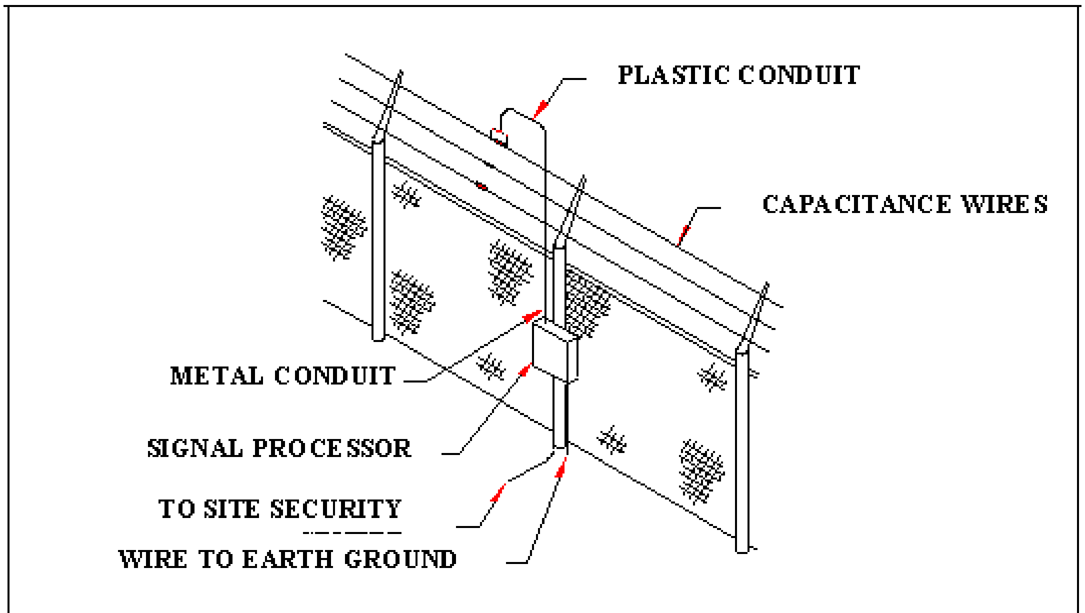
False alarms or unreliable detection can occur from vibrations caused by weather and animals (birds, squirrels and others). Vegetation coming into contact with the fence can also change the capacitance, thereby affecting the detection characteristics. Proper landscaping maintenance of the fence line must be insured (grass cut, trees removed, shrubs removed). Blowing debris or anything making physical contact that changes the characteristics of the fence can create an alarm condition. One countermeasure for this problem is inducing tension with springs at the termination points.

40_3.4.0 Defeating Proximity and Capacitance Sensors

Capacitance and proximity sensors can be defeated by a number of techniques, including:

- **Disconnection from protective detection loop while the system is disarmed. This will be effective in self-balancing systems only;**
- **Use of insulating blankets, rubber wet suits, or gloves to prevent shorting of the capacitance field to ground;**
- **Bypass the sensor circuit while the system is disarmed;**
- **Tunneling or bridging of the sensors.**

Differential Capacitance Systems, utilized in exterior applications, can be defeated by:



- **Tunneling under the sensor or barrier (such as a fence);**
- **Bridging, two-man or pole vaulting over barrier;**
- **Wearing heavy insulated clothing, gloves or other material;**
- **Alarm stacking;**
- **Avoidance by attacking or penetrating the location at gaps in the sensor coverage;**

Magnetic point and driveway alert sensors can be defeated by:

- **Bridging, two-man or pole vaulting over detection zone;**

- **Use of wooden stilts;**
- **Intruders do not have any metal;**
- **Avoidance;**
- **Alarm stacking.**

CAPACITANCE SENSOR APPLICATIONS

CAPACITANCE FENCE SENSOR CONFIGURATION

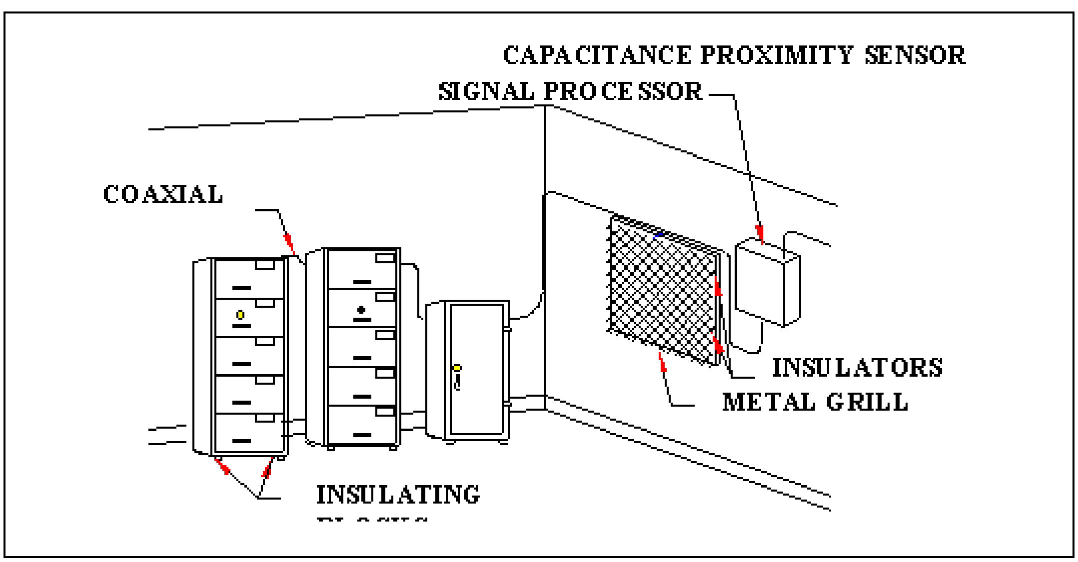


Figure LSS+4022 Capacitance sensor applications

40_3.4.1 Electric E-Field Sensor

LSS401: E Field protection

**Figure LSS+4048 An E field system by Siemens creates an electronic barrier through a series of
parallel wires across the fence line.**

Electric field sensors are designed to generate an electrostatic field between and around an array of wire conductors and an electrical ground. Sensors detect changes or distortion in the field which can be caused by anyone approaching or touching the fence. Sensor zone length can extend up to 1500 feet.

The E-field sensor consists the following components:

- **An alternating current field generator that excites a field wire (two or more sensing wires), around which an electrostatic field is created;**

- **An amplifier signal processor that detects changes in the signal amplitude of the sensing wires.**

The alternating current on the field wire creates an electrostatic field in the air between the field wire to ground. When an intruder enters the "field", large amounts of the electric charge flow through the intruder due to the disruption of the field by the human body.

To reduce false alarms, the signal goes through a filter which rejects high frequencies caused by wind vibration and low frequencies caused by objects striking the fence wires. However, the filter allows frequencies associated with intrusion characteristics to be evaluated by the processor. Three concurrent conditions must be met to signal an alarm:

- **The signal amplitude must exceed a preset value that discriminates small animals;**
- **The frequency must be in a range that is associated with humans;**
- **The signal must persist for a set period of time.**

E-field wire configurations are mounted on free-standing posts or chain link fences. All the wires are placed in parallel with each other and to the ground. This will achieve uniform sensitivity along the fence length. Springs are used at the connectors to ensure tension- reducing vibrations caused by wind.

An advantage that an E-field sensor has in comparison with other fence sensors is the self- adjusting circuitry that is built into the processor. Such systems will reject wind and ambient noise. In order to perform, this circuit requires the amplitude of an intrusion attempt to exceed a preset level for a preset period of time.

E-field sensors have a very low nuisance and false alarm rate. Sometimes, countermeasures such as bridging and tunneling can be detected. This depends upon the proximity of the disturbance activity to the sensor. This system should be considered if bridging or tunneling are anticipated intrusion tactics. Other fence sensors (vibration, taut wire) can be added to provide a higher level of detection probability.

Unreliable detection and operation can result:

- **From adverse weather conditions (such as rain and snow);**
- **Improper installation that results in incorrect tension or insulation coupling;**
- **During an electrical storm;**
- **Vegetation, grass, or shrubbery movement or growth along the fence line;**
- **Animal movement along the fence line;**
- **Large spacing between wires (this condition should be avoided because it can allow someone to move between the wires without causing an alarm);**
- **EMI can be a problem where multiple systems are deployed in a limited area, unless different frequencies are utilized by each system;**

Any action that causes fence vibration (weather, animals, birds)

40_3.4.1.1 Defeat of E-Field Systems

Figure LSS+4057 E-Field systems can be defeated by taking advantage of shadowed areas. Shown is a piece of
lumber that can be used to scale the fence at a vulnerable point. Note in the middle photograph a pizza cutter
can prevent this practice. An individual in shadow coverage (right) is not

detected. Courtesy of DOE Office of Security and Safety Performance Assurance.

E-Field Sensors can be defeated by:

- **Tunneling (six feet or deeper) under the protected area;**
- **Avoidance by attacking a lack of sensor coverage at buildings and other obstructions. Look for gaps in coverage;**
- **Bridging, two-man or pole vaulting over the detection zone;**
- **Alarm stacking.**

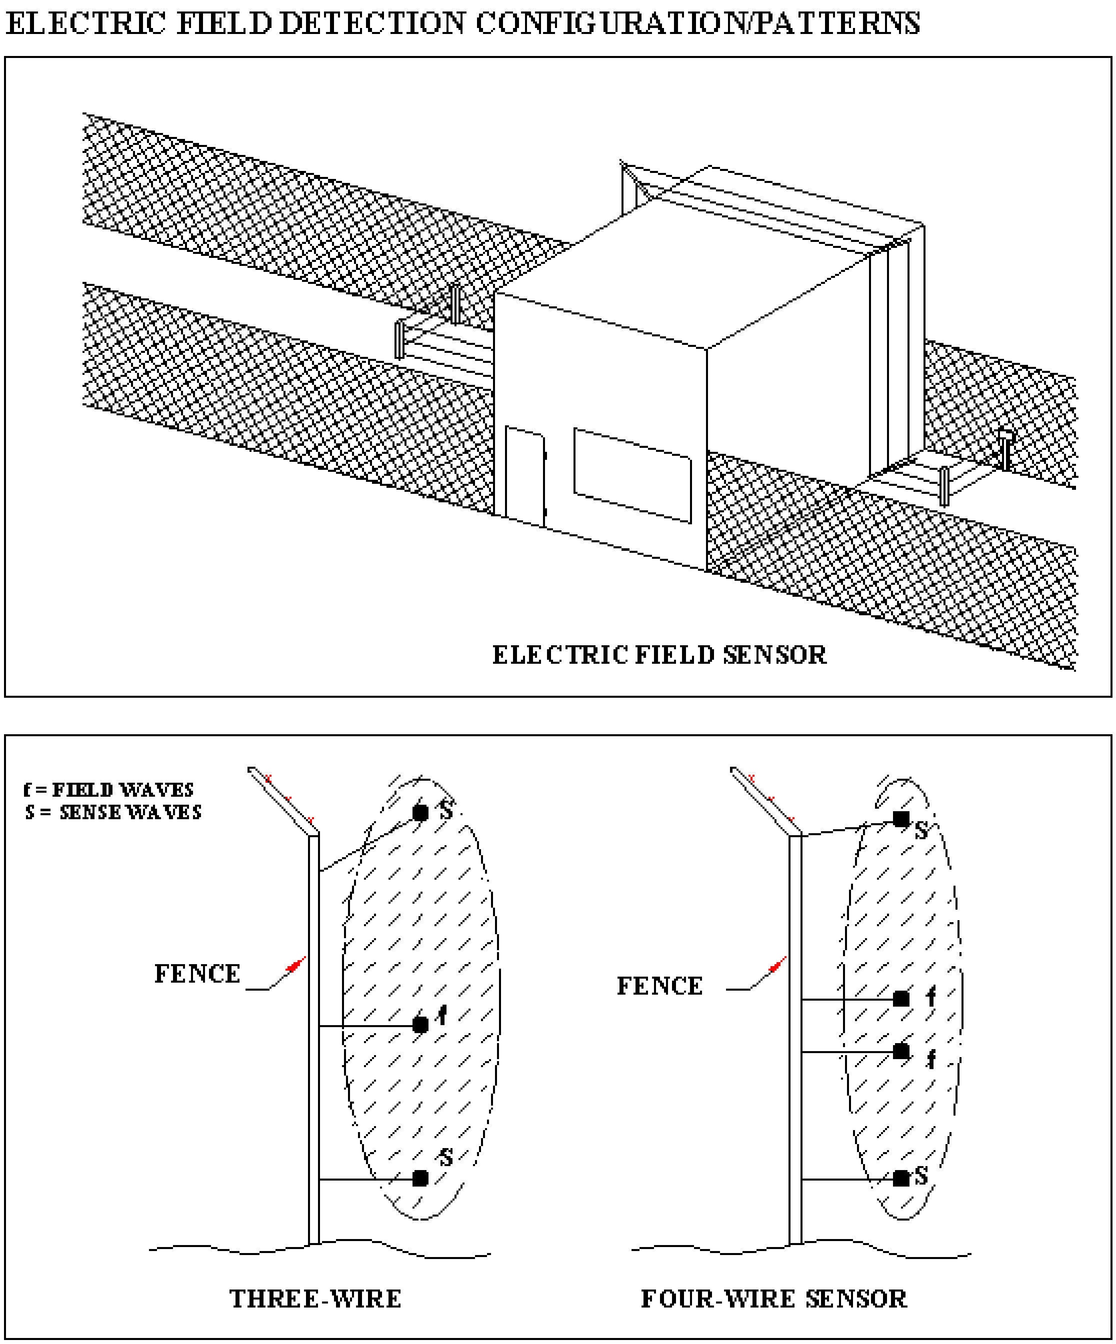

Figure LSS+4021 Electric field detection configuration/patterns

40_3.5 Volumetric Sensors

LSS403: DOE on sensor technology

Volumetric sensors are primarily used for monitoring an intrusion into enclosed areas where entry is through walls, floors, or ceiling. They utilize air pressure, ultrasonic sound, and radio frequency energy as a transmission medium to permeate an entire area and provide information as to changes resulting from penetration.

Volumetric systems are extremely economical where large areas are to be monitored. Because the sensors do not respond until an intruder is within a protected area, they should be installed as part of a comprehensive system of trips. Many different kinds of sensors are available that are reliable, sophisticated, and inexpensive. Often, two different technologies are combined within one detector in order to minimize the potential for false alarms. The most common example is the motion detector that contains microwave and passive infrared.

Volumetric monitoring does not rely upon the physical breaking of circuits that is required when using magnetic trips, foil, or photoelectric devices. The sensors can provide surveillance completely throughout an area from floor to ceiling and wall to wall, rather than just a specific door or window. This is a major advantage.

40_3.5.1 Microwave Systems

LSS401: Microwave sensor systems

LSS402: Issues with microwave sensors

Sensor technology based upon the transmission of microwaves utilizes radio frequency energy above 10 GHz to protect an enclosed space. The RF will penetrate everything within the target area as well as adjacent barriers. Minute changes in transmitted and received frequencies are compared by a microprocessor for a specific threshold. When the limit is exceeded, an alarm is initiated.

Microwave sensors are motion detection devices that transmit an RF field throughout a protected area. These systems can be utilized for both internal and external applications.

Microwave devices utilize Gunn diodes to emit low power energy in the "X" band up to 400 feet (line of sight). Microwave devices rely upon the Doppler frequency shift principle that measures a frequency shift between 20 Hz and 120 Hz. These frequencies are generated upon human movement within a protected area.

There are two basic types of microwave sensors: **monostatic**, which have their transmitter and receiver encased within a single housing unit, and **bistatic**, wherein the transmitter and receiver are separated, and create a detection zone between them. There are significant differences between the two systems, detailed below.

40_3.5.1.A Monostatic Units

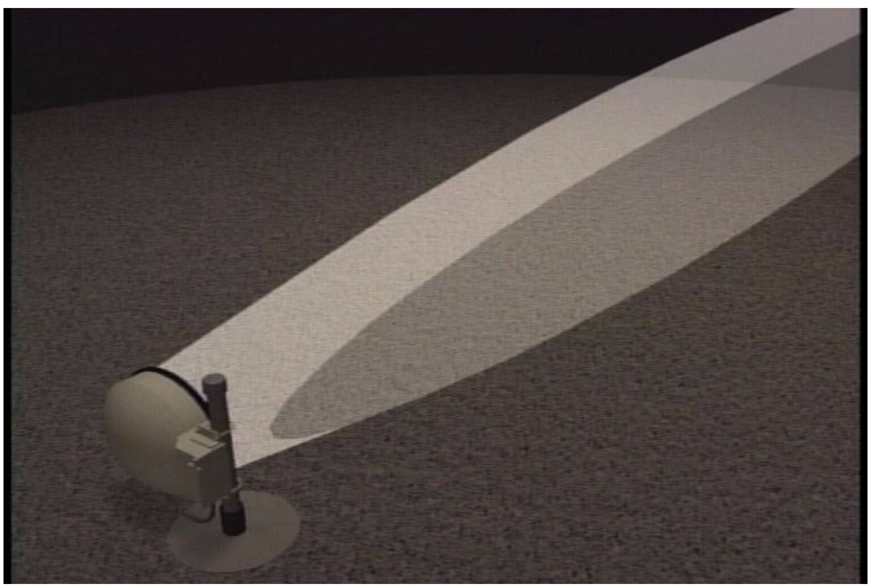

Figure LSS+4059 A monostatic system radiates a coverage pattern much like a flashlight beam. The dark gray area
shows diminshed coverage. Courtesy of DOE Office of Security and Safety Performance Assurance.

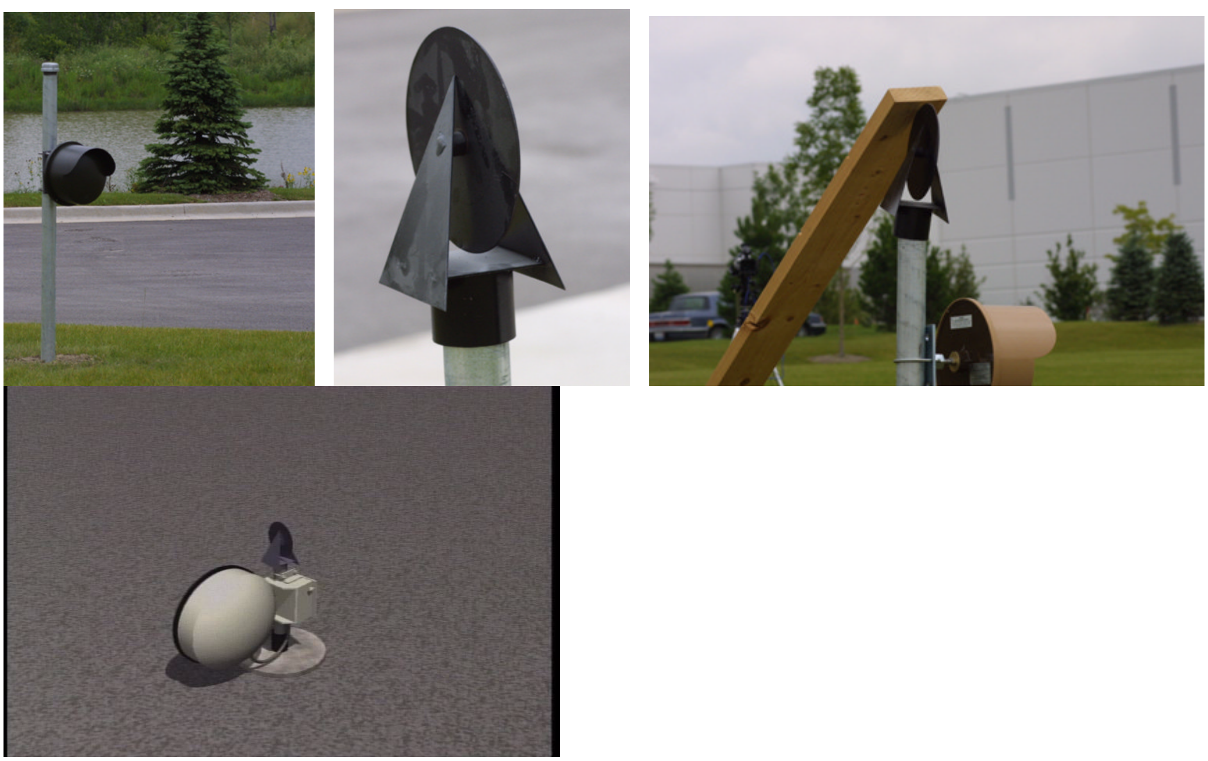

Figure LSS+4049 A microwave system must be protected against a bypass technique of climbing over the sensor.

A pizza cutter is one method to prevent this practice. The mounting pole should be cut just above the sensor.

In this configuration, the transmitter and receiver elements are packaged within a single dual function unit. The antenna is mounted within the microwave cavity, and its radiation pattern can be shaped to cover a specific area or detection zone. The actual shape of the beam can be changed to transmit a long, slender beam or a short oval one.

Monostatic systems operate at two distinct frequencies which are rapidly alternated. As each transmitted frequency is turned on or off, the receiver is shut down for a short interval after each transmission. Microwaves propagate at a constant speed; thus the receiver can be specifically programmed to receive those reflected signals that are sent and received from the receiver cut off (RCO) area within a specific time period. This system design allows the user to protect a well defined area and create a "zone of coverage."

40_3.5.1.B Bistatic Units

Figure LSS+4050 Bistatic microwave system

This configuration requires that the transmitter and receiver be separate units, physically located at opposite sides of the protected zone. The antenna can be configured to alter the signal field (width, height), thereby creating different detection zones. A bistatic system can cover a larger area and would typically be used if more than one sensor is required.

40_3.5.1.C Placement of Sensors

Microwave sensors can be used for monitoring exterior areas as well as interior confined spaces such as vaults, special storage areas, hallways and service passageways.

40_3.5.C.1 Exterior Sensors

Exterior sensors are utilized to protect an area or a definitive perimeter line, as well as to serve as an early warning alert of intruders approaching a door or wall. Where a well-defined area of coverage is required, monostatic sensors should be used, keeping in mind a coverage limitation of 400 feet. Bistatic sensors can extend their range up to 1,500 feet. Supplementary coverage is recommended for these systems.

Microwave sensors can suffer from false alarms as a result of several factors.

- **Close proximity to other high frequency signals can adversely affect the detection reliability of these sensors because of their operation in the x-band;**

- **Those areas that contain strong emitters of electric fields (radio transmitters) or magnetic fields (large electric motors or generators) can effect the ability of microwave sensors to function properly and should be avoided or compensated for by distinct signal separation;**

- **It is easy to determine the presence of these sensors with commonly available radar detectors;**

- **Bistatic systems are somewhat limited by poorly defined detection patterns. Nuisance alarms may be a problem if large metal objects are nearby or if windy conditions exist;**

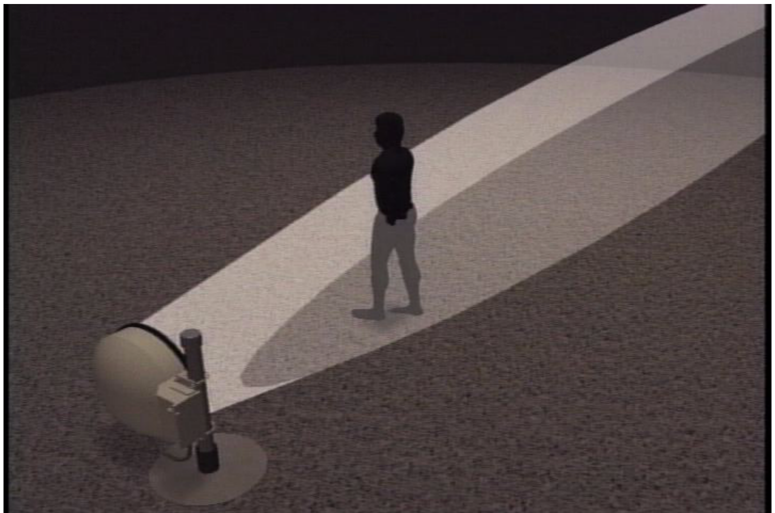
- **Zones that contain fluorescent lights can cause unreliable operation, because the ionization cycle created by fluorescent bulbs can be interpreted as motion;**

- **Self generated signal reflection is a common problem. This is caused by improper placement or mounting by positioning the**

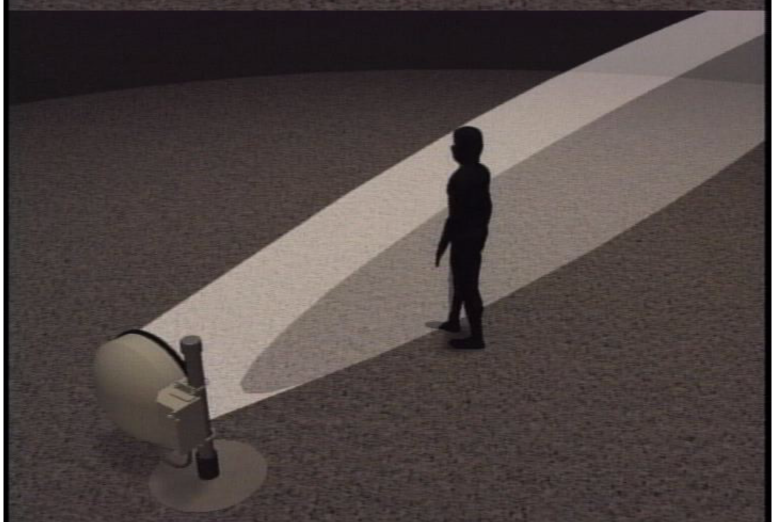
sensor externally and parallel to a wall. The solution is to embed the device within the wall;

- **Large metal objects can reflect signals and provide "dead pockets". Such objects should be kept out of the detection zone;**

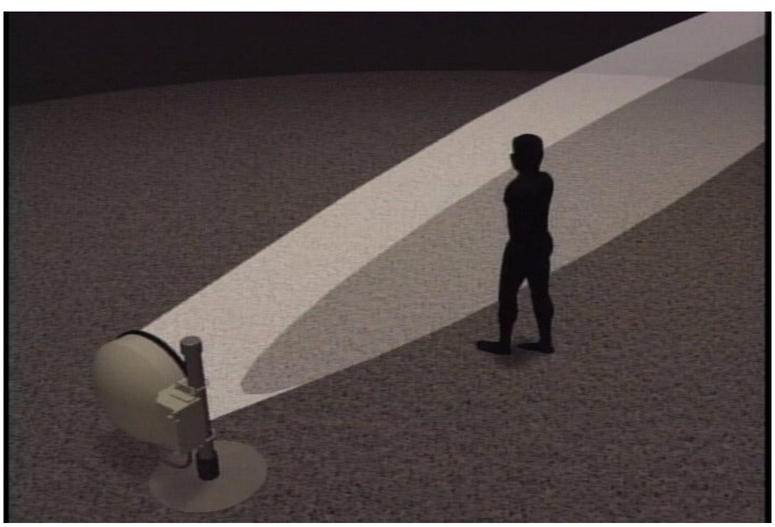
- **Microwave transmission will penetrate and pass through walls, glass, sheet rock and wood. Thus, equipment whose operation involves external movement or rotating functions outside or adjacent to a protected zone can cause a false alarm;**



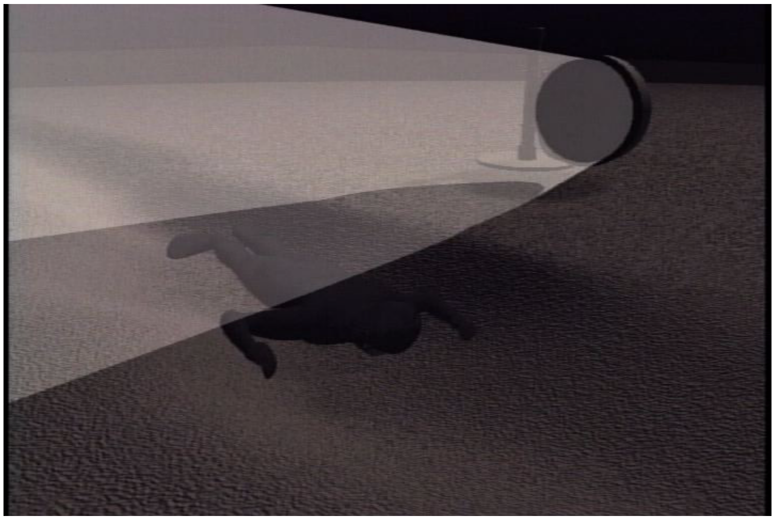
- **Detectors are not affected by moving air and changes in temperature or humidity, due to the high operating frequency;**



- **It is essential to test for, note, and compensate for any dead spots (areas of no detection) created by metal objects such as dumpsters, shipping crates, trash cans, and electrical boxes;**



- **Dead spots and reflected zones can be created by metal objects such as dumpsters, shipping crates, trash cans, and electrical boxes. A careful analysis of such all zones must be made for the presence of non-protected areas. These locations must be noted and compensated for, because they are perfect areas for intrusions. Reflected zones can extend sensor coverage to unintended areas, thus increasing the potential for false alarms;**



Microwave systems can be cased by a knowledgeable individual, and walk-through tests can determine the zones of coverage and conversant dead spots that might allow a bypass of the system. The detectors can also be fooled by extremely slow movement within the radiation pattern. The ability to circumvent these systems is enhanced if there are obstructions, as well as energy absorbing clothing. The placement of sensors must be carefully chosen so as not to allow tampering, disabling, or masking. In many burglary investigations conducted by the author, it was noted that sensors had been covered so as not to protect defined zones.

40_3.5.1.0 Defeat of Monostatic and Bistatic Microwave Sensors

Monostatic and bistatic microwave sensors can be defeated through a variety of techniques. These include:

Monostatic Microwave

- Avoidance of detection zone;
- Careful, slow, and deliberate lateral movement;
- Masking of the target through the use of RADAR absorbing material The technique is utilized to mask and create an intrusion path;
- Alarm stacking;
- Avoidance by exploiting poor sensor coverage;

Bi-Static Microwave

- Tunneling under detection beam pattern;
- Use of a pole or two-man vaulting over detection beam pattern;
- Bridging;
- Stilt walking;
- Slow parallel crawl;
- Slow walk around improper offsets;
- Avoidance;
- Use of noise or RADAR absorption material to create path through detection beam pattern at a very slow movement pace;
- Avoidance by exploiting poor installation coverage, washouts, depressions and snowfall;
- Alarm Stacking.

40_3.5.1.0.1 Defeat of Microwave Sensors: General Issues

Microwave sensors can be defeated through many basic techniques, including:

- **Blocking: physically blocking the microwave energy pattern with a containing material;**
- **Very slow and deliberate speed of movement by the intruder, thus avoiding a significant Doppler shift. Remember that microwave is more sensitive to motion that is toward and away from the sensor;**
- **Avoidance;**
- **Use energy absorbing materials;**
- **Use crosswalk motion;**
- **Take advantage of energy blocking, using man made or natural barriers to create a path past the sensor detection pattern;**
- **Bypass the sensor circuit while the system is disarmed**

40_3.5.1.1 Microwave/Infrared Motion Detector

LSS402: Alarm defeat methods for dual technology devices

LSS403: Dual technology devices utilized in outside environments

A Doppler microwave detector is combined (ANDed) with infrared as a dual-mode or dual-tech sensor. The coincidence of alarms from microwave and infrared provides an extremely reliable (lower FAR) indication of intrusion than is obtainable with either sensor alone.

The Dual-Technology sensor utilizes a passive sensor (infrared PIR) and an active sensor (Microwave) that are packaged within one unit. The two detectors are combined in an AND circuit: they both must trigger before there is a valid alarm condition. The areas of coverage for each of the sensors is optimized for overlap.

Dual-tech systems can be deployed along a perimeter line, a fence or a delineated buffer zone, or as a defense against intruders approaching a door or wall. These systems offer both an advantage and limitation in their operation. Although the false alarm rate

is decreased, so also is the probability of detection. This is because two sensors must sense the same condition at the same time. The mathematical probability of detection for the dual-tech unit is the product of the probability of detection for both individual units. For example, if there is a theoretical individual detection rate of 99 percent and 98 percent, the detection percentage for the Dual-Technology (AND logic configuration) drops to 97.02 percent.

There is an inherent problem with dual-technology sensors: passive and active sensors have differing probabilities of detection based upon the movement of an intruder. Remember, the AND gate logic requires coincident signals from both detectors simultaneously to generate a valid alarm. Passive sensors are most effective when an intruder is moving transversely; active detectors work best when the intruder's movement is radial. Thus, the position of the sensor will require a compromise that can diminish detection capability.

So also, any environmental conditions that affect the performance of either sensor will reduce the effectiveness of the system. Notwithstanding these issues, the dual-tech sensors are cost effective and offer greater protection than individual sensors if deployed in a controlled environment.

False and nuisance alarms for the dual technology sensor are infrequent. However, a combination of environmental conditions (e.g. fluorescent lights, heater exhaust) can cause falsing.

Dual-tech sensors can be defeated in certain conditions:

- **Dead spots in the detection pattern (and an intruders knowledge thereof) will permit bypass of all active regions;**

- **Extreme slow movement can be very difficult for microwave sensors to detect;**

- **Blocking or masking of the infrared sensor's field of view can decrease its sensitivity and reduce the probability of sufficient "heat" being detected by, or focused upon the PIR portion of the sensor. Silicone spray or Vaseline can be used to defeat the sensor unless anti-masking software is operational;**

- **Walking into the PIR sensor, rather than across its field of view can reduce the detection capability of the sensor by not**

"breaking" the boundaries of the PIR detection beams.

This photograph shows a dual-technology microwave/passive infrared sensor that was defeated in a major diamond theft in Antwerp, Belgium. Silicone was used to mask the device and prevent its proper operation.

40_3.5.1.2 RADAR

Radar (RAdio Detection And Ranging) is an active sensor that was introduced in the early 1940s. Since its first deployment as a mode of detection, the technology has been vastly enhanced and improved. These sensors operate in the ultra high frequency region of 100 MHz. to 1 GHz. Transmitted signals are bounced off of objects within zones of protection. A processor will evaluate the signal to determine relative size, azimuth and distance. RADAR and microwave systems are quite similar in concept and design, although their operating parameters are quite different. These systems are quite useful, for example, for the detection of planes or helicopter-borne intrusions that would bypass ground-oriented sensors and microwave systems.

As with the previously described microwave systems, there are two basic types of radar sensors: monostatic and bistatic. However, their operation is different than traditional microwave.

With monostatic sensors, detection of intrusion is achieved by the radar transceiver rotating in a preset "sweep" pattern. During rotation, the transceiver emits high frequency energy pulses, forming and scanning a detection zone. When a moving, foreign, or new object is detected, a Doppler shift in the reflected energy is created. When the magnitude of the reflected energy surpasses the preset criteria stored within the processor, an alarm is generated.

The transmitter in a bistatic configuration is typically creating a designated "sweep" pattern, with receivers at several locations that are designed to maximize the potential for detection. The transmitter generates a field of high frequency energy, which "bounces or reflects" off of "foreign" objects and is sensed by one or more receivers.

Radar sensors are best utilized to monitor exterior areas, although in some situations radar sensors can be used to monitor large interior open areas. Optimum performance requires that the ground be reasonably level and the perimeter boundaries straight. If portions of the perimeter are hilly or have crooked boundaries, the radar unit may be elevated to provide a better line of sight view. Radar sensors can also be used to monitor the straight and level sections of the perimeter, while other types of detectors (e.g. in-ground sensors or video motion detection) can evaluate the remaining sections.

Safe havens for intruders can be provided by "Dead zones" that are created by large objects, buildings or hill masses or depressions. Extreme weather conditions such as rain or snow storms can decrease detection potential of radar. False or nuisance alarms can be caused by the detection of foreign objects not within defined zones resulting from the undesired reflection of RF energy.

Uneven terrain can create "hidden pockets." So also, a slow and low approach by an intruder may defeat sensors.

40_3.5.2 Ultrasonic Systems

LSS402: Ultrasonic alarm sensors

Ultrasonic sensors operate above a frequency of 19 KHz and function similarly to microwave in many respects. They are based upon the Doppler theory and sense minute changes in forward and reflected waves caused by absorption characteristics of the intruder. Whereas microwave systems utilize super high frequency (SHF) radio waves, the ultrasonic device will transmit sound waves above the normal hearing range.

40_3.5.2.1 Passive Ultrasonic

The passive Ultrasonic sensor "listens" for ultrasonic sound energy that has a frequency range between 20-30 KHz in a

protected area. The frequencies in this range are generally associated with intrusion attempts representative of metal striking metal, hissing of an acetylene torch, and shattering of concrete or brick. The sounds thus generated are transmitted through the surrounding air and travel in a wave-type motion. The detector evaluates the patterns against stored characteristics.

Ultrasonic sensors are typically mounted on a wall or ceiling and are frequently used in tandem with another sensor, such as a passive device (Passive Infrared-PIR) to provide a greater probability of detection (PD). Environmental issues can increase FAR, depending upon the variability and uncontrollability of the characteristics of the zone. These devices are unaffected by heat changes within a protected area. Unlike microwave and radar, ultrasonic energy can be easily contained within a defined area because it does not pass through obstructions such as walls, roofs, or partitions. Unfortunately, waves do not pass through furniture or other obstructions such as boxes and crates and can thereby create dead zones which must be protected by other sensors.

False alarms and unreliable detection can result from a number of conditions:

- **Extreme changes in temperature or humidity from those conditions that existed at the time of installation and calibration;**
- **Any noise within the ultrasonic range;**
- **Air movement from heating and air conditioning systems;**
- **Drafts from doors and windows;**
- **Hissing from pipes;**
- **Dead zones which are created from objects and material that block transmission from sensors;**
- **Anything that causes movement, such as animals;**
- **The ringing of a telephone.**

Passive ultrasonic sensors have a limited frequency spectrum; sounds caused by an intrusion that fall outside the unit's spectrum (such as drilling), may not generate an alarm.

PASSIVE ULTRASONIC MOTION SENSOR

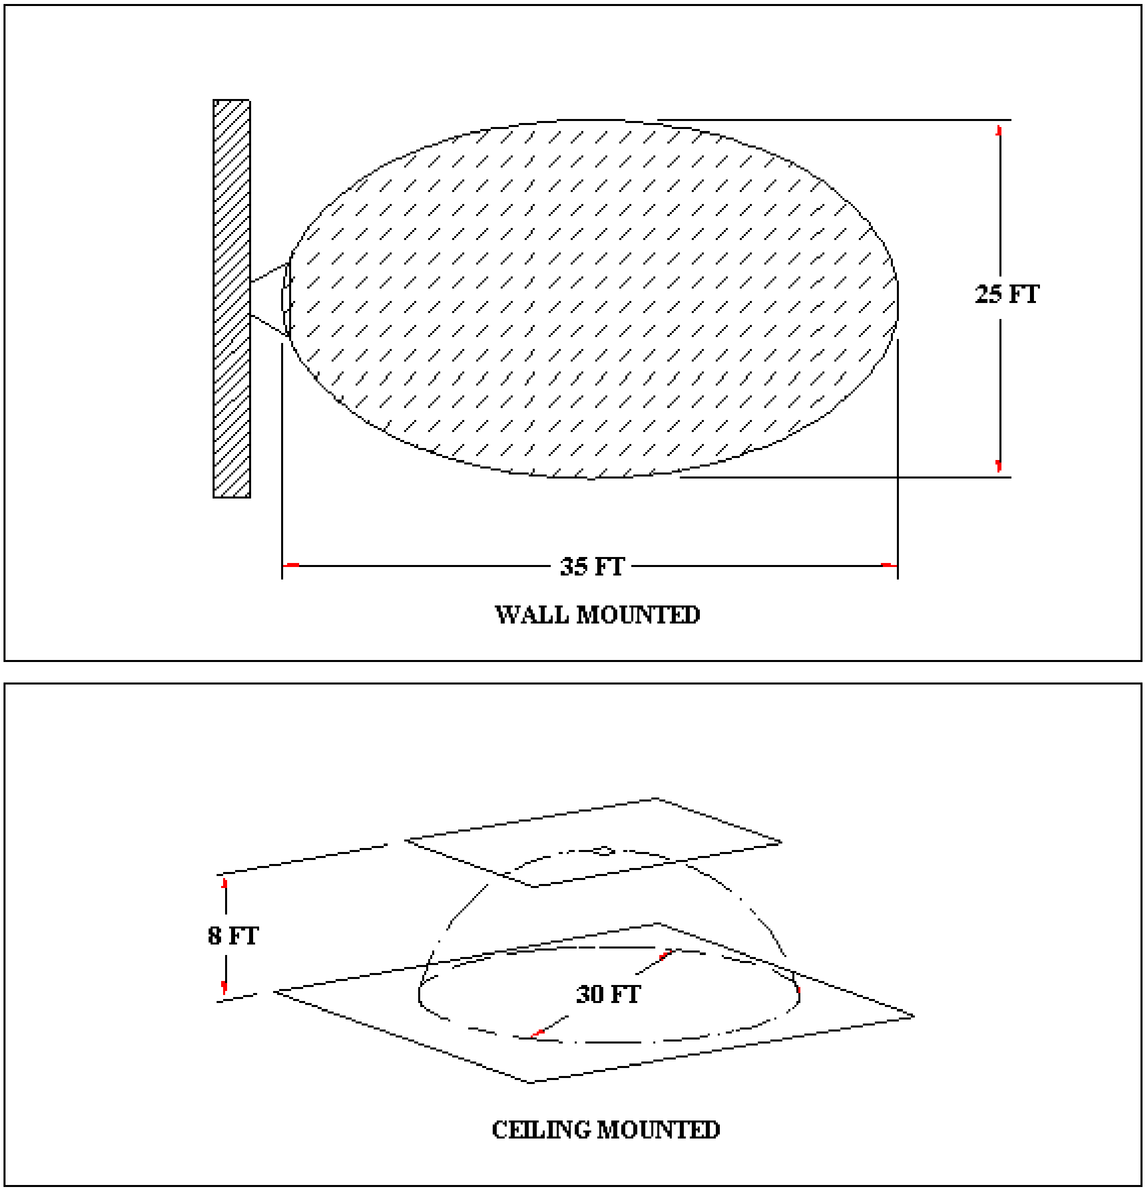


Figure LSS+4011 Passive ultrasonic motion sensor

40_3.5.2.2 Active Ultrasonic

The active ultrasonic sensor emits sound energy into a defined area and reacts to a change in the reflected energy pattern. These sensors operate on a theory based upon a frequency shift in reflected energy. Ultrasonic sound is transmitted from the device

in the form of energy through the air in a wave-type motion. Waves are reflected back to the receiver and provides a sound signature of the protected area. Any disturbance will cause the reflection to occur faster, thus changing the frequency slightly. Both passive and active ultrasonic sensors are installed in virtually the same manner.

Unreliable detection can result from many causes. See the listing of conditions in the above section.

Active ultrasonic systems can often be defeated by slow horizontal movement across the area of coverage. Proper calibration is critical to minimize this potential. A knowledgeable and properly equipped intruder can use special "test lights" to detect coverage patterns and circumvent these areas.

ACTIVE ULTRASONIC MOTION SENSOR

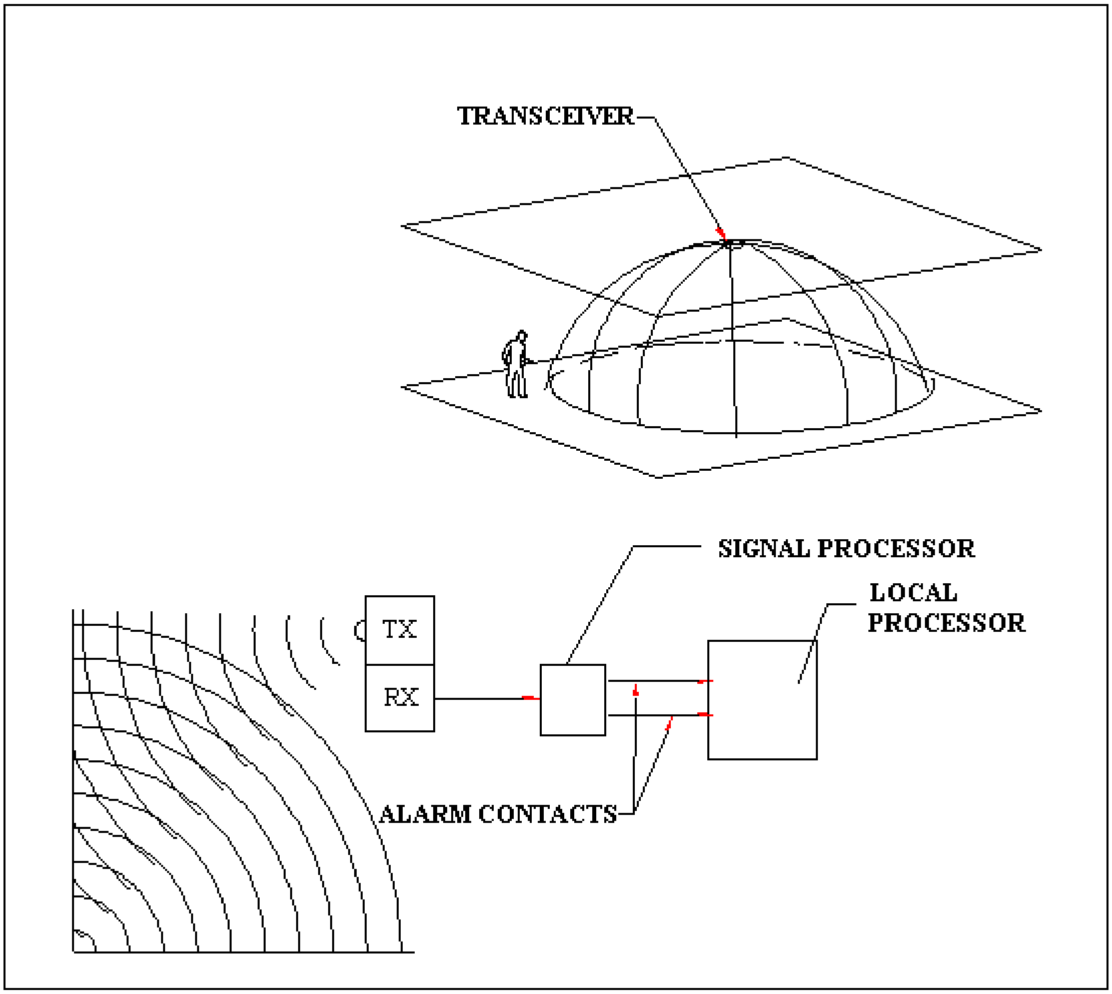

Figure LSS+4012 Active ultrasonic motion sensor

40_3.5.2.3 Audio Sensors

Certain sensors are designed to listen to the audible range for noises that are created by intrusion into protected areas. These detectors are generally utilized within structures rather than being subjected to the outside environment. The system is usually comprised of microphones (transducers) that are mounted on walls or ceilings, and a processor that analyzes noise signatures that are consistent with the protected zones and possible intrusion attempts.

It is essential in the design of these systems that sensors be

located in areas where the predicted intrusion noise will exceed the normal environmental noise floor. Failure to properly calibrate the detectors will result in noise masking, making it impossible to differentiate ambient from intrusion generated sounds. These sensors are generally utilized in conjunction with other systems, such as motion detection or photoelectric, to insure a high probability of detection. Sometimes, audio detection is combined with thermal imaging motion detection. This can provide for a record of both audio and visual tracking of a break-in. Audio sensors are particularly well suited to this application because they are not sensitive to the thermal environment and florescent lighting. If excessive background noise is present, the audio sensor should not be considered.

Erratic or unreliable detection can result from:

- **Improper setup and calibration that affects sensitivity settings either positively or negatively, causing the detector to react to extraneous background noise, such as clocks, office equipment, boilers and heating or air conditioning units;**
- **Excessive background noise, such as airplanes, trains or loud weather conditions (thunderstorms) may cause significant noise levels);**

Slow, deliberate actions by an intruder can defeat these sensors. Likewise, muffling the normal sounds of movement while intentionally allowing sufficient lag time to occur between any noise generated can bypass the detectors.

40_3.5.2.4 Acoustic Detection (Air Turbulence Sensors)

Acoustic air turbulence sensors detect low frequencies (within a range of 20 - 40 Hz, depending on the model) created by helicopters that are in their final landing phase or at close range (one to two miles), and are utilized for intrusion attempts. Some of the quietest helicopters, such as the Hughes 500C, Bell 47, Bell 206, and the Jet Ranger, have been detected at distances up to 500 feet. For increased probability and reliability of detection, detector sensitivity is typically set for a range of 300 feet.

Typically, such detectors are employed because traditional systems, such as perimeter and in-ground technology would be bypassed. These devices "listen" for basic sound pressure

generated by helicopter rotor blades and engine. There are four specific signatures that are sought:

- **Downward wash, caused by the energy that is required by the rotor blades to maintain airborne status;**
- **Blade slap, which originates from the forward traveling blade as it penetrates the trailing tip vertex remaining from the previous blade passage;**
- **Tail rotor, which is directly geared to the main rotor that generates harmonically-related frequencies;**
- **Engine noise, which is not usually muffled because of the power needed for rapid changes in flight performance.**

In order to assure reliable detection of inbound aircraft, regardless of their approach once they enter the protected zone, such areas should be covered by overlapping sensors. With proper design, there is no restriction on the distance of sensors from the main control unit; thus, zones of protection can extend for miles.

Unreliable detection and false alarms can result from the following causes:

- **Location of sensors near to any vehicular or road traffic, especially truck movement;**
- **Location of sensors near railroad right of ways;**
- **Location of sensors near anything that generates pressure or wind turbulence. Sensors are particularly sensitive to broadband noise;**
- **Turbulence generated at a distance and conveyed by air pressure propagation;**
- **Pressure caused by wind viscosity and the roughness of the terrain;**
- **Sensitivity settings set too low to compensate for vehicular traffic;**
- **Improper spacing of the sensors, allowing some areas not to be covered by the detection pattern.**

These systems will not detect airborne assaults that utilize other flying technology, such as glider, parachute, or ultra light.

Figure LSS+4035 Logistic/munitions storage complex

40_3.5.2.5 Defeat Techniques for Infrasonic and Ultrasonic Sensors

Sensors that utilize sound, either below or above the normal range of hearing, are subject to defeat by employing a variety of techniques. These are summarized for all forms of sound energy sensors. It should be noted that these systems, which operate between 20-45 KHz. may bother pets, due to their increased sensitivity to sounds above the normal range of human hearing. This may provide an indication that ultrasonic energy is present.

Infrasonic

- Entry through opening that does not create infrasonic waves, such as a sliding door or window;
- Concealment within protected area;
- Masking detector;

Active Ultrasonic This type of sensor is more sensitive to motion toward and away from sensor.

- Very slow intrusion speed and movement, thereby avoiding a significant Doppler shift;
- Use of ultrasonic energy-absorbing blanket or material, including aerosol Styrofoam filler;
- Blocking the transceiver or using an object to block the transmitter;
- Spoofing the sensor into believing it is secure. Use Freon gas, water or similar substances;
- Create a loud noise to create a false alarm;
- Use of a high power transmitter at the same frequency;
- Use crosswalk motion;
- Take advantage of man made or natural barriers that create a path past the sensor detection pattern;
- Bypass the sensor circuit while the system is disarmed;

Passive Ultrasonic

- These sensors have a limited frequency spectrum of sensitivity. Exploit the fact that certain intrusion sounds outside of the sensitivity of the sensor (such as drilling) will not activate it;
- Alarm stacking;
- Bypass the sensor circuit while the system is disarmed;

Active Sonic

- Use of very slow movement by intruder;
- Use of energy-absorption blanket or other material;
- Block the transceiver by using tape or other material;
- Take advantage of natural barriers in the protected area to avoid detection;

Spoofing;

- Alarm stacking;

- Bypass the sensor circuit while the system is disarmed.

40_3.5.3 Operational Difficulties with Volumetric Systems

Volumetric sensors are prone to technical operating problems and failures if they are not installed correctly. The following guidelines apply to their use:

- **RF fields in microwave systems may penetrate through walls into adjacent facilities, registering movement in areas not intended to be monitored. This can cause a false alarm;**
- **Propagation patterns for microwave systems may not completely cover a desired space. This can be due to irregular shapes of rooms to be protected or a shielding effect of items within the coverage area;**
- **Frequent false alarms may result if precise testing is not periodically done for a specific area, in order to take into account physical differences;**
- **Ultrasonic systems will not penetrate adjacent walls, ceilings or floors;**
- **Ultrasonic sensors will detect heat and can be triggered by hot air turbulence;**
- **Ultrasonic detectors may register a false alarm from heating and air- conditioning equipment, sonic booms, thunder, jet aircraft, and other shocks;**
- **Ultrasonic systems, unlike microwave, cannot be set to protect a close pattern or area;**
- **Microwave is more stable than ultrasonic.**

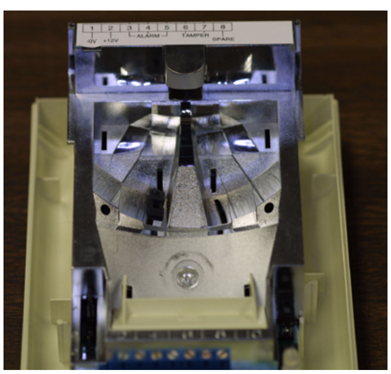
40_3.6 Heat Detection: Passive Infrared Sensors

LSS401: Outside passive infrared sensors

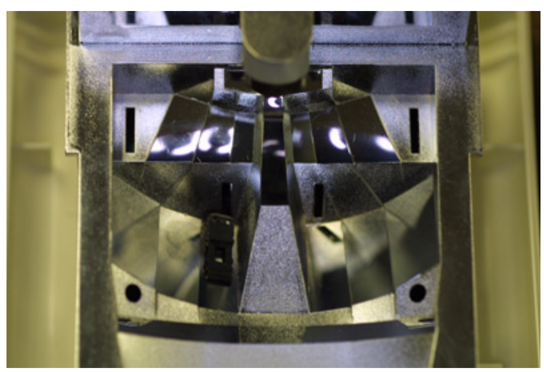
LSS401: Thermal imaging and sensing

LSS402: Passive infrared sensor technology

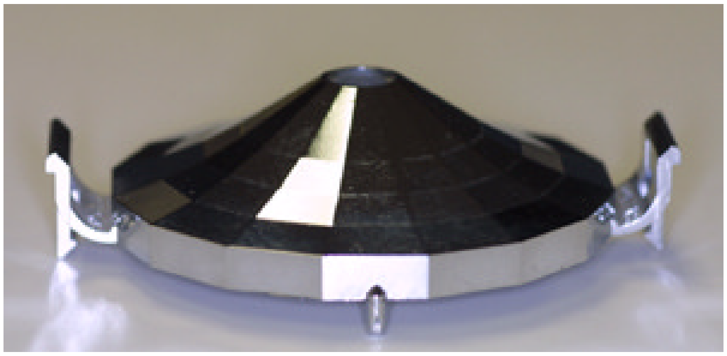
Figure LSS+4051 A thermal imaging sensor will detect body heat of an intruder.



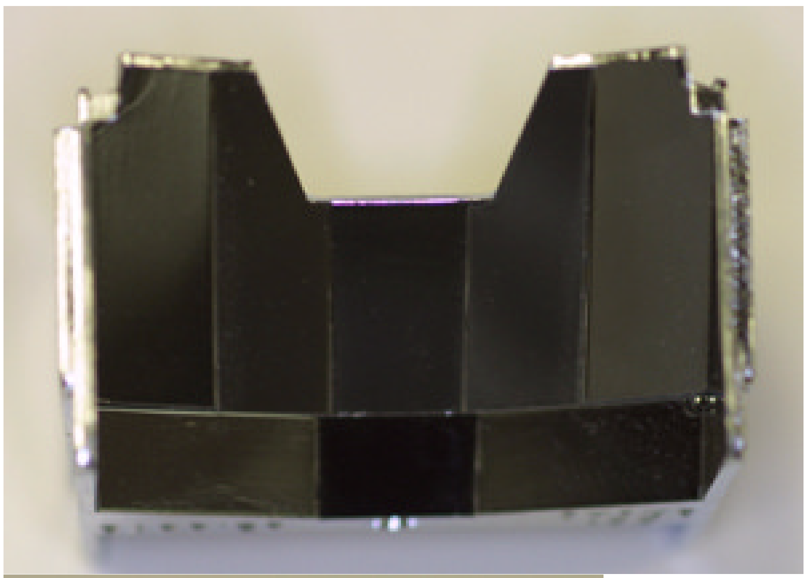
The wavelength of infrared radiation lies between .7 - 100 µm in the electromagnetic spectrum, and is slightly higher than radio waves. It is not visible to the human eye but is perceived by the heat receptors of the skin. Energy in the form of rays is transmitted or reflected by all objects, even a block of ice. The amount of radiation and its frequency are dependent upon and directly proportional to structure and temperature of the surface. Thus the sun, having a surface temperature of 6000 C, radiates IR in the visible spectrum at a wavelength of .3-.8 µm. In comparison, the human body gives off energy at a frequency of 7-14 µm. In order to avoid capturing environmental thermal deviations, rate of change measurement circuitry or



bi-directional pulse counting circuitry is employed.

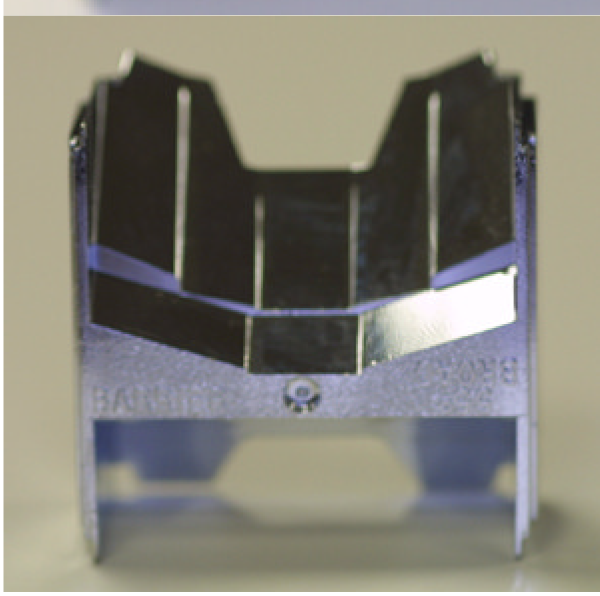


The PIR wavelength is subdivided into two major range detection categories: one covers **near infrared energy** (e.g. thermal energy emitted by TV remote control devices), and the other covers the **far infrared energy** (e.g. thermal energy emitted by people). It is this latter category which is employed in security applications.



The infrared sensor will detect a narrow frequency band of radiated energy in the target area. It is referred to as a passive device because it receives its information from the area being monitored, but does not transmit any energy. Power consumption is low, in contrast to active devices such as microwave that require emission of RF.

Passive IR devices are constructed with a multi-segment concave mirror and infrared measuring sensor at its focal point. The shape, size, and number of such segments will vary, depending upon the design of the detector and the coverage pattern. Some areas of the mirror will be sensitive to IR; others will not. The sensor head is typically divided into several sectors or zones, each correlated and defined for specific boundaries. Detection occurs when thermal energy is emitted from a heat source and this energy crosses two adjacent sector boundaries or crosses the same boundary twice within a specified time.



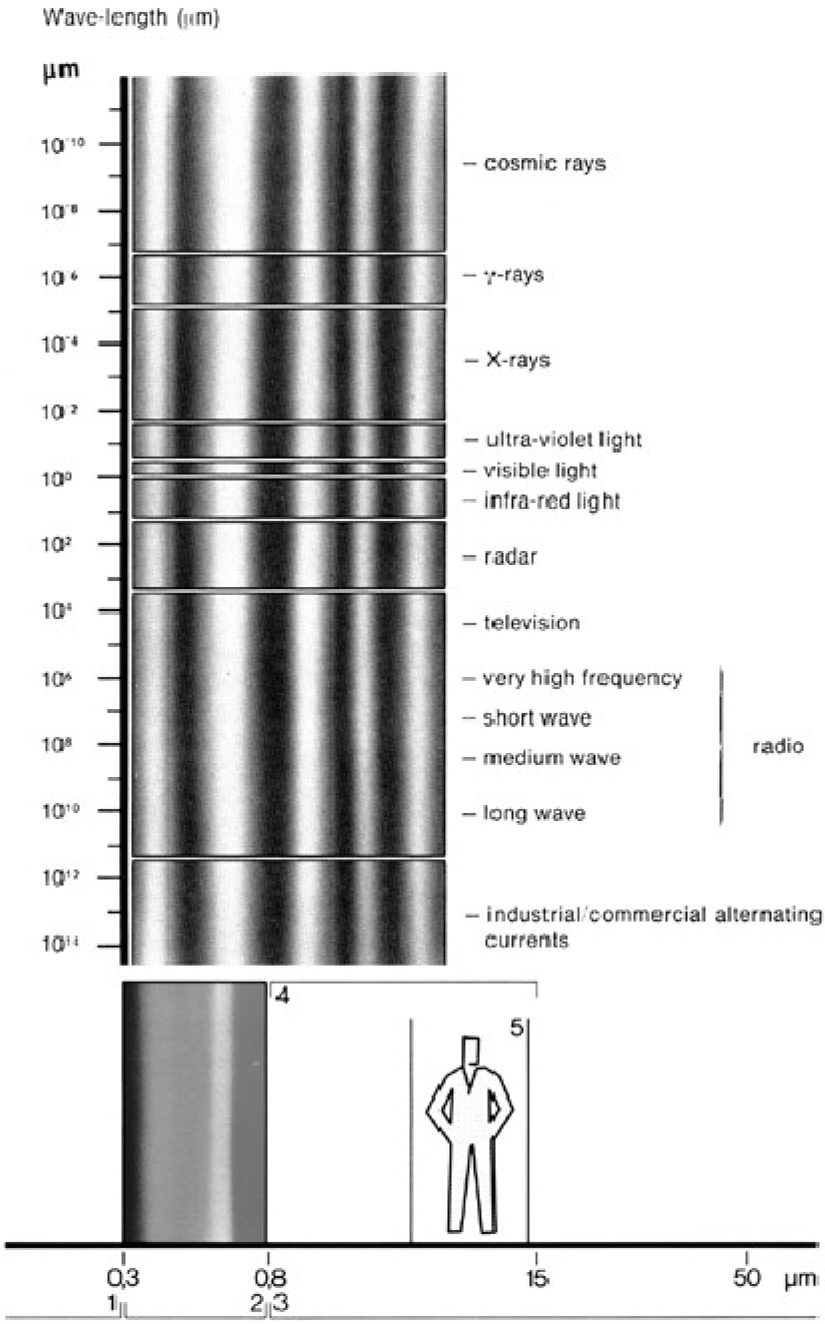


Figure LSS+4052 A variety of lens configurations are utilized for infrared sensors to

focus energy on the sensor and create zones of protection.

The processor will compare the intensity of signals between a moving object and its background, taking into account distance. A threshold value will be set to minimize false alarms. There must be a sudden, rapid, and substantial increase in energy before a valid alarm is triggered. Temperature variations caused by heating, air-conditioning or blowing wind will not be recorded because they do not occur rapidly enough. Passive IR devices operate within a temperature range of –10 C to +50 C.

These sensors detect (but do not measure) electromagnetic radiated energy generated by sources that produce temperatures below that of visible light. They are sensitive to the change of thermal radiation. PIRs "see" or "detect" infrared "hot" images by sensing the contrast between the "hot" image and the "cooler" background.

In rate of change measurement, the processor evaluates the speed at which the energy in this field of view changes. Movement by an intruder in the field produces a very fast rate of change, while gradual temperature fluctuations produce a slow rate of change. In the bi-directional pulse counting technique, signals from separate thermal sensors produce opposite polarity. An unprotected or unshielded human that enters a field of view and moving at a typical speed (walk or above) will normally emit or produce several signals which allow detection to occur.

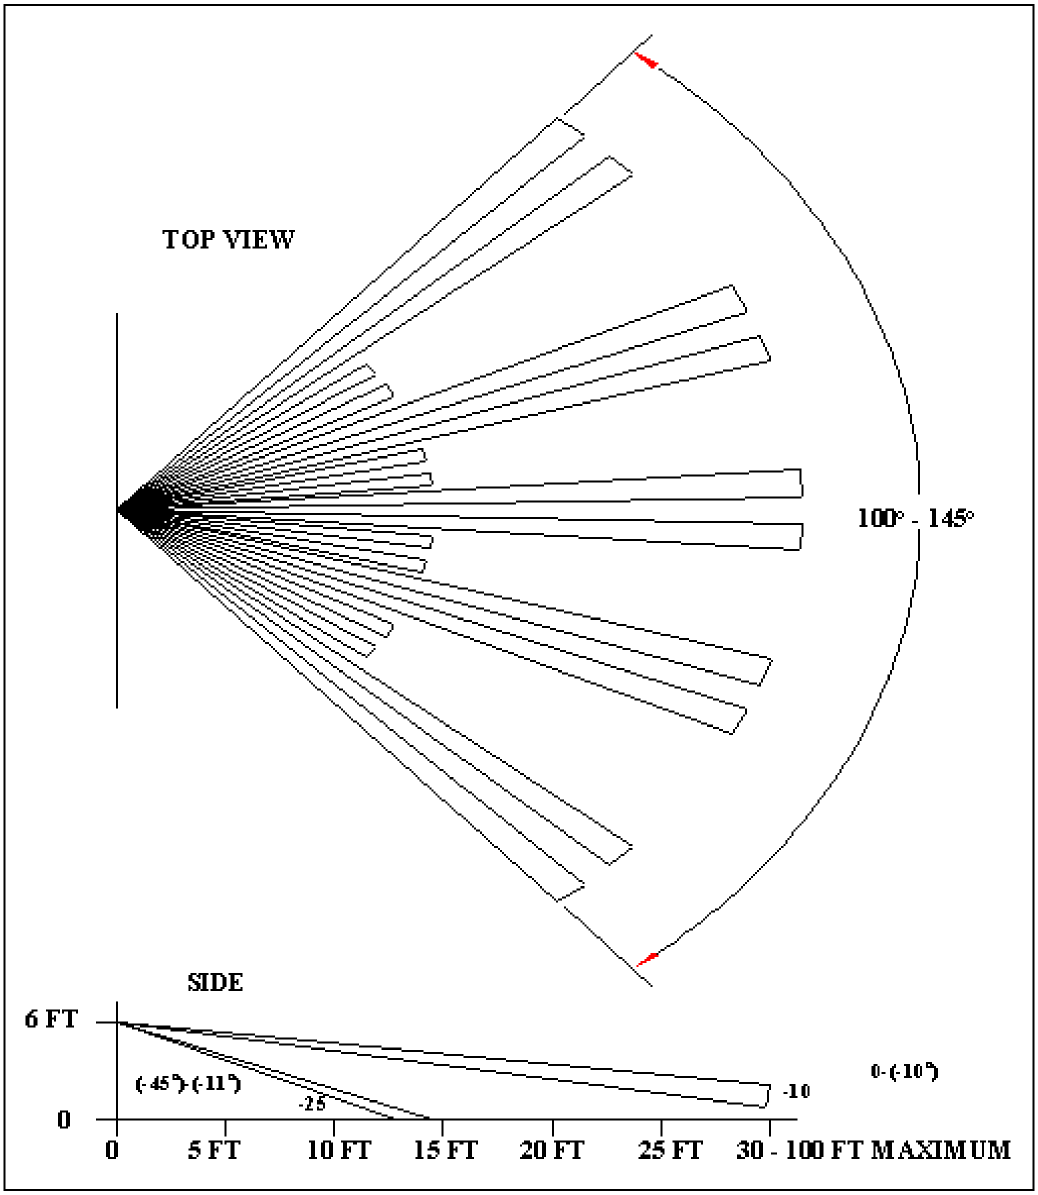
Optics and reflective principles play a very important role in the design and function of PIRs. Because of the need to precisely focus thermal radiation, the reflection and focusing of the energy waves is done in two ways: r**eflective focusing** and the **fresnel lens** method.

Reflective focusing: The energy waves are reflected off a concave mirror and directed into the sensing element. **Fresnel lens:** This technique allows the energy to travel directly to the sensor. Both methods use some type of protective covering on the sensor, so that the loss of some energy is unavoidable. The performance of both sensors is excellent.

Passive infrared sensors are usually installed on walls or ceilings, aimed at and defining the desired protection zone. Each detection/surveillance zone can be thought of as a "searchlight" with the beam width gradually widening as the zone extends farther from the sensor. Different segments will be illuminated while others are "dark". This design characteristic allows the user to focus the "beam" on areas where protection is needed while ignoring other areas, such as known sources of false alarms. Tower or ceiling-mounted PIRs theoretically provide a 360 degree detection pattern.

A PIR looks for thermal radiation projected and in contrast with a cooler background; its sensitivity is based upon the detection and comparison of temperatures. As the environment approaches the same temperature as the intruder, the detector become less sensitive. This is especially true for environments ranging between 80-100 degrees. Theoretically, if a person was radiating the same temperature as the environment, he would be invisible to the sensor.

There are several reasons for false alarms:



- **Heat radiating from small animals or rodents;**
- **Time-activated space heaters, ovens and hot water pipes within the field of view;**
- **PIR sensors that are not designed with the capacity to ignore visible light can be affected by car headlights or other sources of focused light;**
- **Objects in a room can become heated over time and subsequently begin emitting or reflecting infrared energy. This can occur from sunlight. If the light is, in effect, turned on and off, such as by the movement of clouds, an alarm can be generated.**

Figure LSS+4053 An infrared sensor is blocked from proper operation. The sensor is on the far wall in the corner.

Shadowing, cloaking or masking the intruding heat source from the field of view can decrease the probability of detection. This is because it reduces the possibility of sufficient radiated or emitted heat from being focused on the thermal sensor. A knowledge of the dead spots of the detection pattern can permit an intruder to bypass active regions. Walking **into** the sensor rather than **across** the sensor's field of view can also reduce the detection capability. In the photograph above, the sensor is located in a warehouse and is blocked by storage of items, greatly reducing its reliability.

PASSIVE INFRARED SENSOR

THE NUMBER, RANGE, AND PROJECTION ANGLES OF THE DETECTION BEAMS VARY DEPENDING UPON DESIGN.

Figure LSS+4016 Passive infrared

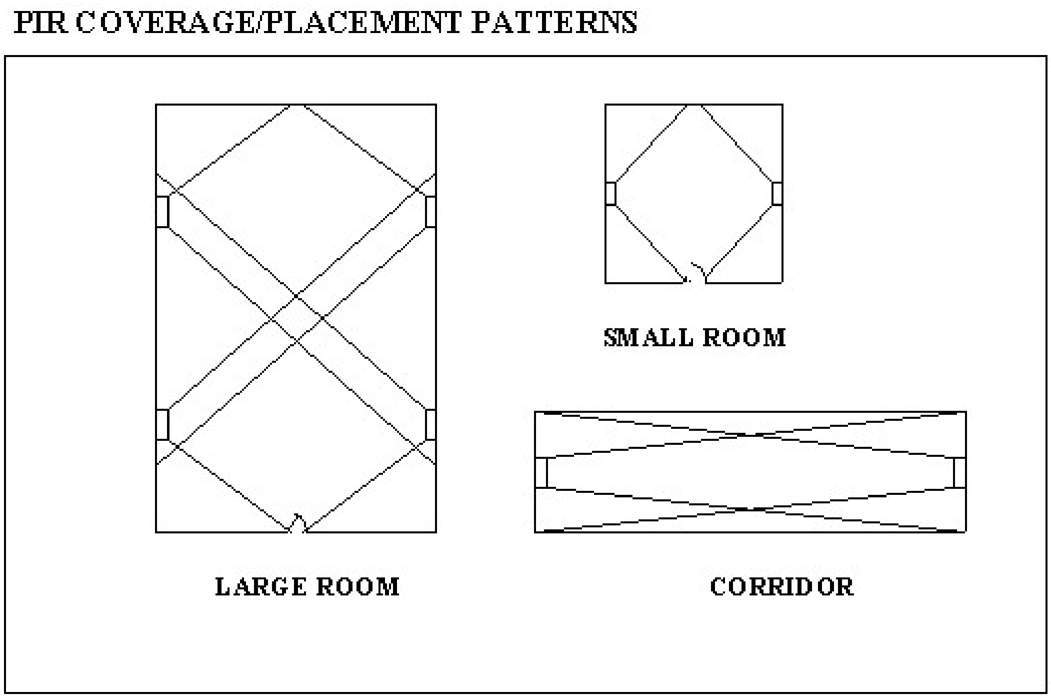

Figure LSS+4017 PIR coverage/placement patterns

40_3.6.A Interior Active Infrared

Interior active infrared sensors transmit a curtain-pattern of modulated infrared energy for a designated area of protection. The sensor reacts to a change in the modulation of the frequency or an interruption in the received energy, both caused by an intruder.

These sensors are comprised of a transmitter and receiver that are packaged within a single unit. A laser is utilized for the source. Its plane is projected onto a special retro-reflective tape that is employed to defines the end or edge of the protection zone.

Energy is reflected from the tape, back to the receiver. This energy passes through a collecting lens that focuses the rays onto a cell which then converts the IR to an electrical signal. The processor evaluates the signal level: if it drops below a specified threshold for a defined period (caused by an intruder), an alarm will be generated.

Depending upon the reflectivity of the tape, coverage patterns can be between 15-25 feet wide by 17-30 feet long. The laser plane angle can be adjusted from 37º to 180º. The temperature of the environment nor the speed or direction of the intruder have any affect on detection characteristics. Thus, the systems are quite reliable.

There are a number of conditions that can cause unreliable operations or false alarms:

- **Dust or other particles collecting on the surface of the reflective tape;**
- **Any degradation of the detection capabilities of the sensor;**
- **Reflective tape must have no gaps and be continuous;**
- **The angle from the sensor to the ends or corners of the tape must not exceed 45 degrees;**
- **The activation of an incandescent light which shines directly into the sensor;**
- **Incandescent lights greater than 100 Watts (or sunlight) falling directly in line with the tape will be reflected back to the receiver with a sufficient magnitude to trigger an alarm;**

Interior active infrared systems can be defeated by the avoidance of the projected laser plane by a knowledgeable intruder. He can determine the location of the field of the potential detection pattern from the placement of reflective tape; he can then plan his movements to avoid detection.

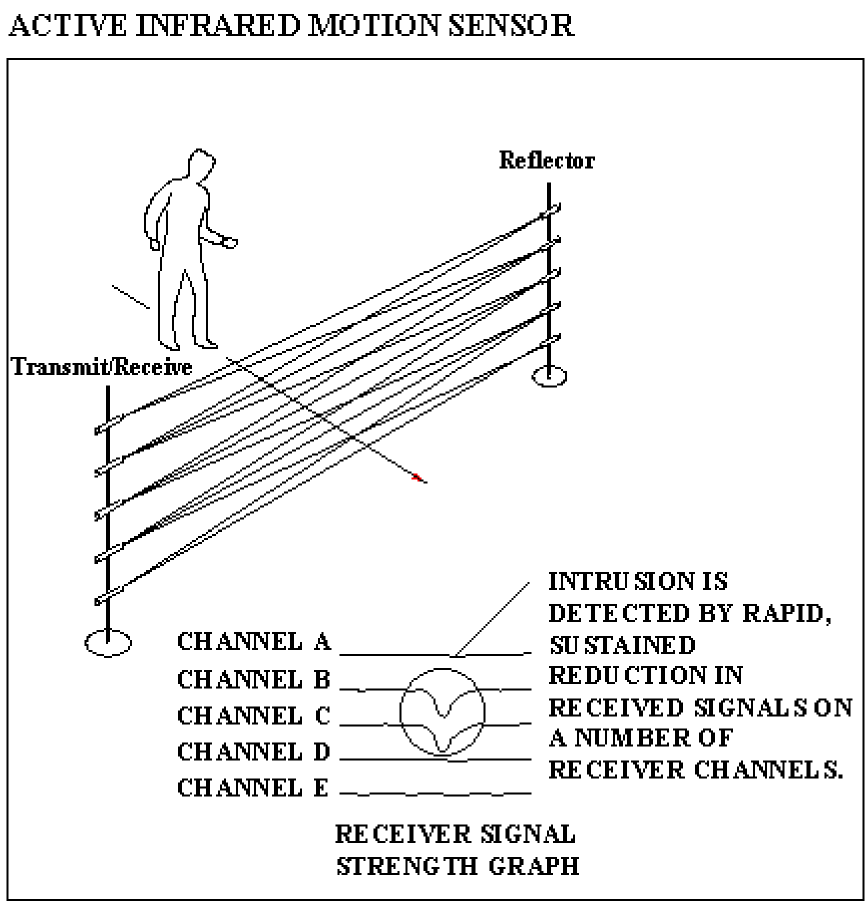

Figure LSS+4018 Active infrared motion sensor (Interior)

40_3.6.B Exterior Active Infrared

In the active infrared design, the transmitter and receiver are separated by the protected zone. A modulated multiple frequency straight-line beam is generated, producing an electronic fence, much like the photoelectric beam system. An interruption in the received energy or the modulating frequency can trigger an alarm.

These sensors are line-of-sight devices, and therefore require that the area between the two units must be uniformly level and clear of all obstacles and obstructions. Holes can be created in coverage by low spots in the terrains that will disrupt the "coverage" pattern. Typically, active infrared systems are employed in conjunction with a single or double fence barrier which defines the perimeter to be covered. A sensor zone length

can extend up to 1,000 feet.

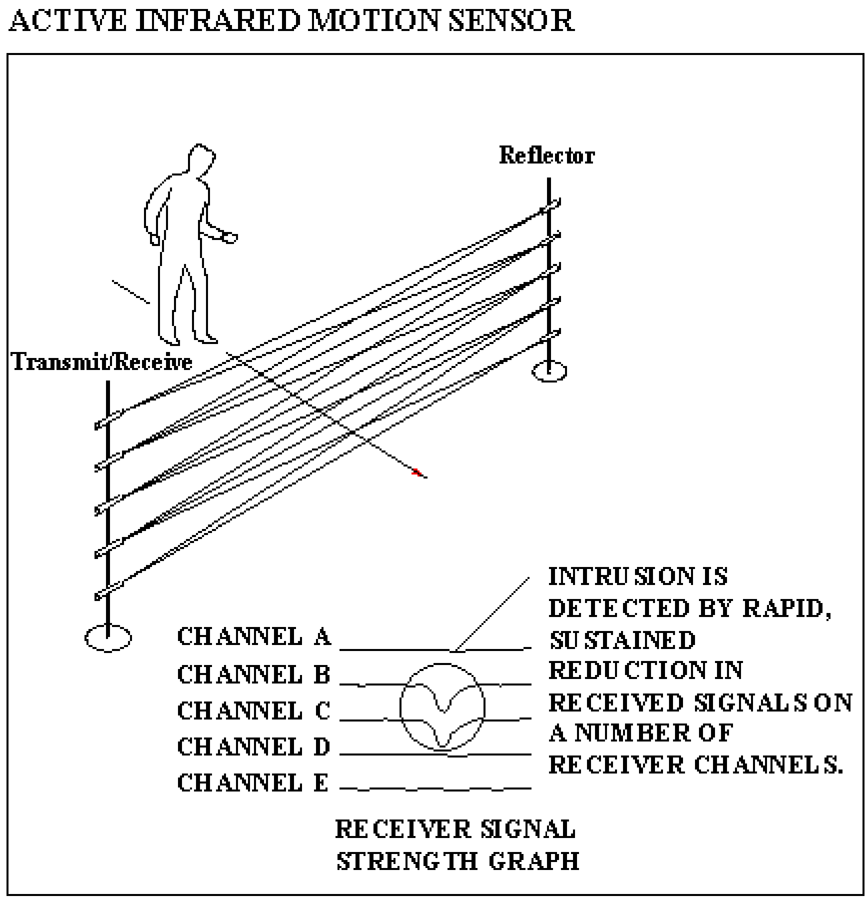
As with all other optical detectors that utilize separate transmitter and receivers, precise alignment of the emitter-receiver path is critical for reliable detection. The beam width is relatively narrow and requires regular calibration and realignment on a frequent basis. Misalignment can be caused by a number of issues:

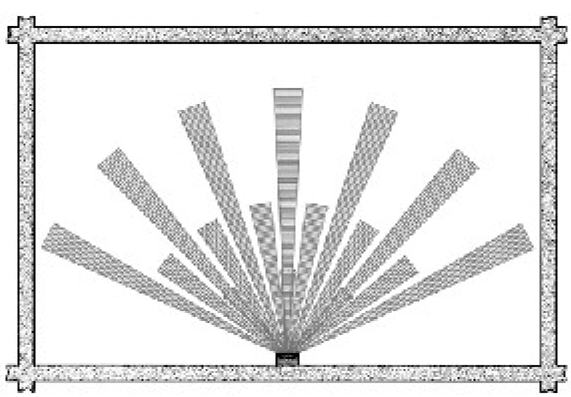
- **Movements in the ground (e.g., earth tremors);**
- **Objects hitting the unit (e.g., falling rocks, vehicles, falling trees);**
- **Freezing and thawing of the ground;**
- **Dirt and dust build-up on the receiver or transmitter;**
- **Inadvertent movement of objects into the transmission path;**
- **Extremely heavy snow or rain.**

Reliable operation and detection can be insured in the following circumstances:

- **Freezing ground or extreme winds: deep foundations for the mounting of transmit and receive sensors to minimize movement;**
- **Sensor hitting or jarring: install protective barriers around the sensors;**
- **Snow and grass around the sensors: remove by hand or blower to prevent damage or misalignment;**
- **Poor weather conditions, such as fog, heavy rain, or severe dust or sand: consider another technology, or decrease detection zone to compensate for energy attenuation;**
- **Interaction of animals in the protected area: provide barriers to entry;**
- **Vegetation: do not let it grow to a size that its movement will interfere with the IR path.**

Bridging or tunneling is a common method of defeat. There should be no dips or gullies between transmitter and receiver, or they should be brought to a uniform level. The pedestals or columns that the sensors are mounted on can be utilized to support vaulting over them. Overlapping beams can prevent this practice.





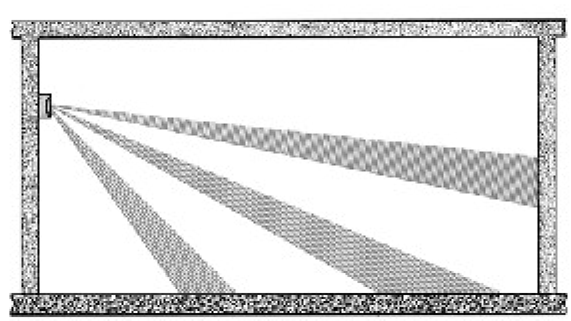


Figure LSS+4019 Active infrared motion sensor (Exterior)

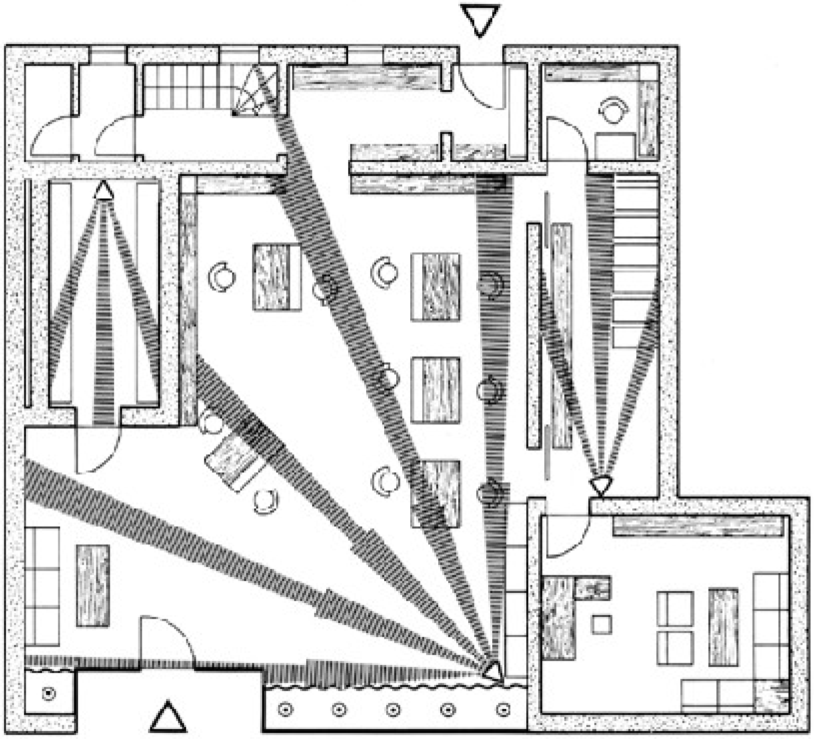
40_3.6.1 Guidelines for Installation of IR Devices



Although passive infrared detectors are an extremely reliable

component of an alarm system, they must be installed correctly to avoid loss of sensitivity and false alarms. The following guidelines apply:

- **Sensors must not be installed so that they face the sun;**
- **Most sensors are designed for indoor use, although some "single beam" devices are available for external application;**
- **Use of different reflectors allows the coverage pattern to be modified. Thus, most sensors can be utilized for any surveillance requirement;**
- **A reduced monitoring angle allows for an increased range, and vice versa;**
- **Sensors can typically monitor an area of up to 60 meters, with a horizontal angle between 7°-120°;**
- **Depending upon the use (trap or room monitoring), the detector should be installed at a height of between 1.5-3 meters;**
- **Individual reflectors within a sensor can be manipulated to control coverage patterns;**
- **False alarms can be caused by detectors responding to rapid changes in radiated energy. Conditions that must be avoided will include:**
    - **Light bulbs being turned on and off;**
    - **A swinging lamp shade;**
    - **Filaments in fan connectors;**
    - **Sunlight interrupted by passing clouds;**
    - **Automobile headlights;**
    - **Humidity;**
    - **Sharp temperature changes;**
    - **Naked flames;**
    - **Direct sunlight.**
- **Pets can trigger an alarm. They should be kept out of areas that are monitored;**
- **Insects can cause a false alarm, thus an insect-repellent strip should be placed near the sensor;**
- **A detector can be desensitized by heating systems and warm-air vents. A sensor must be installed an adequate distance from heat sources;**

- **Ambient temperatures of 32 C to 38 C are unsuitable for fully effective operation of sensors;**
- **Furniture and other components can cause shadow zones in monitored areas because IR energy cannot penetrate such materials. These shadow zones provide the potential for compromise of the system and should be minimized;**
- **A sensor can be neutralized if its optical devices are covered with IR blocking materials before the alarm is set. Most sensors do not contain supervision circuitry to detect this condition;**
- **Sensors can be bypassed and compromised with insulating clothing having a low emissivity. This allows an intruder to appear to radiate the same temperature as the background. Many of the sensors will detect a change in the IR signature of a room, even if the temperature corresponds exactly with that of an intruder. In such a case, the radiation pattern and intensity of a moving person will change. If the sensor stores information about the "normal" signature, then the difference will be detected;**
- **Sensors can be activated by flash flames, or by hot water being poured under a door.**

40_3.6.1.1 Defeat of Infrared and Other Heat Sensors

There are many ways to defeat, bypass, or circumvent these devices. The techniques are summarized below, for exterior and interior applications.

Heat Sensors

- Avoidance, use of non-heat producing methods of attack;
- Bypass sensor circuits while the system is disarmed;

Interior Sensors

- Avoid the sensor. Use the walk-test light to determine boundaries of detection patterns while the system is disarmed;
- Mask the generation or detection of infrared energy by using petroleum jelly, Vaseline, silicone, hairspray, paint, or other foreign substance such as white-out, or an energy absorbing material such as cardboard;
- Utilize mylar covering that will not transmit any body heat;

- Block the detection of IR by taking advantage of man-made or natural barriers in the field of view of the sensor in order to allow penetration into the protection area;
- Use a cardboard box that is allowed to reach room temperature and is placed in the field of view of the sensor, thereby creating a corridor to run past the detection pattern;
- Introduce a higher temperature into the protected area, thus making the sensor less sensitive to temperature changes;
- Use very slow movement by the intruder as he advances toward the detector, taking advantage of the mounting location of the sensor;
- Bypass the sensor circuit while the system is disarmed;

Exterior Sensors

- Avoidance of detection pattern;
- Tunneling under detection pattern;
- Bridging, two-man or pole vaulting over detection zone;
- Masking, by use of petroleum jelly, Vaseline, silicone, hairspray, paint or other foreign substance such as white-out or an energy absorption material such as cardboard;
- Blocking of the sensor, by taking advantage of natural or man made barriers in its field of view, to allow penetration past the detection area. Barriers such as washouts, depressions or snowfall will provide the required cover;
- Exploit detection sensitivity during high outside temperatures when the ambient temperature approaches skin temperature;
- Alarm stacking;
- Determine best intrusion path by walking directly into the sensor. This will reduce its detection capability.

40_3.7 Video Monitoring Systems

LSS401: Video logging and capture systems

LSS403: DOE on alarm assessment

Closed-circuit television can be effective for surveillance of a defined area. Local and remote monitoring of video images is now economically and technically feasible via the Internet. In the

photographs below, several wired (visible and covert) and wireless cameras are shown. Both monochrome and color cameras can be hidden virtually anywhere, and an image monitored at a remote location. Video can be stored on tape, hard drive, optical device, or solid state memory. Video surveillance systems are being employed to an ever increasing degree in public areas, transport, schools, and airports. Extremely sophisticated capture and logging systems have been implemented, especially at security check points, to allow for instant playback and transmission of images to law enforcement and security officers. See **chapter 39** for a more thorough discussion of video systems.

The inherent weakness of any video surveillance system is its operator, due to fatigue and monotony. Thus, an effective system must have the capability to direct the operator's attention to a specific camera display that is triggered by an alarm condition. An intruder must be easily recognized as a result of the image quality, field of view, and picture size. The system must be tamper-resistant, and alarm upon a loss of video. Recorders should operate in an automatic mode upon receipt of an alarm. All images must be buffered, so that there is no loss of data for pre-alarm, alarm, and post-alarm conditions.

ADEMCO
VIDEO
Quartz

40_3.7.1 Video Motion Detector

Images from video cameras, low light level devices, and those that function in the IR range are fed to motion detection sensors to provide for alarm notification in case of intrusion. The systems allow human evaluation of an alarm condition and also provide the means to document the event. These systems employ sophisticated processors to constantly compare a captured image and the "current" view, or compare images in sequence to detect changes in targeted areas. Any movement in the target field, or a

substantial change in lighting over a short period can trigger an alarm.

Video motion detection and analysis systems allow the manipulation of images in terms of zoom, pan, tilt, focus, and contrast, to permit the targeting of specified areas of a picture. Audio monitoring features may also be available. In some instances, cameras are secreted throughout a protected area; in other cases, they are visible and act as a deterrent.

Cameras must be properly installed, positioned, and set to protect the intended area and capture relevant images. Care should be taken to analyze lighting conditions to insure that the target area is sufficiently lit to insure the capture of a useable image.

The use of video as a monitoring system has many applications both overt and covert, and provides excellent redundancy to existing alarm sensors. Some examples of the use of video include:

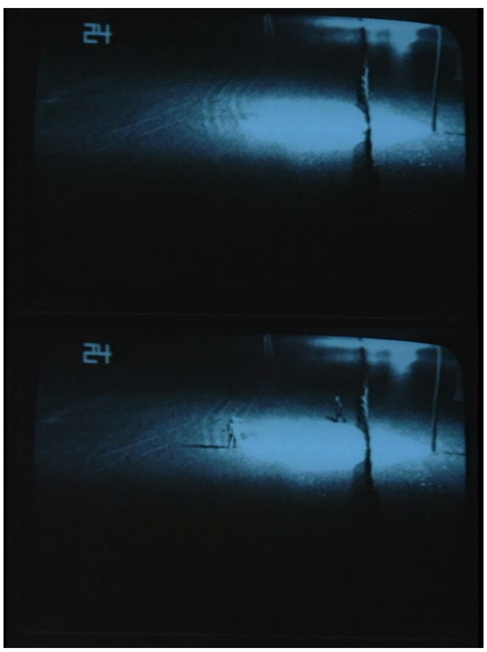
- **Dead zones between two fences;**
- **Security check points;**
- **Gates;**
- **Fence lines;**
- **Outside storage lots;**
- **Interiors of warehouses (particularly at night);**
- **Approaches to "rear doors";**
- **Vehicle/pedestrian entry points;**
- **Loading docks;**
- **Guard posts where the CCTV system can be tied to a Duress Alarm;**
- **Secure internal areas, such as counting rooms, alarm centers, equipment storage, telephone and communications centers;**
- **Interview and interrogation rooms.**

Installation guidelines include:

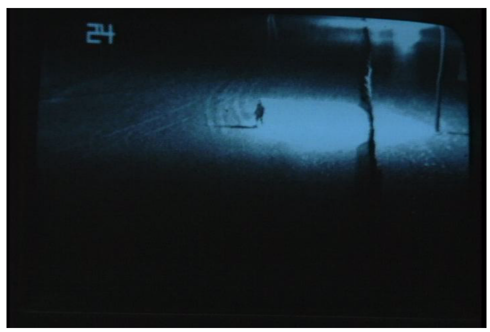
- **Securely mount the cameras;**
- **Deny easy access to cameras and mounts, as well as video recorders that capture information;**
- **Maintain the field of view of the camera as open and uncluttered as possible;**

- **Reduce or eliminate vegetation and obstacles to visual observation.**

Unreliable or erratic operation will result under the following conditions:



- **Camera pointed towards high intensity lighting;**
- **Poor lighting characteristics or extended periods of darkness in targeted zone;**
- **Improper hardware selection. In some circumstances, low light level or IR sensitive cameras may be better suited to the task;**
- **Improper placement of the camera that does not allow a full field of view of the target area;**
- **Changes in angle of lighting from the sun;**
- **Changes in brightness from movement of cloud motion;**
- **Wind-blown objects passing in the target area;**
- **Camera vibration due to wind;**
- **Light source interference, such as from reflected light, headlights, traffic lights, or security lights pattern change;**
- **Flying insects near the lens;**
- **Dirty or dust-covered lens.**

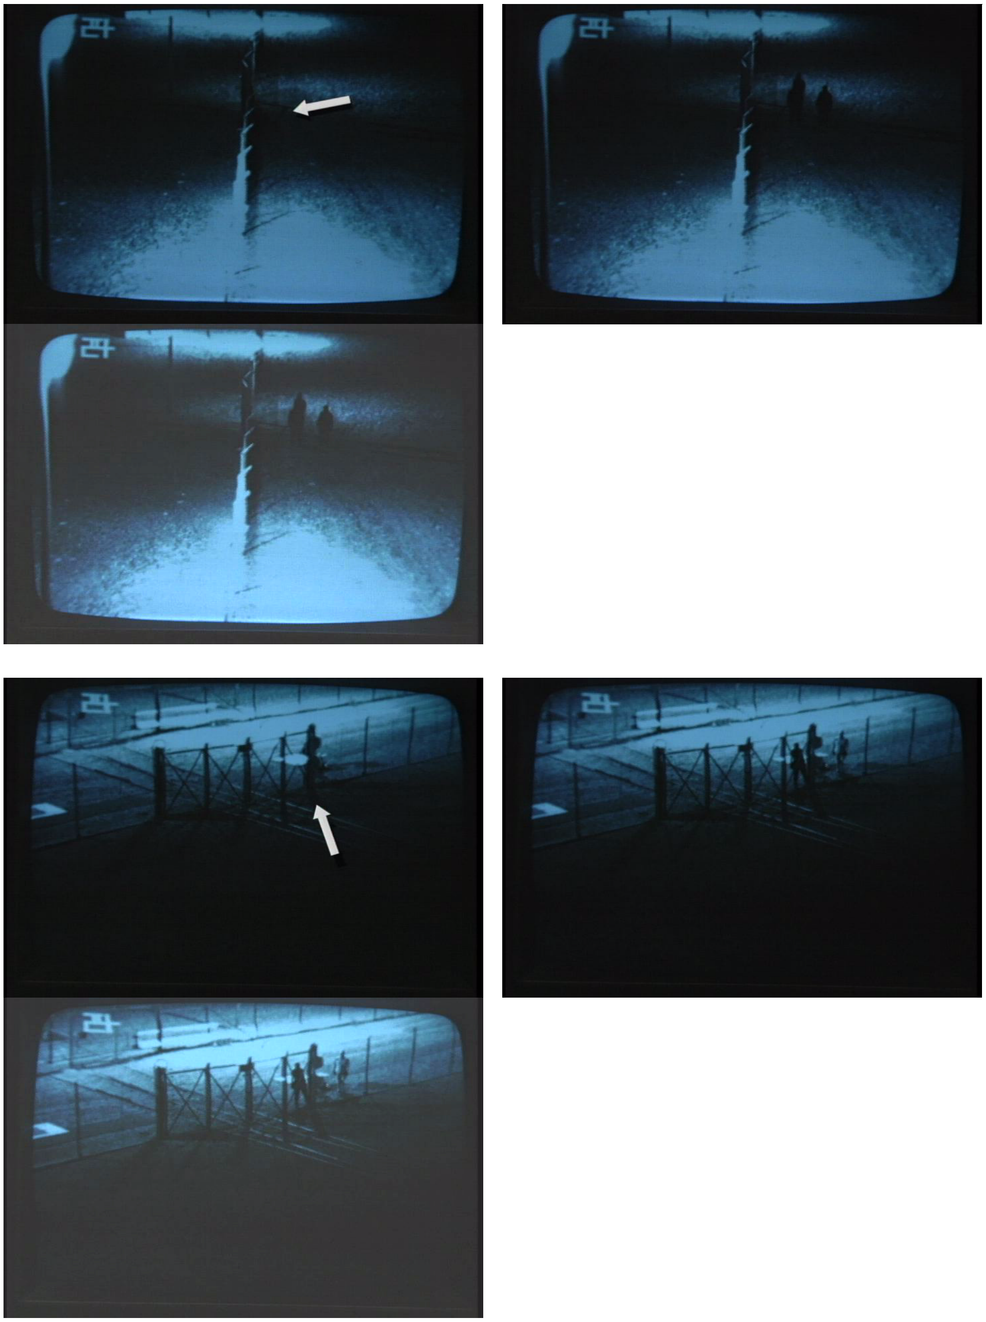


40_3.7.2 Defeat of Video Systems

Improperly installed or maintained systems can be bypassed or neutralized through a variety of techniques that are described in this section. If a knowledgeable intruder can determine the coverage area of the camera, he may be able to avoid detection by moving around, under, or over the field of view. Camera systems can be defeated by blinding, stacking, camouflage or concealment from view. Defense-in-depth, providing for supplemental systems such as motion sensing, should always be deployed to provide for reliable detection. Primary security issues that involve video hardware include:

- **Video multiplexers can be disabled, which will result in a failure to monitor any camera;**
- **Blinding of the camera through the use of infrared light sources;**
- **Stacking of alarms to distract the operator;**
- **Camouflage or concealment of intruders;**
- **Programming errors, either deliberate or inadvertant, may**

render the system insecure;
- **Monitors can be viewed by non-security personnel;**
- **Cameras can be destroyed or damaged. Lenses can be smashed or sprayed with material to make them unusable;**
- **Video recorders may not be properly maintained, resulting in dirty recording heads, erratic mechanical operation, or tape jams;**
- **Video recorder input settings may be tampered with;**
- **Tapes can be stolen;**
- **Failure to properly archive tapes;**
- **Storage of tapes near strong magnetic fields;**
- **Failure to maintain a retention policy;**
- **Use of poor quality or substandard tapes;**
- **Use of old time-lapse recording technology which is inherently unstable;**
- **Use of old tape with drop out errors or media failure;**



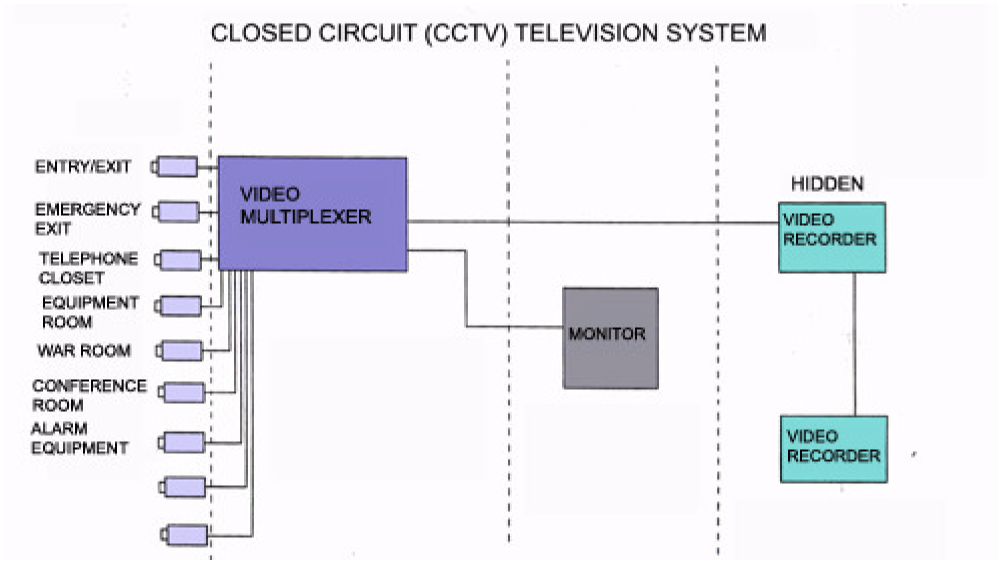


Figure LSS+4054 A camera is blinded by bright light in the photographs in the top and middle rows. Note the enhanced image (middle right) that shows the intruders. In the bottom row of photographs, the inruder is concealed, as shown in the enhancement (bottom right).
Courtesy of DOE Office of Security and Safety Performance Assurance.

40_3.7.2.1 Specific Defeat Techniques to Attack Camera Systems

There are a variety of means that can be employed to neutralize or destroy the effectiveness of a video surveillance system through attacks directed at cameras. These are summarized below. It is important for the security staff to analyze the potential methods to defeat the system, and to take corrective measures to minimize the risk. Reconnaissance by intruders will typically attempt to gather the following information:

- **Learn the territory and any unique characteristics;**
- **Become familiar with every segment of the area of intrusion;**
- **Explore the area to be breached by day and night;**
- **Every alley, bush, tunnel, tree, building, wall, railing, fence or other accesible point will be explored, tested for alarms, and climbed;**
- **Typically, intruders will be careful not to traverse well-used paths, streets, alleys, or other areas that would normally be subject to surveillance;**
- **Intruders will look for areas of cover, especially if aerial surveillance is utilized;**
- **Consider that flares and smoke bombs may be utilized to blind surveillance equipment.**

The following specific defeat techniques may be employed to reduce the reliability and effectiveness of any video

surveillance system, regardless of where the cameras are placed or mounted:

Plastic bag

A plastic trash bag filled with glue can be utilized to take a camera out of service. Cameras are often "bagged" if they are to be repaired. Thus, such action may not draw undue attention.

Sticker and tape

If the camera has been mounted so that it is accesible from the ground, then a sticker or tape can be placed over the lens to render it inoperative.

Paint gun

A paint gun, water pistol, or aerosol spray can be utilized to damage the lens. This is a highly effective method that can be carried out within a few seconds. The action can disable many cameras within a short period of time. Spray glue also works well and will be more difficult to remove from the lens. Effective range can be 5 meters above the ground. Paint splatter may be left on perpetrators, so criminal investigators should check for such evidence.

Laser pointer or infrared light source

A CCD or other video sensor can be disabled with a laser pointer or infrared light source. An emitter with an output of 5 milliwatts or greater can temporarily blind and may even permanently damage a video sensor. A threat from such devices has been recognized for their capability of damaging CCD and other pickup tubes, as well as the potential to cause eye damage or blindness to people up to several hundred feet from the

transmitter. Devices can be secreted in cameras with telephoto lenses or binoculars, and can be difficult or impossible to detect.

Cutting of coaxial cables

Fiber optic, twisted pair, and coaxial cables can be severed or damaged with either a sharp hand axe, fence cutter, or garden pruning tools. When cables are cut, their repair or replacement may be time-consuming and costly. Pins, or the application of heat may also be utilized to break the transmission path, or short circuit the center conductor to ground, thereby preventing any signal from reaching a remote monitoring site.

Block drop

Cameras can be damaged through the application of brute force by dropping weights, cinder blocks, or other objects from above their mounting location. Such action can completely destroy the housing and electronics.

High speed projectile

A camera may be taken out of service if it is penetrated with a projectile such as a bullet from a rifle or handgun.

RF Interference for wireless transmitters

Wireless cameras can be taken out of service by RF interference. Cameras will generally operate in the 900 MHz, 2.4 or 5.8 GHz bands, either on discreet frequencies, or utilizing spread spectrum. If the frequency band can be identified, the receiver can be jammed with a relatively high power signal, regardless of whether analog or digital transmission is employed. Spread spectrum and 802.11 protocol will not prevent this practice. Microwave ovens can also play havoc with 2.4 GHz receivers. This is a popular band for government covert operations, and is also utilized by the news media for remote pickups. Cameras operating with 802.11 protocol can also be received by computers equipped

with this technology. Most notebook computers incorporate WIFI. Inexpensive WIFI 802.11 sniffers are available to locate wireless networks.

40_4.0 Protection for Specific Types of Premises, Construction, or Fixtures

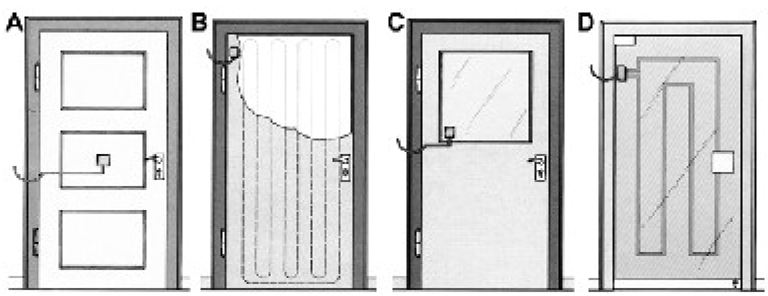
A survey of alarm devices that can be used to protect specific structures or fixtures is provided as a reference.

40_4.1 Windows

Windows and related components can be protected by the following devices:

- **Alarm glass;**
- **Alarm glass with embedded wires;**
- **Bolt contacts;**
- **Glass-breakage detectors. They cannot be used on panes with shatter-resistant films, since the propagation characteristics of the medium is altered;**
- **Laminated glass with wire inserts;**
- **Security alarm glass;**
- **Light barriers;**
- **Magnetic contacts;**
- **Spanned wire;**
- **Surveillance foil;**
- **Transducers sensitive to changes in pressure;**
- **Vacuum alarm glass;**
- **Vibration contacts;**
- **Volumetric protection devices.**

40_4.2 Walls



- **Seismic detectors;**
- **Wallpaper coverings with embedded closed-circuit wiring.**

40_4.2.1 Openings in Walls

- **Taut-wire trips;**
- **Trap loops, consisting of cables or wires placed across openings at narrow intervals. Pressure or severance will trigger an alarm.**

40_4.3 Doors

- **Magnetic contacts;**
- **Micro switch contacts;**
- **Bolt contacts;**
- **Light barriers;**
- **Vibration sensors;**
- **Surface surveillance systems (wires);**
- **Glass-breakage detectors;**
- **Sound detectors;**
- **Volumetric sensors;**
- **Foil.**

Doors should always be protected by more than just magnetic switches; otherwise, they are subject to compromise. If burglars know the precise position of the trip, they can often cut around it and fix the magnet to the door frame.

40_4.4 Small Openings and Confined Areas

- **Dome lights: contacts to prevent the dome from being raised;**
- **Ventilation openings: tubing and wiring;**
- **Showcases: capacitance field change detectors or ultrasonic sensors;**
- **Drawers and doors of cabinets: magnetic contacts;**

- **Locks and Locking Devices: bolt contacts;**
- **Furnishings: closed-circuit wiring in wallpaper.**

40_4.5 Enclosed Rooms

Entire rooms or specific areas or objects can be protected, depending upon exposure of property and character of the environment. The following devices can be utilized to protect enclosed rooms:

- **Volumetric sensors;**
- **Microwave detectors;**
- **Ultrasonic detectors;**
- **Passive infrared detectors;**
- **Proximity detectors.**

40_4.6 Interior Surveillance

Additional interior surveillance is usually necessary, regardless of the extent of protection and monitoring of the external shell. There are always exposed or vulnerable points of access that necessitate localized monitoring within the interior of a building. The following suggestions and guidelines are offered for the use and installation of internal trips:

- **Dead zones must be avoided in any scheme of protection;**
- **The operation of a detector must not be disturbed by external environmental influences;**
- **The risk of false alarms is high when traps are used for surveillance. They should only be installed in very controlled circumstances, as for instance in a small shop with few employees;**
- **Pressure mats can be placed under carpets and doormats;**
- **Large items or decorations can be monitored with magnetic contacts or micro switches;**
- **Contacts embedded within curtain rails will trigger whenever the curtains are closed;**
- **Current-sensing devices can be integrated into the electrical system to determine when interior**

lighting has been turned on or off or when power is drawn through the circuit;
- **Ultrasonic approach switches can be utilized;**
- **Alarm panels must be installed in protected rooms;**
- **Silent alarms should be used in the event of holdup;**
- **Visible and audible alarms should be used for protection against burglary.**

40_4.7 Alarms in Banks

Physical devices and other safeguards must be implemented to insure that a burglary is detected at the earliest possible moment. Monitoring and protection of the perimeter and interior areas is essential. These include approaches to the bank, roofs, and windows. Within the interior spaces, it is imperative to provide localized surveillance of strong rooms, ATMs, and night depositories.

40_4.7.1 Strong Rooms

Because of the prevalence of special forced entry materials and tools such as the thermic lance, diamond drills, and explosives, it is essential that strong rooms and safes be protected by many different physical barriers and alarm devices. These will include:

- **Sound sensors for doors, walls, floors, and ceilings;**
- **Volumetric protection;**
- **Bolt or frame contacts for doors;**
- **Capacitance and motion detection systems for interior areas and safes;**
- **Smoke detectors to sense the use of a thermic lance;**
- **Charged conductors, sunk into or attached to walls;**
- **Closed-circuit television cameras and video recorders;**
- **Proximity sensors.**

Interior safes and depositories may be further protected by an external casing that is alarmed. Automatic teller machines (ATMs) must also be specially monitored. Protection of the area around the ATM, as well as internal cash vaults, is essential.

40_4.8 Protection of Open Land

The reliable protection of open land is difficult because of changes in environmental conditions, animals, passers-by, and the ease of circumvention by experienced criminals. The following technologies may be utilized for monitoring open areas:

- **Closed-circuit television;**
- **Seismic detectors;**
- **Capacitance and pressure monitoring of fence lines;**
- **Microwave motion detection;**
- **Photoelectric sensors;**
- **Volumetric monitoring systems**
- **Fence systems.**

Techniques for exterior perimeter protection have been examined elsewhere in this chapter.

40_5.0 How to Steal $100,000,000 in Diamonds: A Case Study

This section provides an analysis of one of the largest and well executed diamond thefts in history, and demonstrates how vulnerabilities in security were discovered and exploited by a gang of career criminals over a two year period. The Antwerp diamond theft represents the real world of crime, and what lengths professional thieves will pursue in order to accomplish their goals.

This crime is illustrative of an extremely well planned penetration of an ostensibly secured area. In the author's opinion, many mistakes were made by building management and security staff with regard to protection of its perimeter, internal access, and stored valuables. A debriefing of senior case agents by the author offers an insight into the methods that were employed by perpetrators to steal the diamonds, the means that were utilized to catch them, and the chain of evidence that was developed for prosecution. An analysis of the perceived vulnerabilities of the security systems is presented to enhance the materials within this chapter, and to offer the reader a unique perspective of those that are intent on breaching security.

The material presented in this section represents the opinions of the author and other security experts, based upon information provided by law enforcement officials and others that were closely connected with the investigation. No statement of fact or assertion is made or intended with regard to the possible negligence of security staff or failure of security procedures within the Diamond Center. Certain actions of one or more criminal defendants cannot be ascertained as fact unless and until they provide a statement as to precisely how the crime was committed. Certain assumptions have been made by the author and others in reaching certain conclusions within this report. Counsel for the owners of the building in question have advised the author that any inference, suggestions or statements that the building management or staff was in any way negligent or in any way caused or allowed the theft to occur would be false. The author leaves it to the reader to make that determination.

Overview of the Diamond Exchange

Antwerp, Belgium processes and controls approximately eighty five percent of the world's rough cut diamonds. Every major company is represented and buys and sells their diamonds through Antwerp; the entire trade is centered within a square mile. Adjoining the district are hundreds of retail jewelry stores, mainly controlled by Georgians and Russians.

Within the core area, which spans just a few blocks, are all of the vendors, merchants, cutters, polishers, showrooms, banks, money exchange offices, insurance companies, secure couriers, storage vaults and brokers that are required to support the billions of dollars of business that annually flows through Antwerp. The High Council for Diamonds represents all of the companies within the district and is responsible for overall supervision of the diamond area and develops policy for the diamond trade worldwide. Diamonds from mines in Africa, Australia, Canada and elsewhere are all bought, traded and sold through the merchants in Antwerp. Their goods are exported to diamond centers throughout the world, but mainly to India, Thailand, Israel, and New York.

POLITIE

The area is only accessible to authorized vehicles and pedestrians, and is patrolled continually by a special detachment of the Antwerp police. All vehicle traffic ingress and egress is controlled by pneumatic steel barriers at the three entry points to the district. Only those delivery vehicles that are authorized may enter, and all must remain on the street and in plain view. Armored cars are always escorted to their destination. Acts of terrorism in the 1980s, as well as daylight robberies and other crimes have necessitated the heightened state of security during the past few years. Constant video surveillance of the entire area is maintained.

Views of the Diamond area in Antwerp.

Summary of the Offense

During the weekend of February 15, 2003, one of the buildings in the district was burglarized. This facility houses many merchants and hundreds of millions of dollars of diamonds within its vault. There had never been a security problem in the building prior to this theft. It is typical of office buildings within the exchange; a multi-story secure structure with offices and a large strong room that contains hundreds of individual deposit boxes for its tenants.

The main entrance to the Diamond Center.

The burglary required two years to plan and execute, and a total of seven individuals were identified as being involved. At least five of the defendants are career criminals with extensive histories. The ring leader was arrested one week after the crime, and is currently scheduled for trial. The others are awaiting extradited from Italy. It is estimated that in excess of $100,000,000 was stolen from over one hundred boxes in the vault. Virtually none of the diamonds have been recovered. The maximum penalty in Belgium for theft is approximately five years.

Preparations and Planning by the Defendants

The defined target was the main vault in the basement of the Diamond Center in Antwerp. It is not known how this particular building was specifically chosen by the thieves, although the author suspects that information may have been provided to the defendants regarding the security system or the combination to open the vault, and this was the prime reason for the selection of the Diamond Center. With this knowledge, the building certainly would have been an attractive target. The author also suggests that information may have been obtained with regard to the individual tenants in the building and the amount of business that they may have been conducting. This could provide an insight into the value of diamonds that would have been stored within individual safes.

It is surmised by the author that the thieves had advance information with regard to the security system, vault combination, and the design of the safe deposit boxes for a number of reasons:

- **The Lips vault would have been difficult to penetrate by force;**
- **It is doubtful if the combination lock, requiring four digits, could have been manipulated or automatically opened with a robot dialer within a reasonable or predictable time frame;**
- **Becoming a tenant of the Diamond Center would only provide information and access to that building. It would not prove helpful if another building were to be penetrated. Having an ID badge for this specific building would not be particularly helpful for gathering detailed information about another location, although it would permit entry and exit into other facilities during normal business hours;**
- **It is highly unlikely that a gang of thieves would spend the time and expense to prepare for a burglary of this magnitude if there was any uncertainty that they could not successfully reach their target without delay or fear of detection. It is simply not logical that they would approach the vault without knowing the combination.**

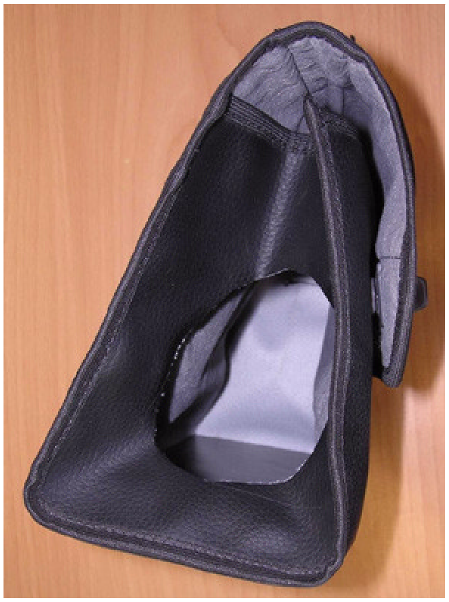
In order to be successful in their operation, the thieves would need to develop a great deal of information regarding all aspects of building security and procedures. It was essential that they were able to gather this information over a period of time and in such a manner that they would not call attention to themselves.

This would require that they establish the following credentials:

- **Bona fide diamond merchant, meeting the requirements for doing business within the Diamond Center, supported by appropriate banking and business references;**
- **Establishment of their business as routine within the Diamond Center, and acceptance by both management and other tenants as legitimate merchants and which would not raise any suspicion;**
- **Obtain an identification card that would allow access through security sensors upon entering and leaving the building, and would allow recognition as an authorized tenant;**
- **Access to interior building areas, including offices, parking garage, and the strong room;**
- **Familiarity with the administrative and security staff, so that their presence would not be questioned, and it would appear to be in the normal course of business;**
- **Rental of safe deposit box;**
- **Routine access to a safe deposit box within the strong room;**
- **Ability to observe all aspects of the alarm and security system;**
- **Acquisition of rental space within the building over a long period of time, so that when the burglary occurred, they would have been evaluated as a long term tenant and not as a suspect;**
- **Establishment of banking and money exchange contacts within the diamond area, creating and confirming the illusion of doing business.**

The following information would have to be gathered, and was critical to the success of the operation:

- **Perimeter security of the building, and the level of surveillance provided by the Antwerp police;**
- **Identification of all entry and exit points to the building;**
- **Identification of non-secured access points to the building;**
- **Analysis of the adjoining parking garage, its access to the building, hours of operation, ability to open overhead gates, and monitoring of traffic;**
- **Identification of all access routes to the strong room;**
- **Physical access control systems;**
- **Access control procedures to enter and exit the building;**
- **Consistency of security procedures;**



- **Traffic patterns into the building, and a correlation with hours of operation;**
- **Access procedures into the vault for building tenants;**
- **Alarm systems, both perimeter, internal, and strong room: blind areas in coverage and methods to bypass specific areas under surveillance;**
- **Identification of alarm system hardware, including each type of sensor that was employed and its location, approximate age and level of technology, the method that would be required to defeat it, and the level of sophistication of each sensor;**
- **Locks and keys, relating to doors, storage areas, master key systems;**
- **Identification of the types of locks, the method of master keying, the potential to compromise the master key system, and whether different types of locks were utilized in the area of the strong room and access doors into that area;**
- **Identification of the specific type of safe door and lock that was utilized for the entry to the strong room;**
- **Determination of whether the safe lock could be manipulated open, or opened with a robot dialer or automatic manipulation machine;**
- **Possible identification of the contract locksmith that performed routine maintenance on locks and safes within the building and the ability to compromise such information;**
- **Identification of specific information regarding the safe deposit vaults, including locking mechanism and the ability to force open the door with the use of a dent puller;**
- **Internal video surveillance systems: location of cameras, coverage, defeat, retention and storage of video tapes;**
- **Internal staffing procedures for all employees: number of staff, hours of work, job responsibilities, distraction level;**
- **Security staff complement: number of staff, duties, surveillance activities, work load, ability to monitor video surveillance systems;**
- **Monitoring procedures while tenants were in the vault.**
- **Observation of other building tenants while they were in the vault, and possible identification of target safe deposit boxes that may contain large amounts of diamonds;**

One of the defendants, identified as the ring leader, formed a diamond brokerage firm in Italy two years prior to the burglary in order to develop a business track record and paper trail.

Appropriate banking contacts were established in Antwerp to provide legitimacy to the newly formed company. He then utilized his credentials as a diamond merchant to begin negotiations with the management of the Diamond Center for an office within the building. This took some time, because appropriate checks have to be made on all tenants to verify that they were diamond merchants or otherwise legitimately involved in the trade, and qualified to be in the building.

After some discussion, an office was rented in the Diamond Center building. For the next two years, the thieves developed significant intelligence about the building, its staff, and its security, which enabled them to determine the precise plan of attack and optimum dates for its execution. They even shot covert videotape within the facility in order to review the layout, identify targets, and provide a working knowledge to all of the gang members. A video camera was secreted in a bag so that it could be utilized without notice.

**This leather case was utilized to hide a video camera that the thieves used for
covert surveillance and documentation within the Diamond Center.**

Security of the Diamond Center

The Diamond Center was thought to be a secure facility. As can be seen in the photographs, there is a guard post at the main entrance, as well as turnstiles that require the use of a proximity card issued to each tenant or visitor. The author was required to show his passport, even though he was escorted by a senior federal police official. The security officer at the desk has the responsibility to log all visitors into the building and issue ID badges. Tenants are provided with permanent identification.

Video surveillance was in operation both in the entry to the strong room and within the vault area only. Additional external video monitoring is maintained by the Antwerp Police. Audio, motion, and light level alarm sensors are in operation inside the vault area, both external to the vault door, and within the strong room. Dual-technology microwave/infrared devices were in use as motion detectors. There was no alarm monitoring on the first floor of the building, no surveillance of the main desk or control room area where video tapes were stored, and no electronic monitoring of the entry from the parking garage to the stairwell that led directly to the vault.

The entire facility utilizes Lips dimple pin tumbler locks for

all doors. These are a relatively low security mechanism that can be easily picked. The design of these locks indicates that a positional master key system was utilized. This type of system would be extremely difficult to decode for the top level master key, and thus would necessitate the picking of individual locks. There is no way to decode such a system without access to many individual keys for comparison and collection of data. They could not have utilized the lock on their office door within the Diamond Center to extrapolate the TMK. See **chapter 11** for a detailed discussion of positional master keying.

A Lips vault and four-wheel combination lock protected the strong room. The safe door was monitored by a balanced magnetic trip, audio, motion detection sensors, and vibration detectors. There was no proximity or capacitance sensor on the door, because it was set into the foundation of the building.

Access to the combination lock internal components for maintenance requires a metal cover with a lever lock to be removed from the back of the vault door. The key for this lock is believed to be standard to all Lips safes. The combination lock on the door had a spy proof dial which required direct vertical observation of the numbers. A high security lever lock is utilized together with the combination lock to secure the vault door. The key was stored in a locked key cabinet in an adjoining room; a low security wafer lock was utilized to secure this cabinet. An adjacent storeroom provided possible implements for the burglars to utilize. Each of the individual safe deposit vaults had a combination lock that utilizes three individually controlled wheel packs and a lever lock. The bolt mechanism is made of brass and can be easily warped out of a locked position.

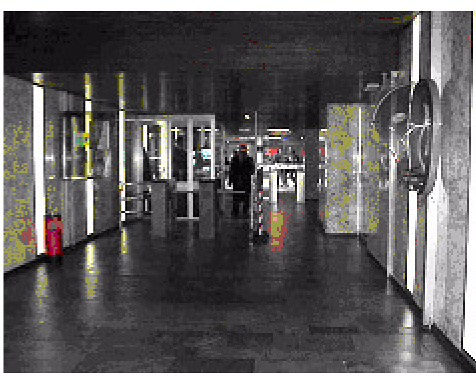
In the view of the author, the security of the Diamond Center was typical of such facilities; multiple issues played a key role in failing to detect or prevent the crime. Management clearly believed that the building was secure: secure enough to protect $100,000,000 in assets. They had never experienced a problem, which leads to complacency. The insurance company, for their part, also believed that there was sufficient security to allow them to underwrite policies.

Management failed to install modern security hardware, which is also a common problem, following the maxim "if it works, don't fix it." The thieves were able to exploit several vulnerabilities in the overall security system to accomplish their mission. It is a classic problem, because the management believed that all

critical areas were protected with multiple layers of security. But a close review shows this was not the case. How much security is enough? That is always the question, and the answer, when dealing with high value targets and professional criminals is quite simple: there is never enough. Clearly, in this instance, more was needed to stop the thieves. Could management have anticipated the methodology of the criminals and taken effective steps to prevent the loss? Perhaps. If one considers the value of the target and the likelihood that professional thieves would plan such an attack, then certain breaches in security could have been foreseen and prevented, which very possibly could have thwarted this burglary.

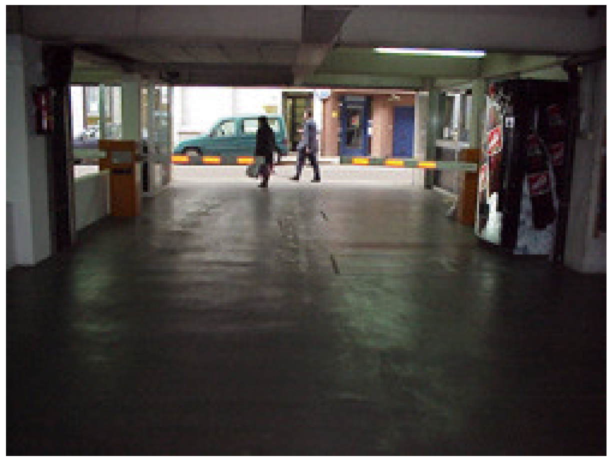
This analysis should provide a model for other like installations, where the apparent security of the facility appears redundant, layered, and more than sufficient to prevent a successful attack. As shown in this case, experienced thieves will spend the time and effort required to analyze their target and devise a plan to exploit vulnerabilities. That is precisely what occurrred in this instance.

The Crime Scene



The Diamond Center building is a fifteen story structure with thirteen floors above ground and two subterranean levels. Approximately two hundred and twenty five diamond companies have their offices in the building. The theft took place in the strong room, situated on the lower level (-2), accessible by elevator or stairway. Within the strong room there are 189 individual deposit safes of various sizes, rented by the different diamond merchants who have their office in the building or in the diamond area. Note that each building has its own vault for the convenience and security of its tenants.

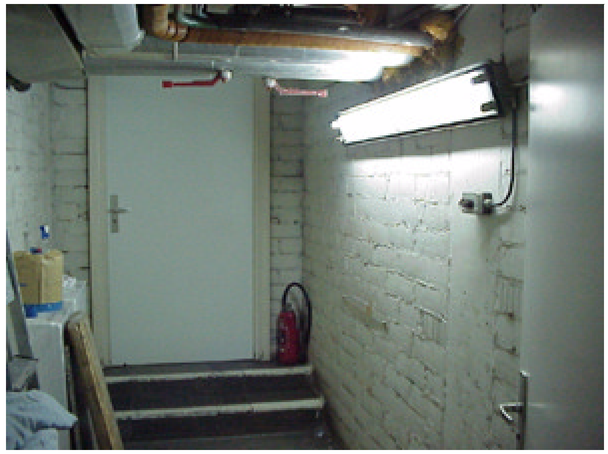
The strong room at the Diamond Center, the morning after the burglary.

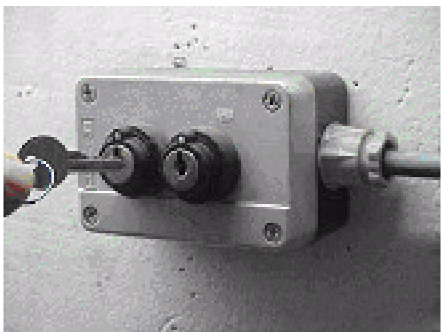


Access Points to the Diamond Center Building

The Diamond Center can be accessed via two entrances. The main entry is situated in the front side of the building along **X** Street. There is a second entrance in the back of the building in **Y** Street.

The garage adjoins the Diamond Center and can be accessed from the street, outside of the core area of the Diamond district. There are no security restrictions with regard to access to the street that leads to this parking garage.





The main entrance in **X** Street is open Monday to Friday between 0700 and 1900. At all other times it is locked by means of an iron shutter. The second entrance on **Y** Street borders the inside parking area adjoining the building and is also open Monday to

Friday between 0700 and 1900. From 1900 and 0700, and every half an hour from 1900 until 2100, the building can be accessed and exited via **Y** Street only. The primary entrance is closed. After 2100 the security officer on duty can be contacted by phone in order for tenants to enter or leave the facility. During the week-end, **only** the second entrance is open on Saturdays between 0800 and 1300. On Sundays this entrance is open between 0900 and 1300. During the opening hours, each entrance is watched by a guard. There exists a third possibility to enter the building which is situated in **W** Street. It is an old emergency exit that has not been in use for the last eight years. This access is a garage door which is permanently monitored by an alarm.

Because the main entrance is only open on workdays between 0700 and 1900 and locked by means of a metal gate and controlled by cameras within the building as well as by those of the Diamond Council, it is nearly impossible to enter the building unseen along the front side, especially outside the normal workdays. The entrance along **Y** street however offers several possibilities to allow entry. During the weekend the garage doors along this entrance are kept open for several hours, which makes it possible to access the parking garage by car or on foot.

To enter the building following the usual procedure, one has to register to obtain a badge from the building security officer on duty. Nevertheless, the investigation has shown that on the same level inside the parking garage, a door offers the possibility to enter the Diamond Center and go directly to the elevators, which would make it possible to descend directly to floor -2 next to the strong room. A door next to the elevators also offers the possibility to descend to floor -2 via the stairways directly.

Within the parking garage, there is a switch box on the ground floor that controls the two overhead garage doors and would allow them to be opened.

The parking garage allowed access directly to the vault without any electronic surveillance. The control for the two steel garage doors could be easily accessed.

Electronic Access Control

In order to access the building via one of the entrances, each tenant or visitor is issued an electronic proximity identification card. There are four different kinds of access cards: visitors, federation, the access card of another building in the diamond quarter, and the access card of the Diamond Center itself. The card is read electronically and registers the time of entering and leaving the facility.

The main entrance into the Diamond Center.

Electronic Monitoring Systems

The building was not alarmed; only the area surrounding the main vault, and within the vault area itself. The following security systems were implemented to provide appropriate protection:

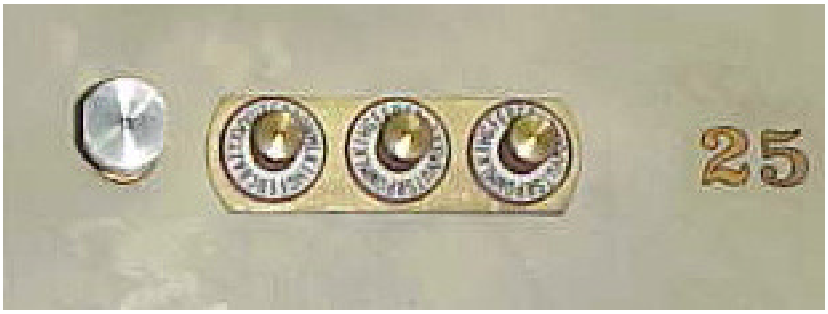
- **Video cameras to monitor the outside of the main vault;**
- **Video camera within the main vault;**
- **Video cameras in the area of the main vault;**
- **Shock and vibration detector on the door of the vault;**
- **Dual-technology (PIR/MCW) sensor within the main vault;**
- **Light level detector in the main vault;**

- **Audio sensor outside of the main vault;**

Access to the Strong Room

The strong room on floor -2 is only accessible Monday through Friday and never during Saturday, Sunday, or holidays. Hours are from 0700 until 1900. Every workday at 0700 the main vault door is opened by the guard on duty, after the alarm has been deactivated. The safe can only be opened by means of a four digit combination and a key. The key for the lever tumbler lock in the vault door is kept in a locked key cabinet in an adjacent room.

Behind the main vault door is a steel gate that presents another barrier to entry into the strong room and is always locked. Only tenants and authorized representatives may request access by calling for assistance with a button mounted on the frame of this gate. The guard on the ground floor main entry point will observe the person requesting access, via a video monitor. Only after he has recognized the person as one of the safe deposit owners will he release the electric lock. The gate will automatically return to the locked position after being opened.



The Lips vault door and barrier gate into the strong room.

The strong room itself is secured with an alarm system consisting of motion sensors, thermal sensors and light detectors. The alarm is controlled by a keypad next to the vault door. A video camera system records all movement into and within the vault. The combination for the vault door is known by four persons, including building management and the guard. The individual safe deposit boxes can only be opened with one unique key and a three-digit code known by the tenant. The key is kept in the possession of the respective safe deposit owners.

Each safe deposit box had a three wheel combination lock and a lever key lock.

When police entered the strong room on the 17th of February 2003, the vault door and the gate were both wide open. Many individual deposit safes were broken into and several documents, bank notes, bags, boxes, jewelry, and other items were spread out on the floor. Physical evidence was gathered at the crime scene from items that were utilized or handled by the perpetrators. Forensic evidence related to the following specimens and types were developed from the crime scene.

Fingerprints and Glove Marks

Members of the technical laboratory detected and registered, by means of dactyloscopic powder, nine fingerprints on the main vault door. Each one of the individual deposit safes was dusted, but no latent fingerprints were discovered. However, technicians did find fragmentary impressions of three different glove marks.

Shoe prints

An envelope was found on the floor of the strong room that had an observable fragmentary shoe print, caused by one of the perpetrators walking over it.

DNA Evidence

A number of items yielded evidence that identified four different suspects from DNA profiles left in the vault. DNA was obtained from evidence within the vault, from the apartment of the ring leader, and from materials retrieved at Machelen. DNA evidence included:

- **Tape that was used on the plastic bags that were used to cover video cameras;**
- **Material that was in the sports bags that was left in the**

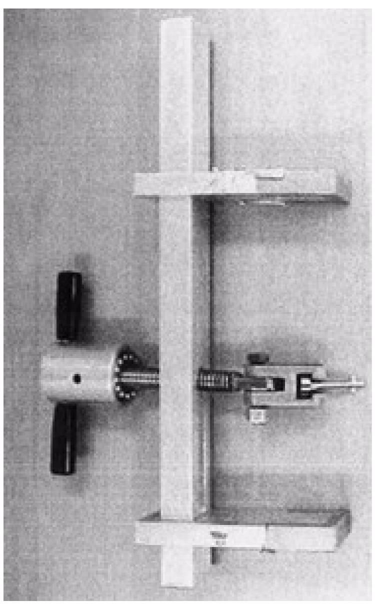
strong room;

- **Spare parts for dent puller. All were taped together, from which different DNA profiles were identified;**
- **Food (salami, cheese, wine, yogurt, and other items) at Machelen and at the apartment;**
- **Work gloves with DNA profiles of defendants were found at Machelen;**

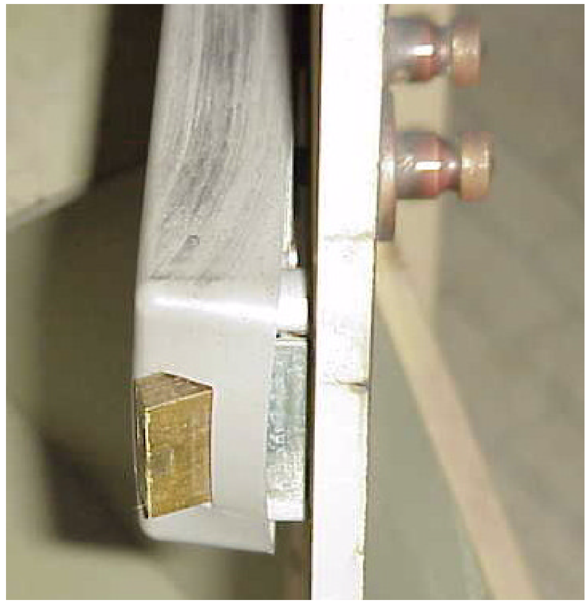
In the strong room, a sports bag was found that contained crowbars, chisels, a putty knife, pliers, aluminum colored accessories, bolts, nuts, and miscellaneous implements. The crowbars and the chisels were wrapped in grey tape, and were matched to various defendants.

A panel of foam that was mounted on a metal handle was found, which apparently had been employed to mask the motion sensor. A multicolor work glove was also left just outside the strong room in the elevator hall on floor -2. DNA evidence was also developed from food left by the criminals at the apartment. It was matched to other food items that were found in trash bags left in the field at Machelen. Also, three different traces of gloves found at Machelen were tied to defendants inside of the vault.

Tool Mark Evidence



On floor -2 on the left side of the strong room, investigators observed that a door had been forced at the level of the lock. The door provides access to a room where, on the right-hand side, was located a metal key cabinet that contained the key for the lever lock in the vault door. This key cabinet was forced open and the key was removed.



The key for the safe was kept in the small locked box on the wall. This key cabinet was easily opened with force.

In the strong room, approximately 110 individual deposit safes were forced open with a modified dent puller. This was comprised of a steel key that had been inserted into the lever lock of each safe, then reverse pressure was applied against an aluminum brace, causing the bolt for each lock to be bent to the extent that it would clear the strike.

A modified dent puller was utilized to apply reverse pressure to the door of each individual safe deposit box in order to bend the brass bolt. A steel key was inserted into the lock to allow the application of pressure. The dent puller required a number of components, which were found in the woods at Machelen.

Telephone Records

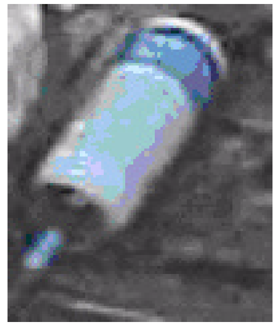
Cellular and other telephone records identified at least four suspects that were in the vault from 2300 until at least 0500 on the night of the burglary. The cell site was identified from where the calls originated.

Bypass of Alarm Systems and Sensors

Thieves entered the building through the parking garage, and used a stairway to get to the main vault on the lower level. There was no electronic monitoring of this route, and thus, the only alarm sensors that were of concern were on the vault door, the balanced magnetic trip to detect its opening, and the internal dual-technology sensor (motion and thermal) within the strong room. It appears that the light level sensor within the vault had been covered with black tape, and the video cameras that were located outside of the vault door and within the vault itself were covered with a plastic garbage bag by the thieves prior to the burglary. The control room that contained video tape recorders and stored media was also not alarmed. Although it is possible that the thieves worked in the dark prior to covering the cameras and sensors, it seems unlikely.

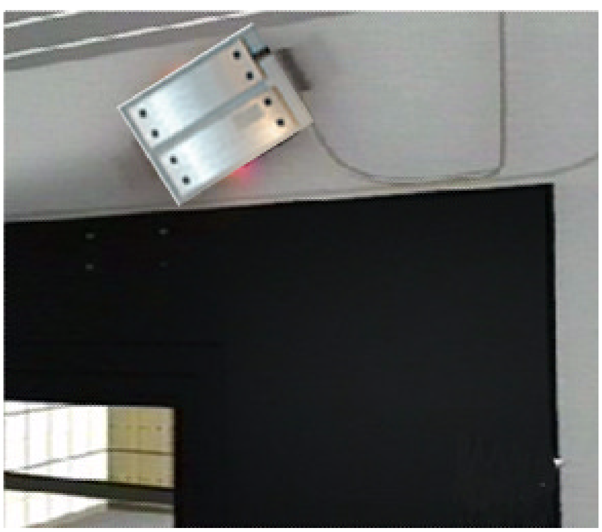
It is believed that a number of separate sensors and systems were bypassed prior to the burglary in order to allow undetected entry:

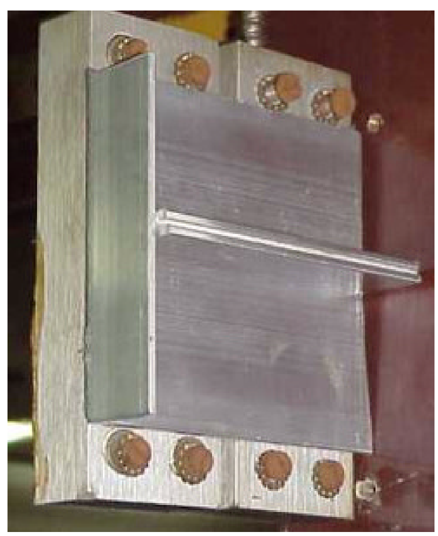
- **Light level detector;**
- **Dual-technology (motion/thermal) sensor;**
- **Balanced magnetic switch on vault door;**
- **Video cameras, located within and outside of the vault;**



Investigators arriving on scene noted the following conditions immediately after they entered the strong room:

- **The alarm system that protects the strong room was still armed (on);**
- **The light level sensor in the vault has not activated the alarm;**
- **The light level sensor is covered with tape, masking the photoelectric detector;**
- **A cable in the ceiling has been completely stripped, without having been cut, thus indicating that a circuit may have been intercepted or tapped into, and that the burglars were aware of the function of this circuit and avoided tripping an alarm. The alarm circuits are supervised to protect against breaking or tampering;**
- **The balanced magnetic switch on the vault door is not mounted in its original position;**
- **The cameras in the vault, as well as the ones in the hall located on floor -2 are covered with dark plastic bags and sealed with tape.**





Cabling in an adjoining room were spliced into.

The motion sensor within the vault employs dual-technology and uses a combination of infrared and microwave for reliability. In order for the detector to function properly, body heat (infrared energy) and movement must be detected before an alarm condition is reported. If one of the sensors is disabled, then an alarm will not be detected or reported. An examination of the detector revealed that its housing and lens was covered with a greasy layer of material, believed to be silicone. The chemical will mask the infrared sensor, resulting in a failure to detect thermal energy. It appears that the thieves utilized a large panel of Styrofoam material to defeat the microwave circuitry of the dual-technology detector. It is believed that this material was contained within the storage room adjacent to the vault.

Dual-technology sensor, covered with silicone

The magnetic contacts on the vault door had been moved from their original position, and after making the bolts shorter, they were put back on the vault door with double-sided tape. It was not possible for staff to discover that the screws had been removed prior to the burglary, unless pressure would have been applied to the magnetic switch to insure that it was mounted securely. Prior to the burglary, the thieves removed the magnetic switch and actuating magnet as a pair. The two devices were slid sideways from their normal position. This was accomplished with a hand-made aluminum profile and double-sided tape. In this manner, the function of the switch was bypassed.

Simulation (left) of how the balanced magnetic switch was bypassed by removing both the sensor and actuating magnet and moving it above the vault door. The BMS was affixed to a piece of aluminum with double sided tape.

The light level detector module is a photoelectric cell to sense the presence of illumination. The sensor in the strong room was covered to block any light from reaching it. The sensor and associated alarm processor did not have anti-masking safeguards, so its failure to operate was not detected.

Light sensor, mounted in strong room.

A seismic detector was also mounted on the main vault door, which is designed to react to any mechanical vibrations. This sensor would not be affected by attacks on individual safe deposit boxes, and would not have been activated by normal opening of the

vault door.

Lips safe door, showing combination lock (left), bolt actuating handle (right) and lever lock (center)

BYPASS OF LOCKS AND SAFES

In order to open the vault door, both the combination lock and lever lock had to be compromised.

Lever lock on main vault door

The vault door could only be opened by the simultaneous entry of the combination and use of the key to turn the lever lock. With regard to the lever lock, this was not a problem because the key was kept in a key cabinet in an adjoining room. The thieves entered that room and opened the container with force. It is interesting that the simple wafer lock was not picked on this box.

Combination lock on main vault door

The Lips combination lock requires four numbers in sequence to properly align the wheel pack in order to open the vault. A spy proof dial restricts viewing of the entered code. It is clear that the thieves had the combination prior to approaching the strong room, given the amount of preparation before the crime. It would be highly improbable that two years of planning would all be jeopardized if the vault could not be unlocked.

As described elsewhere in this text, there are several ways that the combination could have been obtained by the burglars, although many procedures can be eliminated in this investigation. Section **36_2.1** details the known methods of compromising the combination of a lock. From this list, an analysis of the Diamond Center burglary can provide possible means that the Lips combination lock was opened.

- **Capture of combination;**
- **Capture of remote authorization or log in;**
- **Decoding the lock;**
- **Deduction of combination through physical means:**
    - **Paper marking;**
    - **Fingerprints;**
- **Audio capture;**
- **Employee compromise;**
- **Position of dial after entry of combination;**
- **Factory tryout combinations;**
- **Drilling;**
- **Removal of the access panel and cover plate of the lock and decode the wheel pack;**
- **Manipulation, using sound, feel, and touch;**
- **Radio frequency energy interception;**
- **Radio frequency interference or disturbance;**
- **Radiographic imaging;**
- **Reversal of day locking;**
- **Robot dialing;**
- **Simulated burglary or maintenance to secure information;**
- **Observation of combination through surveillance;**
- **Vibration;**
- **Wear of internal components;**
- **User negligence;**
- **Use of the Mas-Hamilton Soft Drill manipulation system.**

In this case one or more of the following modes of attack would appear most likely;

- **Inside information from an employee, vendor, contractor (the most likely);**

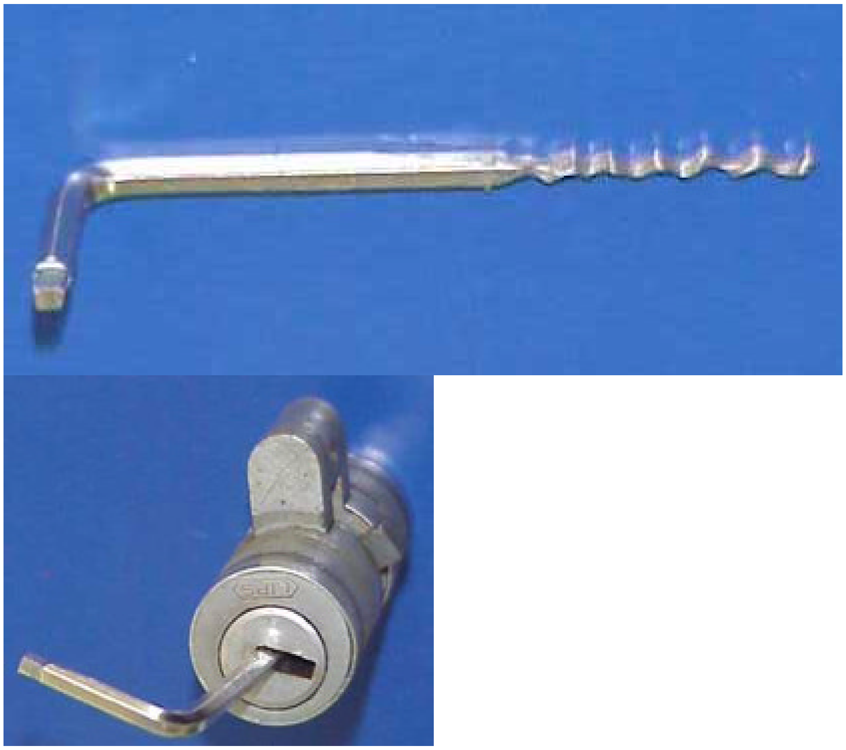
- **Covert recording of the combination during an authorized opening of the safe. This would require the placement of a video camera directly above the lock and a method to record the movement of the dial. This would be possible with a wired or wireless video link and a pinhole camera, which could have been stored within one of the safe deposit boxes within the strong room;**
- **Obtain the combination from the locksmith that services the vault;**
- **Compromise the database that is likely maintained by the locksmith that performs routine maintenance, or who recently reset the combination;**
- **The combination was compromised by a former employee. After the employee left the Diamond Center, the code was not changed;**
- **The combination was provided by a current employee. Extensive interviews by police failed to develop any leads with regard to this possibility;**
- **Use of a recording medium that is placed on the dial, and which would document the number of turns in each direction and stop position for each revolution. The combination could potentially be extrapolated from this raw data;**
- **Poor security procedures upon the part of one or more employees who had possession of the combination. It was determined by investigators that one of the authorized individuals having the combination at the Diamond Center kept the numbers written on a piece of paper in his wallet. It is possible that this information was obtained by someone having access to his wallet;**
- **Observance of the opening of the safe in order to determine the left-right-left pattern. This could be correlated with other information to make derivation of the combination simpler;**
- **Use of a known or probable sequence of numbers, which would be easy to determine by trial and error by thieves (highly unlikely);**
- **Failure to reset the original factory combination (did not occur);**
- **Radiographic imaging.**

The following entry possibilities would appear least likely:

- **Manipulation;**

- **Auto robot dialer;**
- **Access to the combination lock was obtained during normal business hours by the thieves. This could potentially have been possible if a tenant had direct access to the service panel of the vault door. Assuming that the key that allows removal of this panel is standard to all Lips vaults, then direct access to the lock and a viewing of the wheel pack would have been possible. It would then be a simple matter to determine the gate position of each of the four wheels;**
- **Use of sound recording device to derive rotational information from the dial. Potentially, the rotations could be correlated to provide a rough indication of the individual numbers of the combination;**
- **Observance of the opening of the safe in order to determine the left-right-left pattern for opening. This could be correlated with other information to make derivation of the combination simpler;**
- **Use of a known or probable sequence of numbers, which would be easy to determine by trial and error by thieves (highly unlikely);**
- **Failure to reset the original factory combination (did not occur);**

Four-wheel combination lock on Lips safe



Individual safe deposit boxes

Individual safe deposit boxes were opened by using a modified dent puller, described in **chapter 32.**

A special steel key was manufactured that would fit into the lever lock on each box. This would provide the required link to the vault door that was needed to apply a pulling pressure against the lock and its bolt. Upon the application of sufficient force, the brass bolt could easily be bent inward to allow it to clear the strike and the edge of the enclosure. The thieves were able to open over 100 safe deposit boxes during the five hours that they were inside the main vault.

Lips Dimple Locks to Secure all Doors

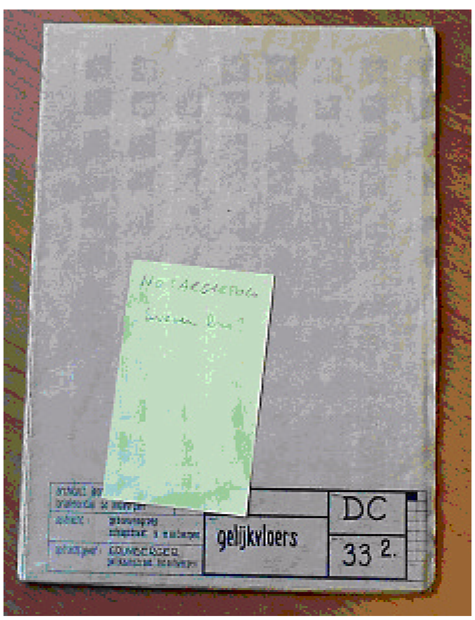
Lips dimple pin tumbler locks are used on all doors within the facility. This system would utilize a positional master keying system and thus it would be very difficult to decode the top level master key. For this reason, picking of each lock was required. It is believed that individual locks were picked, using a modified rake picking tool that was found with the materials left by the thieves at Machelen. This tool, approximately 6.5 cm in length, was fashioned from an Allen wrench and would be quite easy to fabricate. The lock is relatively simple to bypass by using raking techniques with the tool.

Rake picking tool for Lips lock, fashioned from an Allen wrench

In the presence of the responsible person of the Diamond Center building, the rake pick was utilized by investigators to open several locks, including the door on the ground floor between the enclosed parking garage and the hall, and the lock to the storeroom on floor -2 that is adjacent to the main vault. Investigators believe that this tool was used to open all required locks within the facility, rather than a compromise of the master key system.

Key cabinet

The locked cabinet that contained the key for the lever lock on the main vault door was forced open without difficulty. It was secured with a wafer lock which could have easily been picked.



Security and Storage of Video Cassettes

Video recording equipment and tape storage is within the security control room at the main entry point to the building. No alarm system protects this area. Investigators noted that the video cassettes that were recorded from the 10th, 15th, and 16th of February were missing. It is believed that certain preparations

were made on February 10 by the thieves, which necessitated the removal of that tape. These dates could indicate that at least one of the video cameras had not been masked prior to the burglary, and/or that the thieves initially worked in the dark until all cameras were disabled. It is simply not known.

Control room of Diamond Center.

The criminals also took the video cassettes that would have contained images that were captured during the night of the burglary; thus, there was no record of the movements inside the building or the parking garage.

Videotape package and note.

Adjacent Storeroom Areas

An adjacent storeroom is located on floor -2 immediately opposite the main vault. The access door of this room has two ventilation grilles. Along the inner side of the door these grilles had been sealed with grey tape. The guard who discovered the burglary declares that, at the moment of his discovery, the access door of the storeroom stood open. Once inside the storeroom, investigators found several paint buckets that had been used to stop the iron gate at the entrance to the strong room from closing automatically. A pair of work gloves that do not belong to any employee of the Diamond Center were also found, as well as foam, tape and rubbish bags. It appears very likely that the thieves were hiding in this storeroom prior to the theft. The burglars may also have been using this storeroom while preparing for the burglary.

They may also have let themselves into the building and storeroom during the day on Saturday, and may have waited until Saturday evening before entering the strong room. This would have allowed the thieves to enter the vault area without worrying about tripping any alarm systems within other parts of the building, if sensors had been active.

Items Recovered at Machelen

Wooded area near Machelen.

Trash bags, boxes and other objects were hidden in a remote area approximately thirty miles from Antwerp. It is believed that the thieves left the items while on their way to Italy. Among the items that were secreted were empty cardboard jackets for Sony video cassettes, similar to the type that was used at the Diamond Center. Empty spools of video tape from cassettes were also found near the cardboard boxes. It is clear that the magnetic tape had been removed from the cassettes by the burglars. Portions of other rolls of magnetic tape were recovered near the hiding spot for the majority of items. All the recovered tapes were taken to SONY headquarters for analysis in an attempt to view the images. The results of this investigation were negative. A number of pieces of evidence from this location, including keys, tapes, receipts, documents, food, and DNA provided critical evidence that linked the perpetrators to the crime scene.

MISTAKES THAT WERE MADE: WHAT WENT WRONG

A review of the relevant issues involved in this case reveal a number of apparent failures in security, both physical and procedural. The analysis of this investigation can provide valuable insight for those charged with ensuring appropriate security for their own facilities. In this case, a number of problems contributed to the success of the burglary. Although many of the issues have been discussed throughout this text, it is important to summarize those factors that might have prevented this crime from occurring. The author has dealt with investigations involving theft for the past thirty years. In most instances, the opportunity to steal was created by a failure to establish and enforce appropriate operational procedures, as well as the failure to utilize the proper hardware to assure the requisite level of protection. At the end of the day, seven thieves were able to steal more than $100,000,000 in diamonds in part because of lapses in security that might have been prevented. The thieves selected their target, gathered information over a two year period, and executed their plan. They would not have been caught but for two mistakes.

Security Hardware: Locks and Keys

- **The Lips door locks are inadequate for critical areas. Their pick resistance is minimal. High security cylinders should have been installed;**

- **The key to the main vault should never have been left in a locked box adjacent to the strong room. There was essentially no security to protect this key. The result was that the main vault was less secure than if dual locking had been in effect. Proper procedure requires that one individual have the key, and another individual have the combination.**

- **The safe deposit vaults should have been analyzed for bypass and protected against the use of dent pullers;**

Security Hardware: Alarms

The bypass of alarm system sensors was critical to the success of the plan. Until one or more of the perpetrators provides a full statement of the crime, all of the facts will never be known. Some of the listed issues did not contribute to the theft in this case, but could have. The author believes that the following failures occurred:

- **The main vault door should have been protected by a shock and vibration sensor that is supervised;**

- **It appears that there was no smoke detector or rate of rise detector to protect access to the main vault door from a thermic lance or torch;**

- **The light level sensor was bypassed by masking the photoelectric cell. Evidently no anti-masking circuitry or software was operational, with the subsequent result that when the sensor was bypassed, nobody was aware of it;**

- **Failure to utilize anti-masking dual-technology sensors;**

- **Balanced magnetic switch was bypassed by physically removing it from the vault door;**

- **Failure to utilize anti-pry mounting plate with the balanced magnetic switch. When the sensor and actuating magnets were temporarily removed from the vault door, and then reapplied with double-sided tape, this movement would have been detected if the sensor had been supervised;**

- **Failure to mount the BMS with security screws, which would have**

made removal more difficult;

- **Failure to inspect, on a daily basis, all of the alarm sensors, and to test for proper operation. This likely would have revealed the bypass of all of the critical sensors.**

- **Failure of Operational Procedures;**

- **It appears that control room personnel failed to adequately monitor the video surveillance system. Personnel may have been detailed to other tasks and did not have time to watch monitors for unusual activity;**

- **Failure to maintain videotapes in a secure, off-site environment, so that critical evidence could not be removed, as occurred in this case;**

- **Failure to adequately assess and protect entry and exit points to the building, which allowed entry without tripping any alarms;**

- **Failure to properly alarm all access points to the vault. In this case, it appears that there was complete access to the vault entrance without detection. The thieves could enter directly from the parking garage, through two flights of stairs, without ever encountering an alarm sensor;**

- **There was no alarm system to protect the control room and critical systems control functions;**

- **There was no alarm to indicate entry or exit from the adjoining parking garage;**

- **There was no security in controlling the electric garage doors. Keys were openly available to the thieves;**

- **Storage rooms were located adjacent to the main vault. These rooms were not adequately secured and allowed access to the criminals for storage of implements, use of materials in the storeroom, and a hiding place for the thieves;**

- **There evidently was no standard procedure to conduct routine inspections of all areas to insure that no hardware had been**

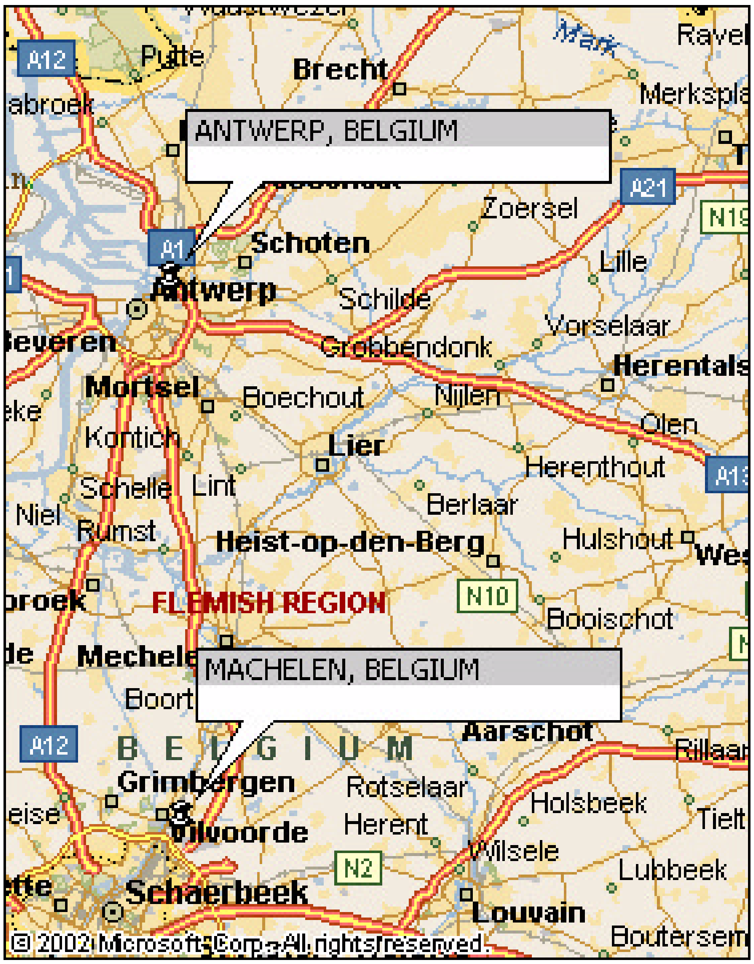
tampered with;

- **No rigid cable runs were utilized to protect critical circuits in ceilings;**

Can it be said that the Diamond Center could have prevented this burglary? Maybe. It was their responsibility to provide adequate security to protect the valuables of its tenants in its vault. Even if the thieves had initially worked in the dark and used low light level binoculars to enter the vault and disable cameras and light sensors, there were four critical failures in the author's view which enabled the theft.

- **No alarm on the access route to the vault;**
- **Failure to adequately protect the balanced magnetic switch which was the primary monitor of the status of the vault door;**
- **Failure to remove and protect the vault key from unauthorized access;**
- **Failure to employ a motion detector in the vault which could not be masked.**

If the thieves had the combination to the vault, as the author speculates, then the single most critical issue was the BMS, and the failure of staff to detect or observe its movement prior to the crime. Unless the thieves were able to bypass this circuit, then this was the critical component which, if not compromised, would have signaled an intrusion. And, of course, if the circuit could have been bypassed, then this would have constituted another failure in security.



How They Got Caught

This theft would likely have remained unsolved but for two critical mistakes on the part of the thieves, which rapidly lead to their identification and the arrest of the gang leader. The burglary occurred late Saturday evening, when at least four thieves entered the main vault at about 2300 hours. They worked for more than five hours emptying over one hundred safe deposit boxes of their contents. They gathered up their tools and other items from the vault floor and placed the materials into trash bags and boxes, which they took with them.

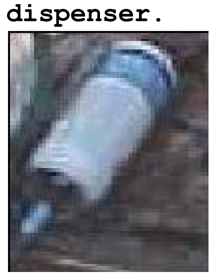
It is estimated that they left the Diamond Center about 0600 on Sunday morning, and went to the apartment rented by one of the gang members in Antwerp. There, it is believed they presorted

their loot, had some food, wine, and cheese. They gathered some of the garbage in the apartment before they left and headed for Italy by car.

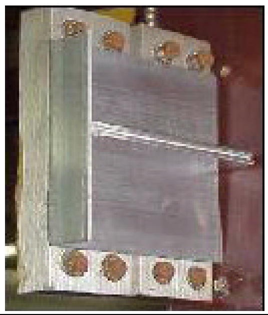
About thirty miles south from Antwerp, they stopped at a remote piece of property in Machelen, which was heavily wooded. They thought that because it was such a remote place that they would be secure in burying their trash there.

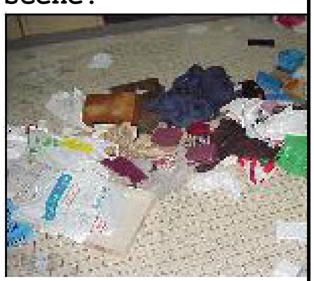
On Monday morning, the staff at the Diamond Center went to open the safe and found the contents strewn all over the floor. Almost at the same time, the landowner, Mr. Floordambos, found the trash bags and other materials that had been left by the thieves. It seems that he had had problems with others leaving garbage on his property, so he was especially vigilant. When the trash bags and other items were examined, the landowner noticed that there were diamond envelopes that were identified with the names of

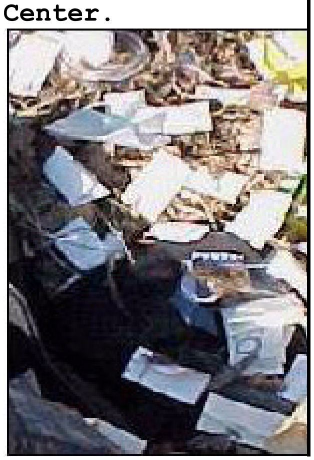
merchants in the Diamond Center. He heard the news accounts of the spectacular theft and called police. They responded to the scene, and were able to rapidly determine that the material on his property was from the crime scene. Torn pieces of a receipt amongst the trash led police to identify one of the perpetrators (the ring leader of the gang). He was the individual that had rented an office in the Diamond Center. His associates were rapidly identified from the Italian police.



One week after the theft, on Friday evening, this individual returned to Antwerp and to his office at the Diamond Center, where security was on alert. They notified the Diamond Squad of the Belgium Federal police, who responded and arrested this individual. A search warrant was executed on his apartment, where incriminating evidence was found, including several diamonds in the carpeting which are believed to have come from the Diamond Center. It is thought that the gang leader returned to Antwerp for two reasons: to collect the remaining materials in the apartment, and to make an appearance at the Diamond Center so that there would be no suspicion that he was the only tenant missing after the burglary.

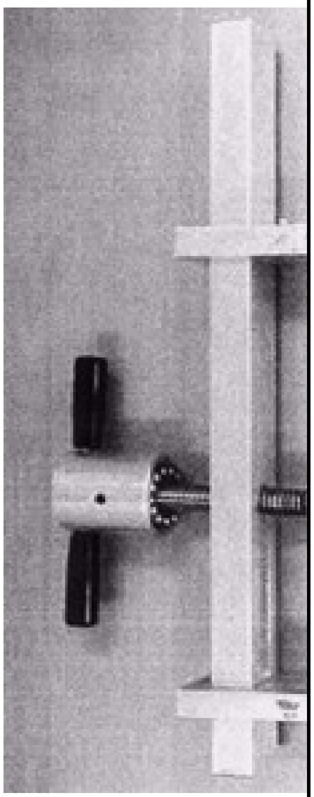


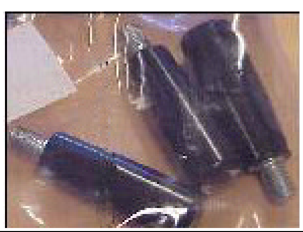


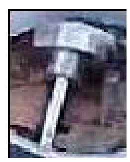


International arrest warrants were issued for the other gang members, who are awaiting arrest and extradition from Italy. Police estimate that more than $100,000,000 in diamonds were stolen. None have been recovered.

Evidence Links







The following critical pieces of evidence were discovered at the crime scene, at the remote location near Antwerp, and at the apartment of one of the thieves. A full-size diagram of individual pieces of evidence and their relation to the crime scene is also accessible through the link.

ANTWERP DIAMOND CENTER BURGLARY: EVIDENCE LINKS

	Shoe prints.		
	Fingerprints and glove marks.		
	DNA evidence.		
	Tool marks.		

MASTER PATENT BIBLIOGRAPHY

The following listing provides a master index of United States

and British patents that were researched, or cited within the text. The full text of all patents may be found at **www.security.org**. Organization is by chronological patent number, and by classification.

PRIMARY INDEX BY PATENT NUMBER

7917	SWIVEL TYPE KEY	2/1851
7918	HYDRAULIC RAM	1/1851
14958	LOCK AND KEY	5/1856
99013	DISC TUMBLER LOCK	1/18/1870
103837	LEVER LOCK	6/7/1870
135600	WARDED KEY IMPROVEMENT	2/1873
234057	WARDED KEY	11/1880
414720	P&F CORBIN RING SLEEVE	11/1889
457753	ANTI-PICK KEYWAY	8/11/1891
947913	LOCKING DEVICE	2/1910
1202019	REFERENCE	3/27/28
1254990	REFERENCE	1/29/18
1287882	PICK RESISTANT LOCK	12/1918
1345406	REFERENCE	7/6/20
1403753	REFERENCE	1922
1639919	PICK TOOL, IMPACT	8/23/27
1667223	PICK TOOL, IMPACT	4/24/28
1687649	REFERENCE	10/16/28
1775140	REFERENCE	9/6/50
1826337	REFERENCE	1932
1853525	PROGRAMMABLE LOCK	6/14/32
1860712	PICK RESISTANT LOCK	5/32
1863525	LOCK	6/14/32
1899739	REFERENCE	1933
1944006	IMPACT PICK	1/34
1965336	REFERENCE	1934
1977362	REFERENCE	10/16/34
1990972	REFERENCE	2/12/35
1991151	KEY DECODER	2/12/35
1994532	IMPACT PICK GUN	1935
2015322	CODE FINDING KEY	9/35
2023945	REFERENCE	12/10/35
2027009	REFERENCE	1936
2055129	REFERENCE	9/22/36
2059129	ANTI-PICK LOCK	10/36
2059376	PICK TOOL, TUBULAR	11/3/36
2064818	PICKING DEVICE	12/22/36

2066645	COMBINATION FINDER	1/5/37
2070228	KEY DECODER	2/37
2070233	CYLINDER LOCK	2/9/37
2070342	PICK TOOL, TUBULAR	3/14/36
2087423	PIN DECODER	7/20/37
2158501	TUMBLER LOCK	8/38
2194959	ANTI-PICK LOCK	3/26/40
2268654	REFERENCE	1/6/42
2279592	PICK TOOL, DOUBLE SIDED	4/14/42
2281714	ANTI-PICK LOCK	5/5/42
2283489	CYLINDER LOCK	5/42
2309677	PICK TOOL, IMPACT GUN	2/2/43
2338768	LOCK DECODER	1/11/44
2343041	BORESCOPE	2/29/44
2350250	CAR OPENER	1944
2424278	REFERENCE	7/22/47
2565254	POWER LOCK PICK	8/21/51
2575674	COMBINATION LOCK	3/49
2625032	COMBINATION SCRAMBLER	1/13/53
2629249	ANTI-PICK LOCK	2/24/53
2655808	PICK TOOL, TUBULAR	10/20/53
2673457	EXPOSED SHACKLE PADLOCK	3/30/54
2673458	PADLOCK	3/54
2674457	COMBINATION PADLOCK	3/54
2720032	LOCK DECODER	10/11/55
2727312	LOCK DECODER	12/20/55
2763027	IMPRESSION DECODER	1956
2775112	PROGRAMMABLE PADLOCK	12/25/56
2791840	REFERENCE	1957
2814940	COMBINATION PADLOCK	12/3/57
2830447	PROGRAMMABLE PADLOCK	4/15/58
2831447	PROGRAMMABLE LOCK	4/58
2852928	LOCK ACTUATOR	9/23/58
2907237	AUTOMOBILE UNLOCKING	1959
2974517	COMBINATION LOCK OPENER	3/61
3024640	X-RAY PROTECTIVE LOCK	3/13/62
3087050	BORESCOPE	4/23/63
3149487	PICK TOOL, BARREL LOCK	9/22/64
3206958	INTERCHANGEABLE LOCK CORES	9/21/65
3206959	INTERCHANGEABLE LOCK CORES	9/21/65
3251206	PICK TOOL, TUBULAR LOCK	5/17/66
3264908	VIBRATING PICK	8/9/66
3267706	PICK PROOF AXIAL LOCK	8/66
3270534	PADLOCK	9/6/66
3270538	TAMPER PROOF AXIAL LOCK	9/66

3330141	RESETABLE KEY	7/11/67
3367156	LOCK CYLINDER ASSEMBLY	2/6/68
3402581	TELEPHONE LEVER LOCK	9/24/68
3413831	ROTARY CYLINDER LOCK	12/3/68
3438290	AUTOMOBILE OPENING TOOL	4/15/69
3452562	LOCK PICK HOLDER	1969
3475934	LOCKOUT ASSEMBLY	11/4/69
3499302	MEDECO SIDEBAR LOCK	3/10/70
3499303	MEDECO SIDEBAR LOCK	3/10/70
3533253	CHANGEABLE COMBINATION	10/13/70
3541819	AXIAL LOCK	11/24/70
3572070	PROGRAMMABLE LOCK	3/23/71
3603123	PIN TUMBLER LOCK	9/7/71
3604231	PICK PROOF LOCK	9/71
3611763	MAGNETIC CARD LOCK	10/12/71
3633393	MAGNETIC LOCK	1/11/72
3664211	CAR LOCK RELEASE	1972
3722240	MEDECO CYLINDER LOCK	3/73
3738136	MASTER KEYING AXIAL LOCK	6/12/73
3762193	PICK RESISTANT LOCK	10/2/73
3813906	AXIAL LOCK	1/4/74
3819221	VEHICLE DOOR OPENER	1974
3827151	PIN DECODER	8/6/74
3834197	MAGNETIC CARD LOCK	9/10/74
3837197	DOUBLE BITTED LOCK	9/74
3868838	LOCK COMBINATION CHANGER	3/4/75
3916657	AXIAL PIN TUMBLER LOCK	11/4/75
3948065	CYLINDER LOCK	4/6/76
3983724	PROGRAMMABLE PADLOCK	10/5/76
3985010	MEDECO DECODER	10/12/76
3987654	MEDECO DECODER	10/26/76
3990275	TAMPER PROOF PADLOCK	11/76
4006613	LOCK PICK MECHANISM	2/8/77
4006615	AXIAL LOCK	2/8/77
4047406	ANTIRAP LOCK MOUNTING	9/13/77
4056956	SAFE LOCK DECODER	11/77
4069407	UNDERWATER CUTTING ROD	1/17/78
4069694	RESETTABLE LOCK ASSEMBLY	1/24/78
4073166	MAGNETIC LOCK PICK	1978
4074548	LOCK CYLINDER ASSEMBLY	2/21/78
4078406	PICK RESISTANT LOCK	3/14/78
4094176	PICK TOOL TUBULAR LOCK	6/13/78
4133194	MAGNETIC LOCK	1/9/79
4144778	CAR OPENER	1979
4149394	CARD LOCK	4/79

4156375	PICK, IMPACT, ELECTRIC	5/29/79
4182947	UNDERWATER CUTTING ROD	1/8/80
4185482	DECODING MECHANISM	1/29/80
4186577	KEY BLANK PICK TOOL	2/5/80
4229959	MAGNETIC LOCK READER	10/28/80
4266488	RELOCKING DEVICE, SAFES	5/12/81
4300416	IMPRESSIONING TOOL	11/17/81
4375159	PROGRAMMABLE LOCK	3/1/83
4376382	RESETTABLE LOCK ASSEMBLY	3/15/83
4386510	KEY-CHANGEABLE LOCK CORE	6/7/83
4400956	IMPRESSIONING TOOL	8/30/83
4404823	VIEW LIMITING DIAL	9/20/83
4433563	ELECTRONIC LOCK DECODER	2/84
4444034	PULL RESISTANT LOCK CORE	4/24/84
4457191	PICK TOOL, LEVER LOCK	7/3/84
4462230	PROGRAMMABLE LOCK	7/31/84
4470275	SECURITY ENCLOSURES	9/11/84
4507944	MAGNETIC LOCK	4/2/85
4517746	WAFER DECODER	5/21/85
4535546	LOCK ELEMENT DECODER	8/20/85
4549176	INDUCED FIELD LOCK	10/22/85
4602253	TRANSDUCER LOCK	7/22/86
4606204	PICK GUN, VIBRATING	8/19/86
4608886	AUTO UNLOCK TOOL	9/2/86
4616491	ELECTRONIC LOCK	10/14/86
4617813	TUBAR PICK TOOL	10/21/86
4655102	AUTO UNLOCK TOOL	4/7/87
4667494	SIDEBAR DECODER	5/26/87
4669394	ELECTRONIC SAFE	2/87
4676083	LOCKING MECHANISM	6/30/87
4683783	AUTO UNLOCK TOOL	8/4/87
4684945	ELECTRONIC LOCK	8/4/87
4712398	ELECTRONIC LOCKING	12/15/87
4723427	MEDECO SIDEBAR LOCK	2/9/88
4730467	COMBINATION LOCK	3/15/88
4745784	ELECTRONIC DIAL LOCK	5/24/88
4766433	OPTICAL CARD READER	8/23/88
4802353	ELECTRONIC DOOR LOCK	2/7/89
4802354	HIGH-SECURITY AXIAL LOCK	2/7/89
4803860	COMBINATION LOCK DECODER	2/89
4817406	IMPRESSIONING TOOL	4/4/89
4836000	LEVER TUMBLER LOCK	6/6/89
4856309	PIN TUMBLER LOCK	8/15/89
4866962	ELECTRONIC KEY LOCK	9/19/89
4868409	VEHICULAR ANTITHEFT	9/19/89

4868559	OPTICAL KEY READER	9/19/89
4887445	ELECTRONIC LOCK	12/19/89
4891636	ELECTRONIC KEYLOCK SYSTEM	1/2/90
4901545	ELECTROMECHANICAL LOCK	2/20/90
4905490	ELECTRONIC DECODER	3/90
4966021	REPROGRAMMABLE LOCK	10/30/90
4972694	ELECTRIC STRIKE	11/27/90
4977767	EVVA WAFER LOCK	12/18/90
4977768	PICK RESISTANT AXIAL LOCK	12/90
5003801	PROGRAMMABLE KEY	4/2/91
5010750	MAGNETIC LOCK CYLINDER	4/30/91
5017851	COMBINATION LOCK DECODER	5/91
5020345	ELECTRONIC LOCK	6/4/91
5043593	OPTICAL THEFT SYSTEM	8/27/91
5058404	PUSH-BUTTON LOCK	10/91
5058465	IMPRESSION KEY HOLDER	10/91
5061923	ELECTRONIC COMB LOCK	10/29/91
5079936	HIGH-SECURITY LOCK	1/92
5083122	PROGRAMMABLE LOCK	1/21/92
5083362	VEHICLE ANTI THEFT	1/28/92
5086631	DISC CYLINDER LOCK	2/11/92
5094093	ELECTRONIC LOCK	3/10/92
5109684	CHANGEABLE PADLOCK	5/5/92
5133202	DECODING TOOL	7/92
5172578	DECODING TOOL	12/92
5224365	SIDEBAR LOCK DECODER	7/93
5325691	SIDEBAR LOCK PICK TOOL	7/94
5355701	METHOD OF DECODING	10/94
5402661	FORD SIDEBAR CYLINDERS	4/4/95
5454245	REMOVING SIDEBAR LOCK	10/3/95
5956984	LOCK PICKING APPARATUS	9/28/99
5987946	LOCK PICKING APPARATUS	11/23/99
6041629	LOCK PICKING APPARATUS	3/28/00
6082159	POCKET LOCK PICK	7/4/00
6134928	DECODING LOCK CYLINDERS	10/24/00
6138486	LOCK PICKING APPARATUS	10/31/00
6148652	DISC TUMBLER PICKING TOOL	11/21/00
6151936	APPARATUS FOR LOCK PICK KIT	11/28/00
6173595	LOCK PICKING APPARATUS	1/16/01
GB 2069589	SAFE LOCKING MECHANISM	1/30/81
GB 2112055A	ELECTRONIC LOCK	1982
GB 2114649	SAFE LOCKING MECHANISM	2/11/82
GB 2119011	SAFE LOCKING MECHANISM	4/8/83

MASTER PATENT ABSTRACTS FOR CLASS 70/394

The following listing provides abstracts for selected patents relating to lock picking and bypass. All of these patents are available in full-text format throughout this Infobase.

United States Patent 6,382,007 Wright May 7, 2002

Electro-mechanical system for determining key cuts for tumbler and wafer locks

A system for decoding locks having a sequence of spring-urged sliding members such as tumbler pins or wafers includes a probe device having the general contour of a key having a head portion and a straight shank fabricated of electrically insulative material and terminating in a tip portion having an oblique ramp surface. A series of spaced apart electrical conductors embedded within the shank in parallel relationship extend from the head portion to the ramp surface where they emerge as electrical contacts. An electrical circuit which includes an electronic monitoring and display apparatus detects when a given sliding member touches a most distant electrical contact, thereby representing a travel distance. The travel distance is correlated with a particular pin or wafer to produce the key code for the lock.

Inventors: Wright; Jesse M. (2929 S. Locust St., Denver, CO 80222)

United States Patent 6230529 Persson May 15, 2001

Tool for tubular key locks

A tool is disclosed for opening tubular locks in which a tubular key is receivable. The tool includes a plurality of probes that are releasably retained and secured in a given position to align the shear points in the lock in an opening position. The probes can be ergonomically and individually manipulated and have a course and a fine adjustment, such that the shear point of each tumbler can be easily and efficiently determined. Once the shear point is determined, the probe may be fixed in the position to maintain each tumbler driver.

Inventors: Persson; Kenneth E. (330 E. Elem St., East Rochester, NY 14445) Appl. No.: 365327 Filed: July 30, 1999

United States Patent 6173595 Hughes January 16, 2001

Lock picking apparatus

The method and apparatus for picking a lock which utilizes a single blade or pair of elongated thin, rigid, interchangeable blades which are to be inserted within the keyway of the lock. Each of the blades have an upper hiatused surface and can have an off-center sharpened edge so that the sharpened edge will contact the cylindrical lock pins of the lock spaced from the center of each of the lock pins. The off-center sharpened edge could be formed by beveling the side of the blade or by making a cut-out in the blade. The hiatused surface of the blades cause the "V" shaped tips of the cylindrical lock pins of the lock to move lineally with the sharpened edge causing the lock pins to pivot. Instead of a hiatused surface, there could be used one or more deflectable members, tufts of bristles or a brush. The blades are to be driven in a reciprocal manner with one blade moving in and the opposite blade moving out. The driving of the blades in an in and out linear motion can be accomplished either by an electrical motor or by a mechanical manually operated mechanism.

Inventors: Hughes; Donald R. (6120 W. Tropicana, Suite A-16-176, Las Vegas, NV 89103-4694) Appl. No.: 595062 Filed: June 16, 2000

United States Patent 6151936 Randall November 28, 2000

Method and apparatus for lock pick kit

A lock pick kit and method for opening a padlock without the padlock key, through the use of a conventional drill bit and a pair of specialized tools. The lock pick kit comprises a chisel having a shaft with first and second ends, a chisel handle attached to the first end, and a cylindrical protrusion attached to the second end. The second end of the shaft further includes a beveled cutting edge being positioned below and proximate a base portion of the protrusion. The kit further includes a pick having a shaft with first and second ends, a pick handle attached to the first end of the pick, with the pick handle configured to bend at a right angle to the longitudinal axis of the shaft, at its midpoint, an elongated tab extending from the second end of the pick at a right angle to the longitudinal axis of the shaft and a cylindrical protrusion extending from a free end of the elongated tab parallel to the axis of the shaft.

Inventors: Randall; Donald Lee (153 Redwood Ave., Hamilton Square, NJ 08610) Appl. No.: 390397Filed: September 3, 1999

United States Patent 6148652 Magini , et al. November 21, 2000

Picking tool for a disc tumbler lock

A lock picking tool for a high-security four-track disc tumbler lock, the tool probing all four tracks simultaneously.

Inventors: Magini; Mark A. (1021 E. Weldon, Phoenix, AZ 85014); Bradlee; Michael K. (1021 E. Weldon, Phoenix, AZ 85014) Appl. No.: 326323Filed: June 7, 1999

United States Patent 6138486 Hughes October 31, 2000

Lock picking apparatus

The method and apparatus for picking a lock which utilizes a single blade or pair of elongated thin, rigid, interchangeable blades which are to be inserted within the keyway of the lock. Each of the blades have an upper hiatused surface and can have an off-center sharpened edge so that the sharpened edge will contact the cylindrical lock pins of the lock spaced from the center of each of the lock pins. The off-center sharpened edge could be formed by beveling the side of the blade or by making a cut-out in the blade. The hiatused surface of the blades cause the lock pins of the lock to move lineally with the sharpened edge causing the lock pins to pivot. Instead of a hiatused surface, there could be used one or more deflectable members, tufts of bristles or a brush. The blades are to be driven in a reciprocal manner with one blade moving in and the opposite blade moving out. The driving of the blades in an in and out linear motion can be accomplished either by an electrical motor or by a mechanical manually operated mechanism.

Inventors: Hughes; Donald R. (6120 W. Tropicana, Suite A16-176, Las Vegas, NV 89103-4694) Appl. No.: 368920 Filed: August 6, 1999

United States Patent 6134928 Kang October 24, 2000

Method and apparatus for decoding lock cylinders

A method and apparatus for decoding locks having a guide member, an alignment member, a reader, and a recording medium, which a guide member is inserted into a lock to open the lock to receive an alignment member which aligns the tumbler members of a lock, thereby permitting a reader to be inserted into the lock, and withdrawn therefrom to cause a displacement of a pivotally connected reader arm which records an image of the lock profile on a recording medium.

Inventors: Kang; Samuel (863 Hyun Nae Ri Ha Bin Myun Dal Sung Goon, Taegu, KR) Appl. No.: 150711 Filed: September 10, 1998

United States Patent 6082159 Larsen July 4, 2000

Pocket lock pick

A compact lock pick assembly constructed and configured to be carried in a shirt pocket comprising the combination of a lock pick tool that is retractable into a generally tubular handle and a tension tool mounted on the tubular handle to act as a pocket clip is disclosed.

Inventors: Larsen; Ernest F. (2544 E. Holmes Ave., Mesa, AZ 85204) Appl. No.: 699262 Filed: August 19, 1996

United States Patent 6041629 Hughes March 28, 2000

Lock picking apparatus

The method and apparatus for picking a lock which utilizes a single blade or pair of elongated thin, rigid, interchangeable blades which are to be inserted within the keyway of the lock. Each of the blades have an upper hiatused surface and can have an off-center sharpened edge so that the sharpened edge will contact the cylindrical lock pins of the lock spaced from the center of each of the lock pins. The off-center sharpened edge could be formed by beveling the side of the blade or by making a cutout in the blade. The hiatused surface of the blades cause the lock pins of the lock to move lineally with the sharpened edge causing the lock pins to pivot. Instead of a hiatused surface, there could be used one or more deflectable members, tufts of bristles or a brush. The blades are to be driven in a reciprocal manner with one blade moving in and the opposite blade moving out. The driving of the blades in an in and out linear motion can be

accomplished either by an electrical motor or by a mechanical manually operated mechanism.

Inventors: Hughes; Donald R. (6120 W. Tropicana, Suite A16-176, Las Vegas, NV 89103-4694) Appl. No.: 354669 Filed: July 16, 1999

United States Patent 5987946 Watts November 23, 1999

Lock picking method and apparatus

Method and apparatus for non-destructively picking locks which normally are operated by keys, such locks capable of having twisting tumbler pins and sidebars. The method requires that: the pins be raised high in the keyway; the plug be axially bored by a thin drill which enters through a low portion of the keyway, the rear end of the drilled bore opening to the bolt cam operator; the drill bit be removed from the bore; and then the bolt cam operator be directly turned to shift open the bolt. This method does not decode the tumblers nor release any sidebar. The preferred apparatus comprises a pin raiser tool, which is self-retaining due to bias on the pins, which is transmitted to the handle of this tool; and a torquing tool, which is passed through the bore and has a blade which seats in the cam operator for turning the operator to shift open the lock bolt. A unique safety shield can be installed on the tailpiece to prevent picking by the method of this invention.

Inventors: Watts; James A. (2450 W. 82 St., Unit 201, Hialeah, FL 33016) Appl. No.: 911647 Filed: August 15, 1997

United States Patent 5956984 Hughes September 28, 1999

Lock picking apparatus

The method and apparatus for picking a lock which utilizes a single blade or pair of elongated thin, rigid, interchangeable blades which are to be inserted within the keyway of the lock. Each of the blades have an upper hiatused surface and can have an off-center sharpened edge so that the sharpened edge will contact the cylindrical lock pins of the lock spaced from the center of each of the lock pins. The off-center sharpened edge could be formed by beveling the side of the blade or by making a cut-out in the blade. The hiatused surface of the blades cause the lock

pins of the lock to move lineally with the sharpened edge causing the lock pins to pivot. Instead of a hiatused surface, there could be used one or more deflectable members, tufts of bristles or a brush. The blades are to be driven in a reciprocal manner with one blade moving in and the opposite blade moving out. The driving of the blades in an in and out linear motion can be accomplished either by an electrical motor or by a mechanical manually operated mechanism.

Inventors: Hughes; Donald R. (6120 W. Tropicana-Unit A16-176, Las Vegas, NV 89103) Appl. No.: 933128 Filed: September 18, 1997

United States Patent 5921122 Lin July 13, 1999

Device for preventing falling of upper pin tumblers of a lock during change of a lock core in the lock

A lock assembly includes a main body having a compartment defined in a lower part thereof for removably receiving a lock core therein. The main body further includes a number of upper chambers defined in an upper part thereof, each upper chamber including an upper pin tumbler received therein. The lock core includes a number of lower chambers defined therein, each lower chamber including a lower pin tumbler received therein. The main body further includes a number of longitudinally spaced holes defined in a periphery thereof each hole being communicated with a lower end of an associated upper chamber. A member has a number of branches, wherein each branch is removably inserted into an associated hole to support the associated upper pin tumbler during removal of the lock core.

Inventors: Lin; Jesse (Kaohsiung Hsien, TW) Assignee: Taiwan Fu Hsing Industry Co. Ltd. (Kaohsiung Hsien, TW) Appl. No.: 084382 Filed: May 27, 1998

United States Patent 5701773 Markisello December 30, 1997

Dual function apparatus for opening and removing automotive side-bar ignition locks

Apparatus for opening, or removing without damage, automotive side-bar type ignition locks, comprises a combination tool with a plurality of projections extending horizontally and forwardly

from the combination tool to engage the lock's keyway, at least one balanced pair of recesses in the lock's face, or, optionally, when the tool is used as a lock-remover, the inner walls of the lock's hollow wing-nut cylinder cap. When used as a lock-forcing opener, the combination tool is placed in position on the lock cylinder's face and a conventional wrench gripping the tool's hexagonally-shaped portion is turned to create torque applied by the tool's projections against the walls of the lock's recesses, forcing the lock cylinder to turn to its ON position and start the vehicle's engine. When the lock is to be removed without damage, the combination tool is used as a drill guide mounted on the lock by its projections, with its drill guide hole so positioned that an access hole drilled therethrough gives access for a side-bar pressure tool to be inserted and to exert inward pressure on the lock's side-bar, while at the same time a wafer pressure tool is reciprocated in the lock's keyway to urge the lock's wafer elements into lock-opening alignment, allowing the side-bar to be retracted. The lock can then be removed from its automotive mounting, a replacement key made, and the lock returned and reinstalled for continued use. Combination tool, matching drill bit, side-bar pressure tool and wafer pressure tool may be provided as a locksmith's kit.

Inventors: Markisello; Frank (91-10 Liberty Ave., Ozone Park, NY 11417) Appl. No.: 592892 Filed: January 29, 1996

United States Patent 5454245 Markisello October 3, 1995

Apparatus and method for removing side-bar automotive ignition locks without damage

Apparatus and method for removing side-bar automotive ignition locks without damage, a tool kit being provided containing a drill guide block, an adjustably molted drill bit, a side-bar pressure tool for insertion into the access opening created by the drill bit, and a wafer pressure tool for insertion into the keyway of the ignition lock to urge the lock wafer elements into alignment at the same time the side-bar pressure is being applied, causing retraction of the side-bar and consequent opening of the lock to permit its removal. Plugs are provided to reseal the drilled access opening.

Inventors: Markisello; Frank (91-10 Liberty Ave., Ozone Park, NY 11417) Appl. No.: 247577 Filed: May 23, 1994

United States Patent 5402661 Markisello April 4, 1995

Tool and method for turning on ford sidebar type ignition lock cylinders

A tool to start ignition side bar type lock cylinders in all Ford vehicles is provided and consists of using a tool which has a guide key to hold the tool in place, two tabs to cut into the face of the cylinder, a hexagonal shape at rear of tool to accept a wrench for turning the cylinder to the ON position and thus start the vehicle.

Inventors: Markisello; Frank (9-10 Liberty Ave., Ozone Park, NY 11417) Appl. No.: 850791 Filed: March 13, 1992

United States Patent 5355701 Tobias October 18, 1994

Method and apparatus for decoding a pin tumbler lock

Methods and apparatus for decoding pin tumbler locks, and more specifically, a mechanical key card lock. To determine the length and weight of a given pin tumbler, a probe is inserted within the lock, comprised of one or a matrix of many force sensing resistors. The probe will respond to variations in pressure and tension of each pin tumbler, and will thus provide a range of output resistances, directly related to the pressure exerted upon the sensor by a particular pin tumbler. The outputs of the sensors are then electronically sensed and recorded so that a duplicate key can be produced.

Inventors: Tobias; Marc W. (4317 Town Park Pl., Sioux Falls, SD 57105) Appl. No.: 024288 Filed: March 1, 1993

United States Patent 5325691 Embry July 5, 1994

Method and apparatus for use in picking and decoding sidebar locks

The present invention relates to lock picking and decoding tools and a method of using the same. The lock decoding tools comprise a torquing tool, a picking tool, and decoding tools. The method

comprises using the torquing tool to bias the locking bar out of a notch in the inner wall of the cylinder housing, picking the tumblers using the picking tool, turning the cylinder lock slightly so as to permit the torquing tool to be removed, turning the lock cylinder to the "ON" position, and decoding the cylinder lock using the decoding tools.

Inventors: Embry; Donald J. (Cloverport, KY) Assignee: HSL Marketing, Inc. (Atlanta, GA) Appl. No.: 006260 Filed: January 19, 1993

United States Patent 5224365 Dobbs July 6, 1993

Side bar lock decoder

A side bar lock decoder has a pair of guide plates laminarly arranged between a pair of side plates. Key portions of the plates have notches spaced for alignment with the lock wafers. Narrow passages between the guide plates extend from each of the notches to the edges of the base portions of the plates at approximately normal fingertip positions when the base portions are handheld. Wires slidably disposed in each of the passages extend from an outer end of each of the notches beyond the grip edges. One end of the wires abuts one of the wafers when the wafers and the notches are aligned. Springs, bias each of the wires toward a threshold reference position within the notches. Plungers, one connected to each of the wires, extend beyond the grip edges, are independently biased away from their respective edges by the springs. One or more housings secured to the laminar plates have at least one chamber therein for guiding the movement of each of the plungers during manipulation. Windows in the housings allow viewing of the depth of each plunger in its housing and at least one graduated scale on each housing, corresponding to the graduated scale of wafer depths of the lock, indicates the position of each plunger in relation to its threshold reference position when the wafers are shifted into the "open lock" condition. Pins extend from each plunger externally of its housing to facilitate simultaneous finger manipulation of each plunger.

Inventors: Dobbs; Jerry L. (Rte. 2, Box 411E, Sand Springs, OK 74063) Appl. No.: 927466 Filed: August 10, 1992

United States Patent 5172578 Bitzios December 22, 1992

Locksmith tool

An apparatus for determining lengths of locking elements in locks including a key head and wires maintained on the key head and extendable into the lock cylinder for measuring lengths of the lock pins. The distance that the wires will go into the depth of lock can be used to determine the depth of the furrows or the cuts of the needed key. The advantage of this invention is that one can duplicate a key which has been lost, without damaging the lock, or moving it out of the door. In addition to that this mechanism is also used as a "lock-picker" in order that one can lock or unlock a door when the keys have been lost. The invention operates in two different ways and for two different purposes. The first one is to duplicate a key which has been lost. The second one is to lock or unlock a door for different reasons, e.g. when the key has been lost, or when it is still inside the car or the house while the door is still locked.

Inventors: Bitzios; Spiridon A. (Kartall 11, Ioannina, GR) Appl. No.: 785240 Filed: November 1, 1991

United States Patent 5133202 Grant July 28, 1992

Disk tumbler lock decoder

A decoder is provided for disk tumble locks which is electrically rather than mechanically operated. A plurality of separate keys each has a blade sufficiently long to extend through all of the disks in the lock. At least one cut is provided in the blade of each key. The depth of the cut in each key is different, the cut of each key being coordinated to a different depth of disk from among the known alternative disk depths for the given tumbler lock to be decoded. The base surface of each cut contains discrete electrical contact connected by a discrete conductor to a point on the key which is externally accessible when the key is fully inserted into the lock. Each contact is positioned on its key so that, when the key is inserted into the lock keyway, an electrically conductive circuit is completed by the disk if the depth of the disk corresponds to or exceeds the depth of the cut. By alignment of the contact with a disk, a discrete electrical circuit will extend from the externally accessible positive point on the key when the contact is aligned with a disk of appropriate

depth. If keys are sequentially inserted into the keyway, beginning with the key of deepest cut and gradually progressing toward the key of shallowest cut, the key first completing the electrical circuit associated with any disk will complete a circuit indicating the depth of that disk, thus decoding the lock.

Inventors: Grant; Maurice (11390 N 209 E. Ave., Claremore, OK 74017) Appl. No.: 703195 Filed: May 20, 1991

United States Patent 4836000 Hirvi June 6, 1989

Lever tumbler lock

The present invention relates to a lever tumbler lock in which the scrape marks caused by the key bit as it displaces the various tumblers will not be completely informative of the configuration of the key bit. According to the invention the lock includes a device which as a key bit (13) inserted into the lock housing (1) is turned will scrape against at least a part of the cam surface (10) of at least one tumbler (2) such as to create on this cam surface or those cam surfaces scrape marks which cover the scrape marks caused by corresponding cams on the key bit when the key is turned, at least at the beginning and the end of these scrape marks.

Inventors: Hirvi; Jorma (Eskilstuna, SE) Assignee: AB Fas Lasfabrik (Eskilstuna, SE) Appl. No.: 199669 Filed: May 26, 1988

United States Patent 4817406 Martin April 4, 1989

Lock impressioning key

An impressioning key for making an impression of the tumblers of a lock comprises a key blank having a main portion of relatively hard material with a recess in an upper forward edge portion. A tumbler engaging portion consisting substantially wholly of lead is secured to the main portion in the recess, the tumbler engaging portion being a solid preshaped body of lead filling the recess.

Inventors: Martin; William E. (499 John Street N., Hamilton, Ontario, CA) Appl. No.: 082619 Filed: August 7, 1987

United States Patent 4667494 Joosten May 26, 1987

Tool set and method for opening and decoding locks

A tool set and a method of opening and decoding a side bar lock employing wafer type tumblers. A spring compressor tool configured for insertion into the lock mechanism keyway raises all the tumblers to a radially outward position and compresses the springs that normally bias the tumblers inwardly. A spring retainer tool inserted into the keyway with the spring compressor tool engages the tumbler springs to retain the springs in a compressed position but frees the tumblers for movement. A tumbler adjusting tool is inserted to grasp the tumblers, and move the tumblers to a position where the lock mechanism can be opened. A decoding tool is inserted to measure the radial position of each tumbler and provide a number which can be used to make a new key. A dust cover holding tool is provided to hold open the spring actuated dust cover.

Inventors: Joosten; Douglas W. (13513 Auburn NE, Albuquerque, NM 87112) Appl. No.: 818364 Filed: January 13, 1986

United States Patent 4617813 Christopher , et al. October 21, 1986

Lock-picking tool and method of use thereof

A picking tool adapted to open a cylinder lock of the axial pin tumbler type having its tumblers arranged in a coplanar configuration, includes a planar torquing core insertable into the lock keyway in a longitudinal direction, a plurality of longitudinal guideway channels formed on opposing faces of the core, and respective tumbler probes longitudinally reciprocable in the channels. A holder, which acts as a handle for manipulating the picking tool, also serves as a housing surrounding the core and the probes. The holder is formed with a pair of radial openings in opposite sides thereof which receive respective brake segments for exerting a frictional drag on the probes. An adjustable hoop clamp surrounds the brake segments for manually adjusting the frictional drag, so that the proper tumbler displacement action can be achieved. Setscrews are threaded into the body of the holder for clamping the probes in

their final tumbler-displacing positions. At the rear of the holder, the tail ends of the probes fan out circularly so that they can be more easily manipulated individually. The probes have indicia from which the lock code can be read out after the probes reach their final positions.

Inventors: Christopher; Walter S. (Park Ridge, IL); Kriskovich; Robert T. (Roselle, IL); Steinbach; Robert L. (Glendale Heights, IL) Assignee: Chicago Lock Co. (Chicago, IL) Appl. No.: 403094 Filed: July 29, 1982

United States Patent 4606204 Cooke, Jr. August 19, 1986

System and apparatus for opening cylinder locks

A lock opening method and mechanism for opening locks in minimum time while requiring very little skill on the part of the operator. The mechanism includes an adapter assembly, a tension arm and an oscillator unit. The assembly asserts rotary force to a lock cylindrical plug. This causes the lock pins to release and allowing the lock to be opened.

Inventors: Cooke, Jr.; Robert G. (Rte. 2, P.O. Box 29, Ahoskie, NC 27910) Appl. No.: 565403 Filed: December 27, 1983

United States Patent 4535546 Smith August 20, 1985

Locksmith tool apparatus for determining length of locking elements in locks

Locksmith tool apparatus determines the length of a locking element in a lock by engaging a locking element inside a lock and by moving the element to compress a compression spring to a known minimum length and by measuring the distance moved. By subtracting the distance the element is moved from known dimensions, the length of the locking element is determined.

Inventors: Smith; Rodney D. (6550 N. 2nd Dr., Phoenix, AZ 85013) Appl. No.: 583679 Filed: February 27, 1984

United States Patent 4517746 Easley May 21, 1985

Method and apparatus for decoding wafer combination locks

A probe for manually decoding a lock of the wafer combination type having an elongate body to slideably engage the keyway, the body comprising at least two hollow tubular members. Within the hollow members are rotatably disposed detecting members which detect, by means of physical contact, certain identifying portions of wafers therein which form the combination of the lock. An indicator on the outside of the probe, responsive to the detecting members, indicates the presence, type, and orientation of the wafers. The same method may be practiced without the use of the probe by viewing the interior of the lock slightly off center with a pencil beam of light to determine the same characteristic wafer portions.

Inventors: Easley; Thomas E. (1303 Fourth St., La Grande, OR 97850) Appl. No.: 499275 Filed: May 31, 1983

United States Patent 4400956 Martin August 30, 1983

Skeleton key kit

A key kit for opening tumbler locks has a key member with a shaft insertable into a tumbler lock, the shaft having a series of longitudinally-spaced recesses into which the tumblers in the lock can respectively enter. A foil of impressionable material is removably positionable on the shaft over the recesses, and a tumbler displacing member is insertable into the lock with the shaft and foil to displace the tumblers without the tumblers engaging the foil. The tumbler displacing member being removable from the lock after the shaft and foil have been inserted therein to enable the key member to be manipulated to cause the tumblers to make impressions in the foil corresponding to the key shape required to open the lock.

Inventors: Martin; William E. (Hamilton, CA) Assignee: Martin & Starchuk Limited (Dundas, CA) Appl. No.: 290037 Filed: August 5, 1981

United States Patent 4300416 Ross November 17, 1981

Key blank impressioning tool

A key blank impressioning tool has a pair of pivotally, interconnected parts for manipulation by the hands of the user. As one of the parts is grasped by one hand to apply torque to the key blank in the keyway of the lock to in turn tend to turn the plug of the lock, the second part of the tool is used by the other hand of the operator for the purpose of reciprocating a block so as to strike light blows of such nature as to create indentations in one edge of the blank to thereby identify the location and depth of the tumbler cuts to be made in the key blank.

Inventors: Ross; William D. (Kansas City, MO) Assignee: William D. Ross Manufacturing Corporation (Kansas City, MO) Appl. No.: 084620 Filed: October 15, 1979

United States Patent 4229959 Easley October 28, 1980

Method and apparatus for opening a lock

A novel method and apparatus for opening a magnetic cylinder lock of the type having an outer cylinder, a rotatable inner cylinder disposed within the outer cylinder, one or more magnetic pins disposed within chambers of one of the cylinders for engaging the other cylinder to prevent the inner cylinder from rotating, and a keyway within the inner cylinder for insertion of a magnetic key to displace each pin and release the inner cylinder, thereby opening the lock. A probe is provided for insertion within the keyway to determine the presence and polarity orientation of each magnetic pin by detecting its magnetic field. An indexing arm within the probe abuts the lock and provides a signal representative of the position of each pin chamber. Sensor circuitry correlates a signal from the probe representative of the presence and polarity orientation of each pin with a signal from the indexing arm representative of the position of each pin chamber and displays the "combination" of the lock. A selectively-actuable master key with a plurality of electromagnets imbedded therein is provided for insertion into the keyway and a power supply is used to actuate the electromagnets momentarily while turning the master key to displace each pin and open the lock.

Inventors: Easley; Thomas E. (1303 Fourth St., LaGrande, OR 97850) Appl. No.: 025402 Filed: March 30, 1979

United States Patent 4186577 Jarm February 5, 1980

Lock opening device

A device for opening a lock without the use of a key cut to the specific tumbler configuration of the lock, said device comprising a holder having a key blank corresponding to the key slot formed in the lock core mounted at one end thereof. A resilient member is secured to the key blank in such a position that it will engage the tumblers of the lock when the key blank is inserted into the key slot. In addition, a means is secured to the holder for engaging the lock housing in which said core rotates on the side thereof opposite the location of the tumblers and for urging the key blank and core against said engaged side in a manner such that the width of the shear line between the core and lock housing will be increased at the location of the tumblers. By adjusting the alignment of the key blank within the lock core, the spring-loaded tumblers will be caused to deform the resilient member at various depths until they are brought into the desired alignment along the shear line between the core and lock housing thereby permitting the rotation of the core within said lock housing.

Inventors: Jarm; Robert L. (Wauconda, IL) Assignee: Credit Industry Associates, Inc. (Arlington Heights, IL) Appl. No.: 924978 Filed: July 17, 1978

United States Patent 4185482 Nail January 29, 1980

Lock decoding mechanism

A mechanism for opening and/or decoding the bittings of a key for opening a cylinder lock. The mechanism comprises a housing having a forward projection shaped in the form of a key body and an abutment surface spaced from the forward projection disposed to abut the cylindrical plug of the lock when the forward projection of the housing is inserted in the keyway of the lock. A plurality of shims, including at least one shim associated with each lock tumbler, are supported in the housing, for longitudinal movement within the housing. Each of the shims have an elongated portion directed toward and supported in the forward projection of the housing and a tumbler actuating cam extending from the elongated portion. A plurality of actuators are associated with the

plurality of shims respectively. Each actuator is selectively shiftable for moving its respective shim with respect to the associated tumbler to position the tumbler for opening the lock. Indicia on the housing associated with the actuators indicates the positions of the actuators corresponding to the respective positions of each of the tumblers whereby the bittings of a key to move said tumblers to their respective positions to open the lock may be determined.

Inventors: Nail; William B. (247 Terrace Park, Rochester, NY 14619) Appl. No.: 880657 Filed: February 23, 1978

United States Patent 4094176 Hughes June 13, 1978

Pick for tubular cylinder locks

A pick for tubular cylindrical locks which includes a central substantially cylindrical member which has a plurality of grooves thereon, each groove to accommodate an elongated pin. The pins are capable of axial movement with respect to the cylindrical member against the action of a frictional brake in the form of rubber O-ring assembly. The very tip of the pins connect with a head which is adapted to be placed about the rotatable cylinder portion of a tubular lock. The head includes a series of axial slots and upon being moved axially into the cylindrical member, the head slightly deflects and frictionally secures to the cylinder portion of the lock. The head is moved axially by a fastener which connects between the rearwardmost end of the first member and the head.

Inventors: Hughes; Donald R. (2600 Brower Ave., Simi Valley, CA 93065) Appl. No.: 832279 Filed: September 12, 1977

United States Patent 4073166 Clark February 14, 1978

Magnetic lock pick

A device for opening locks with magnetically actuated tumblers or pins is provided with a housing of non-magnetizable composition and a plurality of interlocking gear wheels, pivotably retained in the housing, and also constructed from materials not susceptible to permanent magnetization. The gear wheels are pierced by a plurality of orifices across their thickness and

cylindrical permanent magnets are inset into each orifice with a substantially random distribution of their North and South poles with respect to the faces of the wheels. Means are provided to rotate the wheels simultaneously around their pivot axes, thereby generating a changing, random distribution of magnetic fields arising from the interaction of the inset permanent magnets. By holding the housing of the magnetic pick proximate to the usual placement of the coded magnet key of the lock, the magnetic pins, or tumblers, therein are exposed to a large combination of structured magnetic fields, one of which is likely to correspond to the key code.

Inventors: Clark; William H. (16521 Queenside Dr., Covina, CA 91722) Appl. No.: 756080 Filed: January 3, 1977

United States Patent 4006613 Zion February 8, 1977

Lock pick mechanism

A lock pick mechanism having a plurality of lock picks, a frame and housing members is disclosed. The lock picks, frame and housing members are connected together such that the lock picks may be contained within the frame and enclosed by the housing members when the lock picks are in their storage positions and such that an individual lock pick may be selected and pivotally moved from its storage to its operative position when the housing members are opened. After the selected lock pick has been moved to its operative position, the housing members may be closed to maintain the lock pick in its operative position.

Inventors: Zion; Westley (New York, NY) Assignee: Majestic Lock Co., Inc. (New York, NY) Appl. No.: 657193 Filed: February 11, 1976

United States Patent 3987654 Iaccino , et al. October 26, 1976

Method and apparatus for decoding twisting tumbler locks and locks resistant thereto

Methods and apparatus for decoding twisting tumbler locks and improvements in such locks to resist such methods and apparatus. To determine depth of cut of bit for a given tumbler, a blade is inserted into key way to position a wirelike probe at tumbler to

be decoded. Wirelike probe is advanced upwardly until it engages tit at top of tumbler. Depth of cut of key bit is function of length of tumbler and device can be calibrated to give direct readout of depth of bit cut. Angle of key bit can be measured by hooking a wirelike probe in side gate groove in tumbler and then twisting tumbler until tit engages key plug or shell. Amount of twist permitted is function of angular position required to register tumbler groove with side gate and device can be calibrated to give direct reading of such angle. To defeat depth of cut decoder, twisting tumbler lock wherein tits on tumblers are located at different distances from tops of tumblers is disclosed. Another form of modified twisting tumbler locks that will defeat decoding methods and apparatus herein is tumbler with side gates receiving grooves 180.degree. apart and with no tit.

Inventors: Iaccino; George V. (New Rochelle, NY); Idoni; Robert A. (New Rochelle, NY) Assignee: Lock Technology, Inc. (New Rochelle, NY) Appl. No.: 516465 Filed: October 21, 1974

United States Patent 3985010 Idoni October 12, 1976

Method and apparatus for decoding twisting tumbler lock and twisting tumbler lock resistant thereto

Method and apparatus for decoding twisting tumbler lock of the type wherein side bar is sole locking element and normally bridges shear plane unless radial apertures in twisting tumblers are all in vertical and horizontal register with complementary side bar protrusions. Decoding apparatus comprises three devices each with a blade insertable in keyway and having upwardly and rearwardly sloping front surface angulated at one of three angles to which tumblers must be twisted for horizontal registration of apertures. Each blade has indicia for indicating that front surface is at particular tumbler and further has indicia for determining amount of elevation of tumbler resulting from camming action between chisel shaped tumbler bottom and blade front surface when blade is advanced from initial engagement with tumbler to elevate tumbler. Method includes step of torquing blade during advancement to bias side bar toward tumblers and thus force protrusion into associated tumbler aperture when aperture registers with protrusion. This movement causes small but detectable resistance to further advancement and, thus, yields positive indication of registration. As angle of front surface is known and required tumbler elevation is known, tumbler is decoded. By repeating process with all tumblers, lock is

decoded.

LOCKS AND SAFES: THE CONSTRUCTION OF LOCKS

Compiled from the papers of A. C. HOBBS
and edited by CHARLES TOMLINSON, ES
PHYSICAL SCIENCE KING'S COLLE

TO WHICH IS ADDED A DESCRIPTION OF MR. J. BEVERLEY I
A NOTE UPON IRON SAFES, BY ROBERT MALLET,

Reproduced and Printed in Great Br

Redwood Press Limited, Trowbridge ar
First Published 1868 by Virtue and Co.
Reprinted 1970 SBN 90157130

ADVERTISEMENT

THE first edition of this volume, though at the date of its appearance coordinating with the state of knowledge of the period, and containing matter well arranged and lucidly described, as must have been expected from the reputation of its author, had, through the lapse of the few intervening years,

inevitably become somewhat behind the state of the art of which it treats, one which is daily receiving the attentive consideration of many skilful men, and occasional marked improvements. Amongst those of later years none are more noteworthy than the locks patented by Mr. Fenby, of Birmingham; of these an account, with accurate illustrations, for which the drawings are supplied by the inventor, is now added, together with a brief essay upon the important but popularly ill-understood subject of iron safes.

April, 1868
ROBERT MALLET

In reference to Mr. Smyth's letter, which is given at pp. 130, 131, that gentleman is DESIROUS to state that it was in consequence of the defects there pointed out that Hr. Hobbs was enabled to pick the Bramah lock operated upon, which had been manufactured forty years previously, when the sliders were made of iron instead of steel as they now are, and yet, notwithstanding that and the other defects pointed out, it took Mr. Hobbs sixteen days to pick it.

In proof of the security of the Bramah lock, Mr. Smyth mentions that Mr. Hobbs's best workman failed in picking an ordinary 3" Bramah box lock; and that a person in the employ of Messrs. Johnson and Ravey, of Conduit Street, failed also in his attempt to pick a 6" cellar-door lock, though he had the look in his possession for twelve months, employing his evenings in making instruments and trying to pick it.

Mr. Smyth contradicts the statement that the new lock was removed from the window through any fear of its being opened. On the contrary, it was put up especially to afford an opportunity for Mr. Hobbs to make, if he thought fit, another trial, and it remained in the window four months. The sole cause of its removal was to stop the impertinent applications of men and boars, which interfered too much with the general business of the firm.

Alfred C. Hobbs

PREFACE

THE reader is entitled to know the origin of the small work which he holds in his hands.

In August 1852, being about to write a short article on Locks for a Cyclopedia of Useful Arts, of which I am the editor, I consulted my esteemed and lamented friend, the late Professor Cowper, of King's College, as to the desirability of explaining to the general reader the defects of some of our English locks, which, previous to the celebrated "lock controversy" of 1851, had borne a high character for skilful construction, beauty of workmanship, and undoubted security.

Professor Cowper expressed his strong conviction that by exposing the effects of our locks, the cause of mechanical science, as well as the public in general, would be benefited; that if our locks were defective, inventors would be stimulated to supply the defects, and the art of the locksmith would be raised accordingly.

He considered that Mr. Hobbs had made a considerable step in advance in the constructive details of his art, not only in having detected the weak points of some of our best English locks, but also in having introduced two or three new locks, which appeared to be more secure than any of those previously

produced.

Professor Cowper gave me an introduction to Mr. Hobbs, who placed at my disposal a variety of literary materials relating to the history and construction of locks, and stated his intention at some future time of bringing out a small book on the subject, if he could meet with a publisher. I recommended him to offer the work to Mr. Weale, for insertion in his series of Rudimentary Works. This was accordingly done, and I was invited to prepare the work; but as my engagements did not leave me sufficient leisure to write the book, I requested my friend Mr. George Dodd to put the materials together, and to search for more.

Mr. Dodd acceded to my request; and having completed his part of the work, I subjected it to a careful revision, and added various details which seemed to be necessary to completeness, at least so far as the narrow limits of a small rudimentary work would admit of completeness. The manuscript was then sent to press.

Each sheet as it was received from the printer was submitted to Mr. Hobbs, who read it with care, and made his annotations and corrections thereon. Mr. Hobbs and I then had a meeting, when the additions and corrections were read and discussed, and admitted or rejected as the case might be. The sheet having been thus corrected was sent to press.

It should also be stated that, during the progress of the work, Mr. Weale, at my request, wrote to Messrs. Bramah, and also to Messrs. Chubb, informing them that a Rudimentary Treatise on the Construction of Locks was being prepared, and requesting them to state in writing what alterations or improvements they had made in their locks since the date of the Great Exhibition. The communications which we have received from these celebrated firms are inserted verbatim, in their proper places, in the present work.

Such is the mode in which this small volume has been prepared. I have endeavored to perform an editor's duty conscientiously, without entertaining the feeling of a partisan in the matter. My chief object in superintending the production of this book (an object in which the Publisher fully participates) is to advance the cause of mechanical science, and to supply a deficiency in one of the most interesting portions of its English literature.

C. TOMLINSON.
July 1853.

The Bramah Lock Company was recognized by the Crown as a vendor with whom they chose to do business. The lock produced by Bramah is still made today, and was one of the driving forces for dramatic changes in the design of locking mechanisms during the middle of the nineteenth century.

Chapter 9 The Lock Controversy: during and since the time of the Great Exhibition

CHAPTER ONE: On Locks and Lock-Literature

THE manufacture of looks, and a consideration of the mechanical principles involved in their construction and security, have never yet been treated with any degree of fullness in an English work. Lock-making has occupied a large amount of ingenuity, and lock-patents have been obtained in considerable number, though

not always, we are satisfied, with a commensurate return for the expense incurred, but lock-philosophy (if so it may be designated) has not been largely attended to.

And yet it may safely be said that much which is both mechanically and commercially important is comprised in a lock. Every improvement in the manufacture of iron, steel, and brass, that is, in the tool-making and machine-making processes, may be made to reflect its light on the lock manufacture; the stamping, the casting, the planing, the slotting, the screw-cutting, the polishing of metals, all, in proportion as they are improved, impart some of their aid to the lock-maker.

Then, in the finer kinds of locks, the works are so delicate as to approach to the nicety of clockwork; thereby combining the manipulative skill of a talented artisan with the rougher mechanical work of the smith. The principles of mechanical science are also appreciated by many lock-makers. The lever, the inclined plane, the eccentric, the cam, the screw, the wheel and pinion, the ratchet, the spring, all are brought to bear on the internal mechanism of locks, frequently in many novel combinations.

The commercial importance of locks, though of course never seriously questioned when once fairly brought before one's attention, has been recently rendered so apparent as to have risen to the position of a public topic. If a strong room, containing gold and silver, notes and bills, books and papers, if such a room be necessarily shielded from intrusion, it becomes no less necessary that the shield should be really worthy of its name, trusty and reliable: a good lock is here nearly as indispensable as a faithful cashier.

And without dwelling on such an auriferous picture as a room full of gold, we shall find ample proof of the commercial importance of lock-making in the ordinary circumstances by which we are every day surrounded. Until the world becomes an honest world, or until the honest people bear a larger ratio than at present to the dishonest, the whole of our movables are, more or less, at the mercy of our neighbors. Houses, rooms, vaults, cellars, cabinets, cupboards, caskets, desks, chests, boxes, caddies, all, with the contents of each, ring the changes between *meum* and *tuum* pretty much according to the security of the locks by which they are guarded.

A commercial, and in some respects a social doubt has been

started within the last year or two, whether or not it is right to discuss so openly the security or insecurity of locks. Many well-meaning persons suppose that the discussion respecting the means for baffling the supposed safety of locks offers a premium for dishonesty, by showing others how to be dishonest. This is a fallacy. Rogues are very keen in their profession, and know already much more than we can teach them respecting their several kinds of roguery.

Rogues knew a good deal about lock-picking long before locksmiths discussed it among themselves, as they have lately done. If a lock, let it have been made in whatever country, or by whatever maker, is not so inviolable as it has hitherto been deemed to be, surely it is to the interest of honest persons to know this fact, because the dishonest are tolerably certain to apply the knowledge practically; and the spread of the knowledge is necessary to give fair play to those who might suffer by ignorance.

It cannot be too earnestly urged that an acquaintance with real facts will, in the end, be better for all parties. Some time ago, when the reading public was alarmed at being told how London milk is adulterated, timid persons deprecated the exposure, on the plea that it would give instructions in the art of adulterating milk; a vain fear, milkmen knew all about it before, whether they practiced it or not; and the exposure only taught purchasers the necessity of a little scrutiny and caution, leaving them to obey this necessity or not, as they pleased.

So likewise in respect to bread, sugar, coffee, tea, wine, beer, spirits, vinegar, cheap silks, cheap woolens, all such articles as are susceptible of debasement by admixture with cheaper substances, much more good than harm is effected by stating candidly and scientifically the various methods by which such debasement has been, or can be produced.

The unscrupulous have the command of much of this kind of knowledge without our aid; and there is moral and commercial justice in placing on their guard those who might possibly suffer therefrom. We employ these stray expressions concerning adulteration, debasement, roguery, and so forth, simply as a mode of illustrating a principle, the advantage of publicity.

In respect to lock-making, there can scarcely be such a thing as dishonesty of intention: the inventor produces a lock which he honestly thinks will possess such and such qualities; and he

declares his belief to the world. If others differ from him an opinion concerning those qualities, it is open to them to say so; and the discussion, truthfully conducted, must lead to public advantage: the discussion stimulates curiosity, and the curiosity stimulates invention. Nothing but a partial and limited view of the question could lead to the opinion that harm can result: if there be harm, it will be much more than counterbalanced by good.

The literature of lock-making is, as we have implied, very scanty, both in England and America. The French and Germans, though far below our level as lock-makers, are very superior to us in their descriptions of the construction and manufacture of locks. Take, for instance, the French treatise published more than eighty years ago by the *Academie des Science'*, and forming part of a folio series of manufacturing treatises, illustrated very fully by engravings. It is worth while to examine this work, to see how minutely and faithfully the writers of such treatises performed their task nearly a century ago. The *Art du Serrarier***, with the distinguished name of M. Duhamel du Monceau as the author or editor, was published in 1767.

It occupies 290 folio pages, and is illustrated by 42 folio plates. The first chapter gives us an introduction and general principles, in which the choice and manipulation of materials are touched upon; the different qualities of iron and steel; and the processes of forging, founding, welding, stamping, filing, polishing, etc.

In the copper-plates representing these smiths' operations and the tools employed, there is a smithy, with about a dozen smiths engaged in all these various occupations, with stockings down, and a due amount of workshop slovenliness. The next chapter takes us into what may perhaps be called "smith's work in general," or at least it treats of the manufacture of various kinds of ironmongery for doors, windows, and house-fittings generally.

Then the third chapter treats of "smith's work which serves for the security of houses," consisting of railings, palings, bars, and gates of various kinds, such at least as are made of iron. In chapter four we have a notice of such kinds of smith's work as relate to the fastenings for doors, windows, closets, chests, etc.; such as hinges, hasps, latches, bolts, and other contrivances less complex than an actual lock.

This brings us, by a natural transition, to locks in general, which form the subject of chapter five, to which is attached the

illustrious name of M. de Reaumur as the author. Here are given a hundred folio pages of description, illustrated by twenty folio plates relating to locks, lock-making, and locksmiths. The sixth chapter relates to the iron-work of carriages, or the labors of the coach-smiths; while chapter seven, to wind up the work, relates to bell-hanging.

That chapter of the work which has reference to locks is the only one with which we have to do here. It is arranged in a systematic manner, beginning with the simpler locks, without wards or tumblers, and proceeding thence to others of more complex construction. The period at which the work was written was too early to lead us to expect to find a tumbler-lock described and delineated: there are, however; numerous examples of single tumbler-locks, many of them of great ingenuity.

The use of multiple bolts, that is, of many bolts shot at once by one action of the key, seems to have been familiar enough to the locksmiths of those days. One lock represented is remarkable; it is attached to a strong and ponderous coffer or chest. The chest is open; and the whole under or inner surface of the cover is seen to be occupied by a lock of intricate construction; there are no less than twelve bolts, three on each long side, one on each short side, and one in each corner; these bolts are so placed as to catch under a projecting rim fixed round the top of the coffer. The collection of keys, exhibited on a separate plate, is remarkable for the great variety of forms given to them. We shall by and by copy some of the drawings of this curious work.

It was to be expected that in the *'Encyclopedie Methodique'* published in the same country and in the same century, the locksmith's art would be treated at some such length as in the work just described. Among the two hundred volumes of which the *cyclopedie* consists, several are devoted to arts and manufactures; and one of them contains the article in question.

It occupies 168 quarto pages, and is illustrated by 35 copper-plate engravings, showing in detail not only the parts of various locks, but the tools used by the lock maker. It is proper, however, to remark, that much of the letterpress and many of the plates relate to smith's work generally, and not exclusively to lock-work; the French name *serrurerie* being applied not only to lock-making, but to most of the smith's work required in dwelling-houses.

This affords, indeed, a striking illustration of the fact that until lately a lock-maker has been regarded rather as a smith than as a machinist; rather as a forger and filer of pieces of iron, than as a fabricator of delicate mechanism. One of the most curious features in this treatise is a vocabulary, containing in alphabetical arrangement, a minute account of all the French technical terms employed in the locksmith's art. This vocabulary alone occupies 38 quarto pages.

The Germans, like the French, bestow great attention on the treatises relating to the manufacturing arts. Some of these are, indeed, worked up to a degree of minuteness which would seem superfluous, where little distinction is drawn between the importance of fundamental principles and that of mere technical details. Locks have had their due share.

The article on locks in Prechtl's *Technological Encyclopedia* written by Karmarsch, and published in 1842, occupies about 140 pages. Locks are very minutely classified by the author, according to the purposes and their modes of action, and are illustrated by many plates. One of his classifications is into *German, French,* and *Bastard* locks, referring in part to the extent to which the key turns around in the lock; and the last of the three having an intermediate character between the other two.

After treating of the ordinary warded locks, he comes to the combination principle; and it is profitable here to notice how well the works of our machinists are understood on the continent, when they have anything to recommend them; there are a dozen closely printed pages devoted to a minute description of Bramah's invention, with all the separate parts illustrated by copper-plate engravings. After this comes a more general account of the details and manufacture of locks, similarly illustrated by engravings.

Whatever may be the merits of the different articles relating to locks in the various English cyclopedias, there are none approaching in length to the article in Prechtl's work. But when we consider that Prechtl devotes twenty large volumes to technological or manufacturing subjects, he is of course able to devote a larger space to each article than is given in English works. Both in England and in America, men are more disposed to do the work than to describe it when done.

In the *Encyclopedia Britannica,* in Rees' *Cyclopedia,* in Hebert's *Engineers' and Mechanics' cyclopedia,* in the *Encyclopedia*

Metropolitana, in the *Penny Cyclopedia,* and in other similar works, locks are described as well as can be expected within the limits assigned to the articles. Mr. Bramah's essay on locks, and on his own lock in particular, is one of the few English pamphlets devoted expressly to this subject.

An excerpt from the proceedings of the Institute of Civil Engineers, in 1851, gives an interesting paper on locks by Mr. Chubb; and shorter reports of papers and lectures have been published in various ways. Perhaps the best account of locks which we have, considering the limited space within which a great deal of information is given in a very clear style, is that contained in Mr. Tomlinson's “Cyclopedia of Useful Arts.”

CHAPTER TWO: Ancient Locks: Grecian, Roman, Egyptian

MASTER EXHIBIT LIST

LOCKS and door-fastenings have not, until modern times, been susceptible of any classified arrangement according to their principles of construction. They have been too simple to require it, and too little varied to permit it. That some such fastenings must be employed wherever doors of any kind are used is sufficiently apparent; and there is a little (though only a little) information obtainable, which shows the nature of the fastenings adopted in early times.

The bolt, the hasp, the chain, the bar, the latch, the lock, all were known in one or other of their various forms, in those ages which we are accustomed to consider classical. Travelers, generally speaking, do not descend to locks, or rather they do not think about them; otherwise they might have collected much that would have been novel and applicable to the present work; and indeed, there is some ground for the assertion, that a notice of the door-fastenings of all nations would reveal to us something of the social and domestic habits of various members of

the great human family. Be this as it may, however, we may profitably make a little inquiry into the locks of ancient times.

In the volumes of Lardner's *Cyclopedia* relating to the "Manners and Customs of the ancient Greeks and Romans," we do not find any mention of the kinds of locks used by those nations; but the author, while describing the houses, says: "Doors turned anciently upon large pivots in the center let into sockets in the lintel and threshold, so that one of the sides opened inwards, the other outwards; and Plutarch gives the following curious reason why persons were to knock and alarm the porter, viz. lest the visitor entering unawares should surprise the mistress or daughter of the family busy or undressed, or servants under correction, or the maids quarreling." As the visitors had thus the power (if permitted so to do) to open the outer door of a house, it would appear that very little in the nature of a lock was employed under ordinary circumstances, unless indeed it were a mere latch.

In respect to Roman houses it is stated, that "the doors revolved upon pivots, which worked in a socket below, and were fastened by bolts which hung from chains." There is no mention of locks here. Mr. St. John, in his work on the same subject, says: "The street-door of a Grecian house, usually, when single, opened outwards; but when there were folding-doors, they opened inwards, as with us."

"In the former case it was customary, when any one happened to be going forth, to knock, or call, or ring a bell, in order to warn passengers to make way." After describing the various kinds of wood of which the doors were made, he proceeds: "The doors at first were fastened by long bars passing into the wall on both sides; and by degrees smaller bolts, hasps, latches, and locks and keys succeeded. For example, the outer door of the Thalamos in Homer was secured by a silver hasp, and a leather thong passed around the handle, and tied, perhaps, in a curious knot.

Mr. Yates, in a learned article on this subject in Smith's ***Dictionary of Greek and Roman Antiquities,*** collects numerous details scattered through various early writers. We will string together a few of these details, so far as they have any relation to the fastenings of doors. The outer door of a Roman house was generally called ***janua;*** whereas the inner doors were called ***ostia.*** The doorway, when complete, consisted of four indispensable parts: the threshold or sill, the lintel, and the two jambs. The threshold, on which the feet trod, was often

regarded with a kind of superstitious reverence; the lintel, which crossed the doorway at the top, having a considerable superincumbent weight to bear, was usually made of one piece of timber or stone of great strength. The jambs, or side uprights, were also made in one piece each.

The **doorway**, in every building of the least importance, contained two doors folding together; even the internal doors had their **bi-valve** construction. But in every case each of the two valves was wide enough to allow persons to pass through without opening the other; in some cases even each valve was double, so as to fold like our window-shutters.

These doors, or valves, were not hinged to the side-posts, as with us, but were, as has already been stated, pivoted to the lintel above and the threshold below. The fastening usually consisted of a bolt placed at the base of each valve or half-door, so as to admit of being pushed into a socket made in the sill to receive it.

The doorways in some of the houses at Pompeii still show two holes in the sill, corresponding to the bolts in the two valves. At night, the front door of the house was further secured by means of a wooden and sometimes an iron bar placed across it, and inserted into sockets on each side of the doorway; hence it was necessary to remove the bar in order to open the door. Chamber-doors were often secured in the same manner.

In the ***Odyssey*** there is mention of a contrivance (adverted to by Mr. St. John) for bolting or unbolting a door from the outside; it consisted of a leather thong inserted through a hole in the door, and by means of a loop, ring, or hook, capable of taking hold of the bolt so as to move it in the manner required.

*We have here evidently the elements of a more complete mechanism; for the bolt was a crude lock in the same degree that the thong was a crude key. That the Romans afterwards had real locks end keys is clear; for the keys found at Herculaneum and Pompeii, and those attached to rings, prove that a kind of warded lock must have been well known. There are the remains of a tomb at Pompeii, the door of which is made of a single piece of marble, including the pivots, which were encased in bronze, and turned in sockets of the same metal; it is three feet high, two feet nine inches wide, and four and a quarter inches thick; it is cut in front to resemble panels, and thus approaches nearer in appearance to a modern wooden door; and it was fastened by some

kind of lock, traces of which still remain.

The same facts frequently become more clear when described in different words by different writers. We shall make use of this circumstance. Mr. Donaldson, in his ***Essay on Ancient Doorways,*** presents us with details that illustrate many of the foregoing remarks.

Homer describes the treasures and other valuable objects (mentioned in the *Odyssey)* as being kept in the citadel, secured merely by a cord intricately knotted. This, of course, was soon found to be a very insufficient protection, and therefore a wooden bar was adopted inside the doors of houses, to which it was attached by an iron latch, fastened or removed by a key adapted to it; this key was easily applied from within; but in order to get at it from without, a large hole was made in the door, allowing the introduction of the hand, so as to reach the latch and apply the key.

The lock, called the Lacedemonian, much celebrated by ancient writers, was invented subsequently; it was especially fitted for the inner chambers of houses, the bar fastenings continuing to be employed for closing the outer doors of dwellings and the entrance-gates to cities. The Lacedemonian lock did not require a hole to be made in the door, for it consisted of a bolt placed on that side of the entrance-door which opened, and on the inside of a chamber-door.

When a person who was outside wished to enter, it was necessary for him to insert the key in a little hole and to raise the bolt; and in time this species of fastening was improved by the insertion of the bolt in an iron frame or rim permanently attached to the door by a chain, and fastening the door by the insertion of the hasp, through the eye of which was forced the bolt inside the lock by applying the key.

After quoting a Latin sentence from Varro in elucidation of his subject, Mr. Donaldson proceeds to observe, that for the most part the locks of the ancients were different in principle from those of modern days, not being inserted or mortised into the doors, nor even attached except by a chain; they were, in fact, padlocks.

One of the passages in the *Odyssey* alluding to the primitive mode of fastening the valves or folding-doors of a house runs thus:

"Whilst to his couch himself the prince addressed, The duteous nurse received the purple vest: The purple vest with decent care disposed, The silver ring she pulled, the door reclosed: The bolt, obedient to the silken cord, To the strong staple's inmost depth restored, Secured the valves."

Most of the other great nations of antiquity resembled either the Egyptians or the Greeks and Romans, more or less closely, in their domestic and domiciliary arrangements; or, at any rate, so far as such humble matters as locks and keys are concerned, we need not seek far from those nations for examples.

The Nineveh and other Assyrian explorations have, however, revealed many curious and unexpected facts; from the temples and the palaces we may by and by penetrate into the houses and rooms of the citizens sufficiently to know how their doors were fastened. In the meantime, ancient Egypt awaits our notice.

Sir J. Gardner Wilkinson, in his ***Manners and Customs of the Ancient Egyptians,*** gives the following information concerning the doors and door-fastenings of that remarkable people, on the authority of models, sculptures, and paintings, still existing. The doors were frequently stained so as to imitate foreign and rare woods. They were either of one or two valves, turning on pieces of metal, and were secured within by a bar or by bolts. Some of these bronze pins have been discovered in the tombs of Thebes; they were fastened to the wood with nails of the same metal, the round heads of which served also as ornaments.

In the stone lintels and floors behind the thresholds of the tombs and temples are still frequently to be seen the holes in which the pivot-pins turned, as well as those of the bolts and bars, and the recess for receiving the opened valves. The folding-doors had bolts in the center, sometimes above as well as below; a bar was placed across from one wall to the other.

In many of the ancient Egyptian doors there were wooden locks fixed so as to fasten across the center at the junction where the two folds of the door met. It is difficult, by mere inspection of the bas-reliefs and paintings, to decide whether these locks were opened by a key, or were merely drawn backwards and forwards like a bolt; but if they were really locks, it is probable that they were on the same principle as the Egyptian lock still in use.

For greater security, these modern locks are occasionally sealed with a mass of clay; and there is satisfactory evidence that the

same custom was frequently observed among the ancient inhabitants of that country. Sir J. G. Wilkinson gives a representation of an iron key, now in his possession, which he procured among the tombs at Thebes, and which looks very much like a modern burglar's pick-lock.

In relation to keys generally, and after mentioning the use of bronze for their manufacture, he says: "At a later period, when iron came into general use, keys were made of that metal, and consisted of a straight shank about five inches in length, and a bar at right angles with it, on which were three or more projecting teeth. The ring at the upper extremity was intended for the same purpose as that of our modern keys; but we are ignorant of the exact time when they were brought into use; and the first invention of locks distinct from both is equally uncertain; nor do I know of any positive mention of a key, which, like our own, could be taken out of the lock, previous to the year 1336 before our era; and this is stated to have been used to fasten the door of the summer parlor of Eglon, the king of Moab."

The description here adverted to is that contained in Judges iii. 23-20:

> **"Ehud went forth through the porch, and shut the doors of the parlor upon him, and locked them .... his servants .... took a key, and opened them."**

The curious and ingenious wooden lock of ancient Egypt is still in use in Egypt and Turkey. In Eton's ***Survey of the Turkish Empire,*** published towards the close of the last century, the locks then and there in use are thus described:

> "Nothing can be more clumsy than the door-locks in Turkey; but their mechanism to prevent picking is admirable. It is a curious thing to see wooden locks upon iron doors, particularly in Asia, and on their caravanserais and other great buildings, as well as upon house-doors. The key goes into the back part of the bolt, and is composed of a square stick with five or six iron or wooden pins, about half an inch long, towards the end of it, placed at irregular distances, and answering to holes in the upper part of the bolt, which is pierced with a square hole to receive the key. The key being put in as far as it will go, is then lifted up; and the pins, entering the corresponding holes, raise other pins which had dropped into these holes from the part of the lock immediately above, and which have heads to prevent them falling lower than is necessary."

"The bolt, being thus freed from the upper pins, is drawn back by means of the key; the key is then lowered, and may be drawn out of the bolt. To lock it again, the bolt is only pushed in, and the upper pins fall into the holes in the bolt by their own weight."

Mr. Eton, probably seeing how well the tumbler-principle is here understood, says: "This idea might be improved on; but the Turks never think of improving. The locks on the doors of modern houses in Cairo seem to be of this long-established form, except where iron locks have been imported from Europe."

A letter was inserted in the ***Journal of Design*** for July 1850, from Mr. W. C. Trevelyan; in which, after adverting to the Egyptian lock, he says:

"It is remarkable that the locks which have been in use in the Faroe Islands, probably for centuries, are identical in their construction with the Egyptian. They are, lock and key, in all their parts made of *wood;* of which material, if I mistake not, they have also been found in Egyptian catacombs; and so identical with the Faroes in structure and appearance, that it would not be easy to distinguish one from the other."

The construction of this remarkable Egyptian or pin-lock (pin tumbler) will be understood from the accompanying engravings. The quadrangular portion, in figure 1, is the case of the lock, screwed or otherwise fastened to the door, having a wooden bolt, passing horizontally through a cavity in it. In the part of the case above the bolt are several small cells containing headed pins, arranged in any desired form; and in the top of the bolt itself are an equal number of holes similarly arranged.

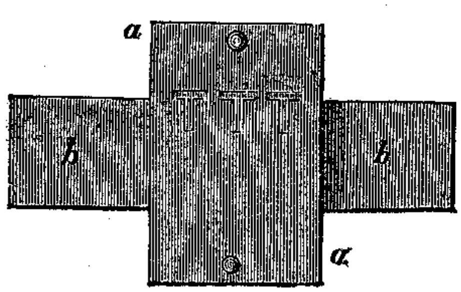

Figure 1

The effect of this arrangement is such that, when brought into

the right position, the lower ends of the headed pins drop into the corresponding holes in the bolt, thereby fastening the bolt in the lock-case. A large hollow, or cavity, is made at the exposed end of the bolt; the cavity extending as far as and beyond the holes occupied by the pins.

The key consists of a piece of wood (shown in two positions, (figures 3 and 4,) having pins arranged like those in the lock, and projecting upwards just to a sufficient distance to reach the upper surface of the bolt. This being the arrangement, whenever the key is introduced and pressed upwards, its pins exactly fill the holes in the bolt, and by so doing dislodge those which had fallen from the upper part of the case.

The bolt may, under these circumstances, be withdrawn (as shown in figure 2), leaving the headed pins elevated in their cells, instead of occupying the position shown by the dotted lines in figure 1. The cavity in the bolt must of course be high enough to receive the thickness of the key, and also the length of the pins protruding from the key.

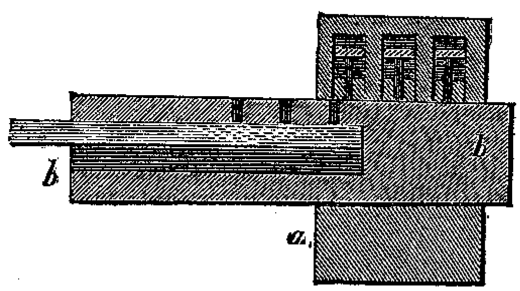

Figure 2

This primitive lock comprises many of the best features of the tumbler or lever-locks of later days, as will be seen in a future chapter. There will also be opportunities of showing how the pin-action has been applied in other ways in some of the modern locks.

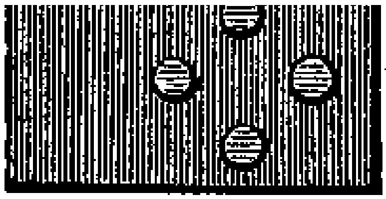

Figure 3

Figure 4

CHAPTER THREE: Lock Classification; the Puzzle-Locks and the Dial-Locks

MASTER EXHIBIT LIST

Figure 5 Puzzle look of the seventeenth century.

In approaching the subject of modern locks, it becomes necessary to decide upon some method of treating the widely-scattered and diverse materials which are presented to our notice. One plan would be to trace the subject chronologically, by describing, in the order of their invention, the most important locks that have been presented to public notice. But this would be attended with some disadvantages: the peculiar characters of the several locks would not be brought out with sufficient distinctness; and the result, so far as the reader is concerned, would rather tend to confusion than to a clear appreciation of the subject.

There are more advantages belonging to a classification of locks under certain headings, according to some marked peculiarities in their modes of action. This is a convenient plan, but it is not an easy one to put in execution; for inventors have not sought to place their locks in any particular class, but rather to call attention to their merits.

Moreover, many locks embody two or three distinct principles so equally, that it will often be difficult to decide in which class to place them. This, nevertheless, may be done with an approach to correctness. It is necessary first, however, to explain certain technical terms by which locks are distinguished one from another.

Locks, in truth, admit of an immense variety, which, however important to be known to locksmiths, carpenters, and others employed by them, need only be glanced at very cursorily by the

general reader. Some locks are named according to the purposes to which they are to be applied; others according to their shape, or the principles of their construction.

In the first place, there is the distinction between *in-door* and *out-door* locks. Of in-door locks, one principal kind is the *draw-back* lock, for street-doors, in which the bolt is capable of maintaining any one of three positions: it may be locked by the key, or left half-way out by the pressure of a spring, or be drawn back by a handle.

In the first position, it can only be withdrawn by the key; in the second, it closes the door, but can easily be withdrawn by the handle; and in the third, it leaves the door unfastened. If these locks are made of iron and carefully finished, they are further called *iron-rim;* but if made of wood, suitable for back-doors and inferior purposes, they are *spring-stock.* For the doors of rooms, there are the *iron-rim,* the *brass-case,* and the *mortise* lock; the second supplants the first, and the third the second, as we advance in the elegance of the door-fittings.

Other designations for room-locks depend on the number of the bolts: thus, if there be only one bolt, it is a *deadlock* or *closet lock;* if there be a second bolt, urged by a spring and drawn back by a handle, it is a *two-bolt lock;* and if there be also a third, a private bolt acting only on one side of the door, it is a *three-bolt lock.* Again, according to the kind of handle employed, it may be a *knob-lock* or a *ring-lock.* According to which edge of the door it is to be fixed, it becomes a *right-hand* or a *left-hand* lock.

If the wards of the lock are of somewhat superior quality, and bent round nearly to a circle, the lock is *one-ward round, two ward round,* and so forth. If the lock has no wards at all, it *is plain;* if the wards are of common character, they are often called *wheels,* and then the lock becomes *one-wheel, two-wheel, etc.* Sometimes the lock is named from certain fancied resemblance in the shape of the ward, as the *L-ward, T-ward,* or *Z-ward.* If the wards are cast in brass, instead of being made of slips of iron or copper, the lock is termed *solid ward*

Of the numerous but smaller varieties known by the collective name of ***cabinet locks,*** there are the *cupboard,* the *bookcase,* the *desk,* the *portable desk,* the *table,* the *drawer,* the *box,* the *caddy,* the *chest,* the *carpet-bag,* and many other locks. All these

locks are further called *straight,* when the plate is to be screwed flat against the wood-work; *cut,* when the wood is to be so cut away as to let in the lock flush with the surface; and *mortise,* when a cavity is excavated in the edge of the door for the reception of the lock.

Out-door locks are usually *wooden stock locks,* for stables, gates, etc.; comprising many varieties of *Banbury bastard, fine, etc*. There are D *locks* and P *locks,* for gates, designated from their shapes; and there are the numerous kinds of *padlocks.*

The above terms are employed chiefly between the makers of the locks and the persons who fix them in their places; but there are other terms and names, more familiarly known, which will come under notice in future pages.

It is scarcely worthwhile to descant upon the "middle age" of lock-making, to impart to the subject so much of dignity as to be susceptible of regular historical treatment. True, we know that *wards* were employed before *tumblers* (unless, indeed, the pins of the Egyptian lock be considered as tumblers (a character to which they present considerable claim), and that wards may be taken as the representative of the medieval period of lock-making; but it may be more profitable to proceed in our notice of the different kinds of locks in an order which will in itself partake somewhat of the historical character.

Apart from all the warded and tumbler locks are the very curious *puzzle* or *letter-locks;* a construction which we propose to dismiss out of hand in the present chapter, before treating of those which have more commercial importance.

The puzzle-lock is generally in the form of a padlock, which is opened and closed without the use of a key, and which has certain difficulties thrown in the way of its being opened by any one who is not in the secret of the person who closed it. It is, in fact, one of the locks in which the doctrine of permutation is made to contribute to the means of security.

The key to open it is a *mnemonic* or *mental* one, instead of one of steel or iron. Two centuries ago, the puzzle-lock attracted far more attention than any other. It has always certain moveable parts, the movement of which constitutes the enigma. Some of these very curious and out-of-the-way locks are so formed as to receive the name of *dial-locks;* but the chief among them are *ring-locks,* a name the meaning of which will be presently

understood.

The puzzle or letter-lock of the ring kind, then, consists essentially of a spindle; a barrel, encompassing the spindle; two end-pieces, to keep the spindle and barrel in their places; and the shackle, hinged to one of these end-pieces. To unfasten the lock, one of the end-pieces must be drawn out a little, to allow the shackle or horseshoe to be turned on its hinge; and the question arises, therefore, how this end-piece is to be acted upon.

This is effected in a very ingenious way: there are four studs or projections in a row on the spindle, and as the spindle fits pretty closely in the barrel, the former cannot be drawn out of the latter unless there be a groove in the interior of the barrel, as a counterpart to the studs on the exterior of the spindle.

Four rings fit on the barrel, on the interior of each of which is a groove; unless all these four grooves coincide in direction, and even lie in the same plane as the groove in the barrel, the studs will not be able to pass, and the spindle cannot be drawn out. Each ring may be easily made to work round the barrel by means of the fingers, and to maintain any position which may be given to it. There are outer rings, one over each of the rings just described, with the letters of the alphabet (or a considerable number of them) inscribed on each; and these outer rings, by means of notches on the inside, govern the movements of the inner rings.

The action is, therefore, as follows: when the padlock is to be locked, the rings are so adjusted that all the grooves shall be in a right line; the spindle is thrust in, the end-piece is fixed on, and the shackle is shut down. The padlock is now fastened; but a reverse order of proceeding would as easily open it again, and therefore the "safety" or "puzzle" principle is brought into requisition.

The outer rings are moved with the finger, so as to throw the various interior grooves out of a right line, and thus prevent the withdrawal of the spindle. As each ring may be turned round through a large or a small arc, and all turned in different degrees, the variations of relative position may be almost infinite.

The letters on the outer rings are to assist the owner to

remember the particular combination which he had adopted in the act of locking; for no other combination than this will suffice to open the lock. There may, for instance, be the four letters L O C K in a line, which line is brought to coincide with two notches or marks at the ends of the apparatus; and until all the four outer rings are again brought into such relative position as to place the letters in a line, the lock cannot be opened.

There are many allusions to locks, apparently belonging to the letter or puzzle principle, by authors who flourished two or three centuries ago. Thus, in Beaumont and Fletcher's play of the *Noble Gentleman,* written in the early part of the seventeenth century, one of the characters speaks of "a cap-case for your linen and your plate. With a strange lock that opens with A M E N" and in some verses by Carew, written about the same time, there is an analogy drawn, in which one of the things compared is:

"A lock that goes with letters; for till every one be known,
The lock's is as fast as if you had found none."

In the *Memorabilia* of Vanhagen von Ense, written about the middle of the seventeenth century, a commendatory notice is given of a letter-lock, or combination lock, invented by M. Regnier, Director of the *Musee d'artillerie* at Paris. "Regnier," we are told, "was a man of some invention, and had taken out a patent for a sort of lock, which made some noise at the time. Everybody praised his invention, and bought his locks. These consisted of broad steel rings, four, five, or eight deep, upon each of which the alphabet was engraved; these turned round on a cylinder of steel, and only separated when the letters forming a particular word were in a straight line with one another.

The word was selected from among a thousand, and the choice was the secret of the purchaser. Anyone not knowing the word might turn the ring round for years without succeeding in finding the right one. The workmanship was excellent, and Regnier was prouder of this than of the invention itself. The latter point might be contested.

I had a vague recollection of having seen something of the sort before; but when I ventured to say so, my suspicions were treated with scorn and indignation, and I was not able to prove my assertion; but many years afterwards, when a book, which as a boy I had often diligently read, fell into my hands, Regnier's lock was suddenly displayed.

The book was called *Silvestri a Petrasancta Symbola Heroica,* printed at Amsterdam in 1682. There was an explanation at p. 254, attached to a picture; these were the words: *Honorius de Bellis, Serulae innescae orbibus volubilibus ac literatis circumscripsit hoc lemma—Sorte ant labore.* However, neither luck nor labor would have done much more towards discovering the secret of opening Regnier's locks, from the variety of their combinations; and their security seemed so great, that the couriers' despatch-boxes were generally fastened with them."

This curious extract, which was brought forward by Mr. Chubb, in a paper on locks and keys (read before the Institution of Civil Engineers in 1850), seems to take away the credit from one (Regnier) with whose name the letter-lock has been most intimately associated. We shall presently explain, however, what it was that Regnier effected towards perfecting the letter-lock. In the meantime it may be interesting to note that the British Museum contains a copy of the work mentioned by Vanhagen.

At the page indicated there is an engraving (a facsimile of which is given in **Figure 5**) containing a drawing of a veritable puzzle or letter-lock; the lock consists of a cylinder or barrel, on which seven rings work; each of these rings is inscribed with letters, and the ends of the cylinder are grasped by a kind of shackle.

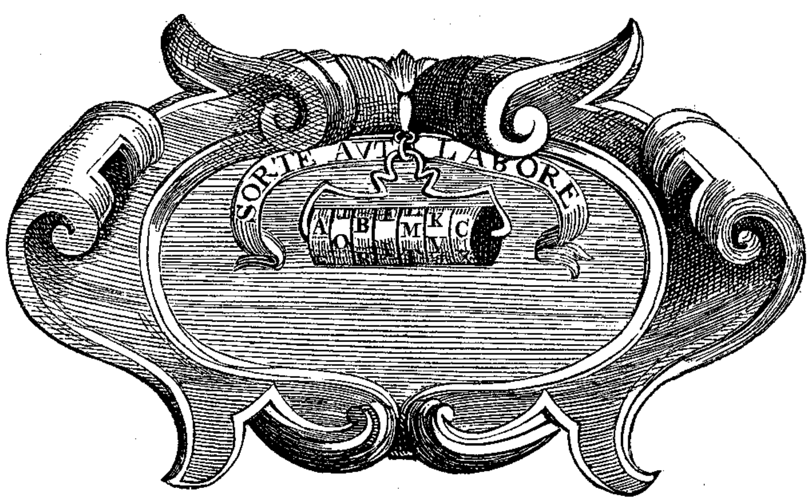

Figure 5 Puzzle look of the seventeenth century.

It was a natural result of the arrangement of the letter lock, as invented (conjecturally) by Cardan, that only one particular word or cipher or key could be used in each lock; and it was to

increase the puzzle-power of the lock that Regnier doubled all the rings, making each pair concentric, and enabling the user to vary the cipher at pleasure.

The principle of the letter-lock, when applied to **doors**, requires that sort of modification which renders it what is termed a *dial-lock.* There are to such a lock one or more dials, with a series of letters or figures stamped on them; there is to each dial a hand or pointer connected by a spindle with a wheel inside the lock; on the wheel is a notch which has to be brought to a certain position before the bolt can be moved. There are false notches, to add to the difficulty of finding the true notch in each wheel.

To adjust the notches to their proper position, a nut on the back of the wheel is loosened, and the pointer is set at any letter or figure chosen by the user. The pointers and the dials perform the part of the outer rings, the wheels that of the inner rings; and it is easy to see that the same leading features prevail in the two kinds of lock, however they may differ in detail.

These dial-locks have not been numerous; they require wheel and pinion work within the body of the lock, which gives delicacy and complication to the mechanism. The letter padlock, be its merits great or small, is strong and durable, not liable to get out of order; and insofar as it requires no key or keyhole, it occupies rather a special position among locks. One of our great "merchant-princes" has been a letter-lock inventor, as the following will show.

Early in 1852, Mr. William Brown, the distinguished member for South Lancashire, read a paper before the Architectural and Archaeological Society of Liverpool, of much interest in relation to our present subject. His object was to describe a letter-lock that he had invented, and which had up to that time given high satisfaction. We cannot do better than transcribe the paper, as reported in one of the Liverpool Journals, with a few abridgments.

"As your society are desirous of seeing any improvements **or** attempts at them, I send you a stock-lock for inspection. The idea for its construction I took from a letter-padlock. I had a lock of this description. made by Mr. Pooley twenty-five years ago, which has been in use ever since on Brown, Shipley, and Co.'s safe.....

"Its advantages I conceive to be as follows: First, it cannot be picked, for there is no keyhole. Second, it cannot be blown up by gunpowder, for the same reason. Third, you cannot drill through the door so as to reach the lock, for you are intercepted by a steel plate on which your tools will not act: thus you cannot introduce gunpowder that way to force the lock off. Fourth, you cannot bounce off the wheels in the interior with a muffled hammer, for vulcanized India-rubber springs resist this. Fifth, you cannot drill the spindles out, as their heads are case-hardened. Sixth, you cannot drive them in, for they are countersunk in the door about half-way through.....

"Now let us set the lock to the word WOOD (any other four letters might be used). When you set the lock, make a private record of them, so that you may not forget them. If parties do not know your letters, nothing but violence, applied by some means or other, can enable them to get into your safe; for the lock will not open to anything but its talisman. Take off all the large wheels and open the lock: you will see that the large wheels have a number of false chambers; if you get the spurs of the bolt into three real chambers and one false, you are as fast as ever, for all four must be right.

"Having placed your key and pointer outside the door to point to **W** on brass-plate No. 1, the small wheel inside **obeys** the same impulse; then maintain your small wheel steadily on this point, and the large wheel No. 1 will only fit on at the right place, the true opening compartment being opposite the spur of the bolt. It being necessary at the time you set your lock that it should be open, proceed with Nos. 2 and 3 in the same way, your pointer, standing steadily at **O**. No. 4 is the same, the pointer being held steadily at **D**.

You should then shoot your lock two or three times, to be sure you have made no mistake. Every time you shoot your bolts out, turn your wheels away from the true chamber, and see when you again turn your pointers to **WOOD** that your lock opens freely; it is the proof that you have made no mistake, and you may now venture to lock your safe.

When you unlock the door, and find it necessary to leave it open for a time, you should shoot the bolts as if locked, and turn the wheels, so that no one may find what your real letters are; and again adjust them to their proper places, in order that the bolt may go back and enable you to relock. Once having locked the door and turned the wheels from your real letters, you need not

trouble yourself with carrying the key, but leave it in any place beside the lock.

"I believe two wheels would make a perfectly safe lock; three would be quite so. I adopted four to make security doubly sure, as it would be impossible in any given time to work the changes. On two wheels by chance the lock might open; you can, however, calculate the chances against this; and also three or four, the false compartment on the outer rim being taken into calculation.

"If this lock is of any value, it should be known; if it has weak points, let them be pointed out, and they may admit of a remedy; for we ought not to be led to believe a lock is safe which is not so."

In relation to the "first advantage" which Mr. Brown not unreasonably supposed to be possessed by his lock, viz. that "it cannot be picked, because it has no keyhole," we shall have something to say in a future page, where certain fallacies on this subject will be noticed. In the meantime we may remark, that it is not a little credible that a leading Liverpool merchant should have invented a lock worthy of occupying a position on his own safe for a quarter of a century; for we may be quite certain that he would not have allowed the lock to maintain that post of honor unless it had really (so far as experience had then gone) served worthily as a safeguard to his treasures.

And if it were possible to collect all the bygone specimens of lock-oddities, we should probably find among them many highly-ingenious letter-locks; for supposing a man to have a mechanical turn of mind, a lock is by no means an unworthy medium for displaying it; the pieces of metal are so small as to be easily manageable at a small workbench in a small room. The fondness for this sort of employment evinced by the unfortunate Louis XVI of France led to the common remark, "He is a capital locksmith, but a very bad king."

In an amusing article in the *Observer*, during the progress of the "lock controversy," was the following paragraph relating to combination locks of the letter or puzzle kind: "The French, in their exposition of 1844, availing themselves of the permutation principle, produced some marvels in the art; but the principle has not been adopted in this country. The *Chariwari* had an amusing quiz upon these locks when they first came out.

It said the proprietor of such a lock must have an excellent memory: forget the letters, and you are clearly shut out from your own house. For instance, a gentleman gets to his door with his family, after a country excursion, at eleven O'clock at night, in the midst of a perfect deluge of rain. He hunts out his alphabetical key, and thrusts it into his alphabetical lock, and says AZBX. The lock remains as firm as ever. 'Plague take it!' says the worthy citizen, as the blinding rain drives in his eyes. He then recollects that that was his combination for the previous day. He scratches his head to facilitate the movement of his intellectual faculties, and makes a random guess BCLO; but he has no better success.

In addition to his being wet, his chances of hitting on the right combinations and permutations are but small, seeing that the number is somewhere about three millions five hundred and fifty-three thousand five hundred and seventy eight. Accordingly, when he comes to the three-hundredth he loses all patience, and begins to kick and batter the door; but a patrol of the National Guard passes by, and the disturber of the streets is marched off to the watch-house."

CHAPTER FOUR: Warded Locks, with their various Appendages

MASTER EXHIBIT LIST

The more ordinary locks are of an oblong quadrangular shape. In nearly all of them, either a bolt shoots out from the lock, to

catch into some kind of staple or box, or a staple enters a hole in the edge of the lock, and is there acted upon by the bolt. A common room-door lock will illustrate the first of these kinds, a tea-caddy lock the second. The key, as is well known, enters a receptacle made for it; and the shaft of the key generally serves as a pivot or axis around which the web or flat part of the key may move in a circular course.

During this movement the web acts directly or indirectly on the bolt, driving it in or out according to the direction in which the key is turned; the key impels the bolt one way, certain springs act upon it in another, and the balance between these two forces determines the locking and unlocking of the bolt. *Wards,* or *wheels,* are contrivances for rendering the opening difficult without the proper key; and it is of warded locks that we shall chiefly treat in this chapter.

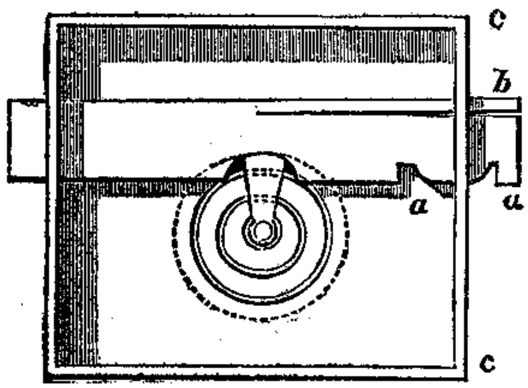

Figure 6 Interior of a back-spring warded lock.

The annexed cut, **figure 6**, represents the interior of an ordinary back-spring lock, without tumblers.

Such a lock may usually be known from a tumbler-lock by this simple circumstance, that it emits a smart snapping noise during the process of locking, occasioned by the pressure of the spring when the bolt is in a particular position. In the woodcut, the bolt is represented half out, or half shot. At **aa** are two notches on the underside of the bolt connected by a curved part; **b** is the back spring, which becomes compressed by the passage of the curve through a limited aperture in the rim ***cc*** of the lock.

When the bolt is wholly withdrawn, one of the notches **a** rests upon the rim ***cc;*** and the force with which the notch falls into this position, urged by the spring **b**, gives rise to the snapping

or clicking noise. When the bolt is wholly shot, the other notch rests in like manner upon the edge of the aperture in the rim.

It must be obvious at a glance, that this back-spring lock is objectionable on the score of security, on account of the facility with which the bolt may be forced back by any pressure applied to its end, a pressure which may often easily be brought to bear. At the center of the lock is seen the end of the key acting on a notch in the bolt, and surrounded by wards.

It is not at a first glance that the relation between the clefts in a key and the wards of a lock can be duly appreciated; because the wards present themselves to view as portions of circles to which nothing in the key seems to correspond but if it be borne in mind that the key has a rotary motion within the keyhole around the pipe or barrel as an axis, the circular form of the wards will be accounted for, and their *section will* be regarded as exhibiting the looked-for relation to the wards of the key.

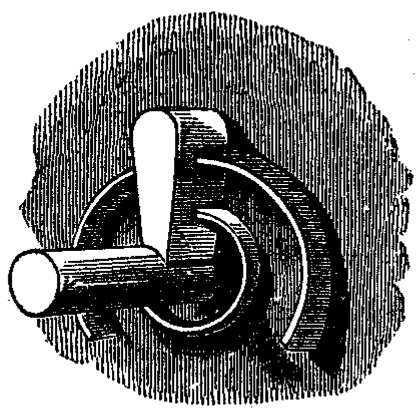

Figure 7 Section to show the action of wards.

In the annexed cut, for example (**Figure 7**), which represents a portion of the interior of a warded lock, the curved pieces of metal are the wards (two in this case); and there are two clefts in the bit of the key to enable the latter to take its circular course without interruption from the wards. If the clefts were other than they are, either in number, position, or size, this freedom of the key's movement could not be obtained.

When once the opinion became established that a lock is rendered secure by virtue of its wards, (a theory which we shall have to discuss in a later page), much ingenuity was displayed in varying the wards of the lock, the clefts of the key, and the shape of the keyhole. Even if the two former were unchanged, a change in

the latter might add to the puzzlement of the arrangement.

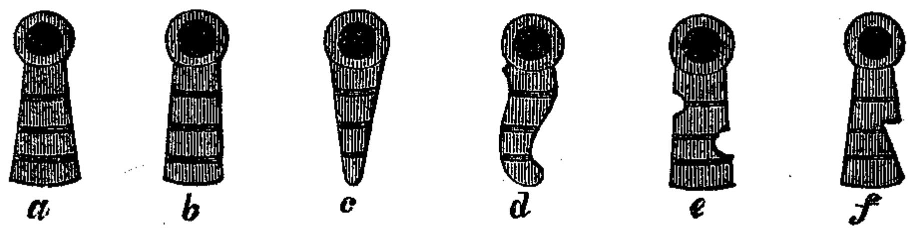

Figure 8

For instance, in the annexed cut (**figure 8**), all the six keys represented may have clefts or cuts exactly alike, all adapted to the wards of one particular lock; yet the differences in the *thickness* of the web are such, that if the keyholes were shaped in conformity therewith, each keyhole would be entered by one of these keys; **b** and **c** differing from **a** in the relative thickness at different points, and **d**, **e**, and **f** having certain curvatures and cavities not to be found in the other three.

But without waiting for the detailed examination of the relative security and insecurity of locks, we may at once show how simple is the principle which renders the warded system fallacious. In **figure 9** we shall be able to illustrate this.

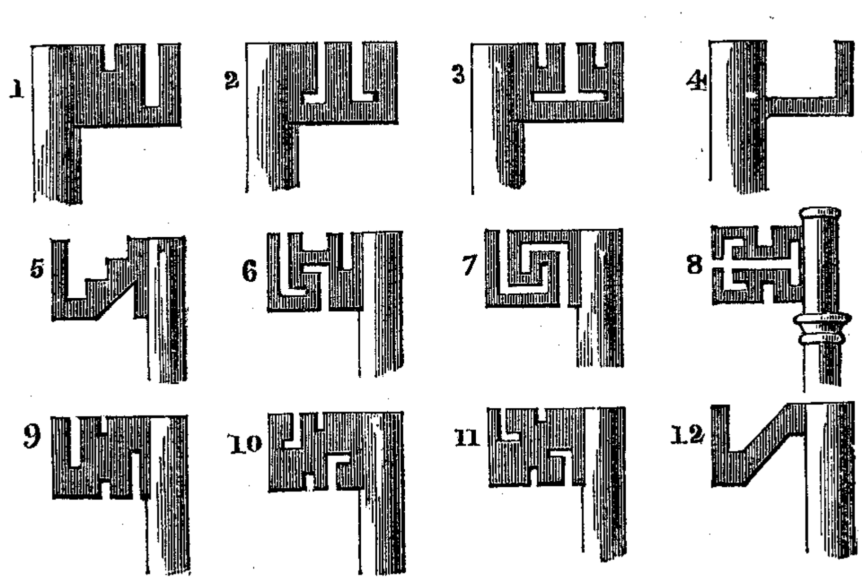

Figure 9 Examples to show the action of "master," or "skeleton keys."

Numbers 1, 2, and 3, all appear very different keys and it is quite true that neither one would open a lock adapted for either of the other two; and yet the very simple arrangement No. 4 would

open all three. This No.4 is called a ***skeleton key;*** and the relation which it bears to the others may be expressed in the form of a proposition thus: at any point where there is solid metal in *all* the keys, there must (or may) be solid metal in the corresponding part of the skeleton key; but at any point where there is a vacancy or cavity in any of the keys, there must be a cavity in the corresponding part of the skeleton key.

If Nos. 1, 2, 3, 4, be examined, this proposition will be found to be borne out; there is so much cavity in No. 4 that it avoids the wards in all the three locks, nothing being required but the tongue of metal to move the bolt. Sometimes to add to the safety, wards are attached to the front as well as the back plate of the lock; and then there may be a double series of notches required in the key, such as in No. 5; but if this be compared with Nos. 9, 10, 11, it will be found that although no one of the four would open a lock adapted for either of the other three, yet the skeleton key No. 12 would master them all, having cavities wherever any of the others have cavities.

This is the theory of the *master key,* by which one key may be made to command many locks. Nos. 6 and 7 have complicated wards; but the key is so much cut up as to be weakened more than is desirable. No. 8 enables as to point out the difference between two distinct **classes of** keys.

Keys with pipes or barrels fitting on a pin or pipe shaft can only open a lock on one side of the door or box; but a key with a solid stem, as No. 8, has the clefts so cut as to open the lock from either side, as in a street-door lock: it is, in fact, two warded keys fixed end to end, only half of which is employed at one time in opening the lock.

Some of the warded locks of the last century are curious. While the idea prevailed that a complicated ward gave security, there was room for the exercise of ingenuity in varying the shape of the wards. **Figure 10** is copied from the great French work. It represents the cuts in the key, and also (seen from a perspective) the complicated forms of the pieces of metal which constitute the wards corresponding with those cuts.

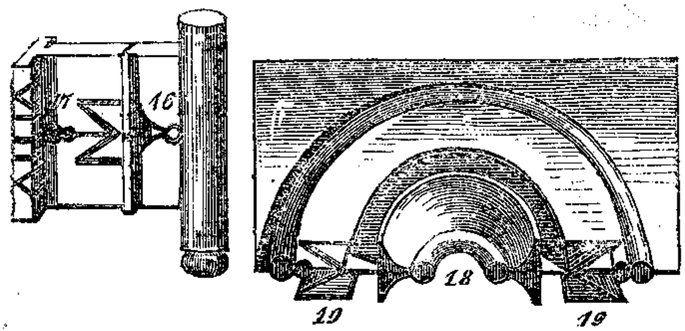

Figure 10 Cuts of a French key.

The aperture in the key at 16 fits upon the metal surrounding the keyhole at 18; and the M-shaped cuts at 17 fit in like manner upon the similarly-shaped metal pieces at 19.

Another example of a similar kind is shown in figure 11, where an anchor appears to have been the favorite form. The anchor-cuts in the key are shown at 26; while in the wards the bottom of the anchor is near the keyhole at 28, and the top at 29.

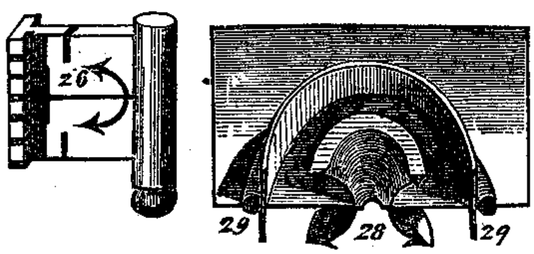

Figure 11 Wards of an old French lock.

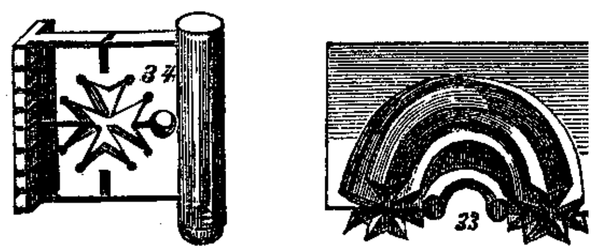

Figure 12 Wards of an old French look.

A similar illustration occurs in figure 12, where the star-like cuts at 34 on the key correspond with the star-like wards at 33.

From the fifteenth to the eighteenth centuries, locks were made in France, on which a vast amount of care and expense was bestowed. They were, in an especial degree, decorative appendages as well as fastenings. They were of three kinds: room-locks, buffet-locks, and chest-locks; they were fixed on the outside of the door or lid, so as to be fully visible.

The key had a multitude of perforations which bore no particular relation to the wards of the lock, but which were regarded as tests of the workman's skill. The honorary distinctions awarded to apprentices and aspirants in the art depended very much on the number and fine execution of these perforated keys. The locks,

considered as fastenings, had slender merit; although usually throwing four bolts, they were not very secure.

Figure 13 represents the exterior of a lock made about the year 1730, by Bridou, a celebrated Parisian locksmith. It was a lock belonging to a coffer or strong chest; all the works being sunk below the level of a carved architectural molding or ornament. There is a secret opening near the part **c**, forming a portion of the ornamental design; it allows a bolt, shown at **D**, figure 14, acted on by the spring **E**, to be touched, by which a doorway opens upon the hinges at **B B A A** are a sort of pilasters, which aid in forming a hold for the bolts.

The little ornament at **c** is drawn down by the hand, opening the secret door and revealing the keyhole **G. S S. O O. z z**, are ornaments fastened on at **b c d**, figure 14, by nuts and screws, intended to display the skill of the workman The lock itself, access to the keyhole of which is obtained within the secret door, has nothing very remarkable about it.

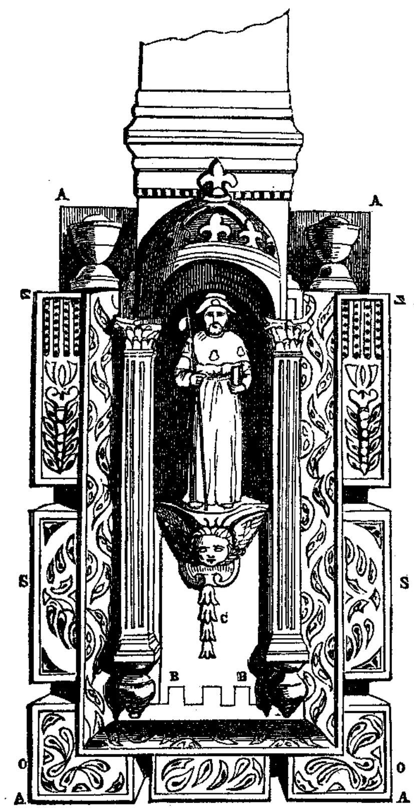

Figure 13 Exterior of an old secret lock.

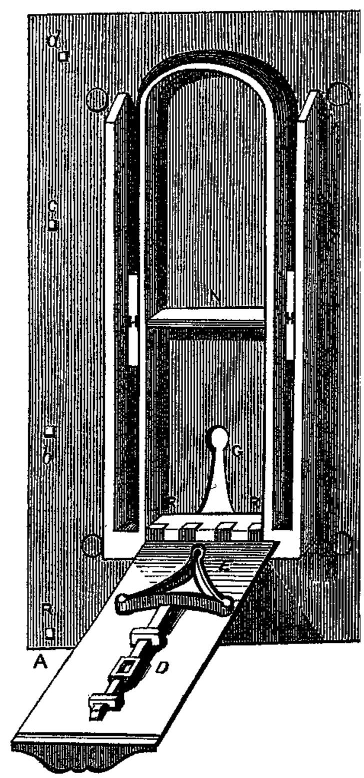

Figure 14 The same with a portion of the front letdown showing the keyhole.

Mr. Chubb, in his paper read before the Institute of Civil Engineers, illustrated the insecurity of the warded lock by the example of one which had actually been placed in the strong room of a banking house, and which is represented in the annexed cut (figure 15).

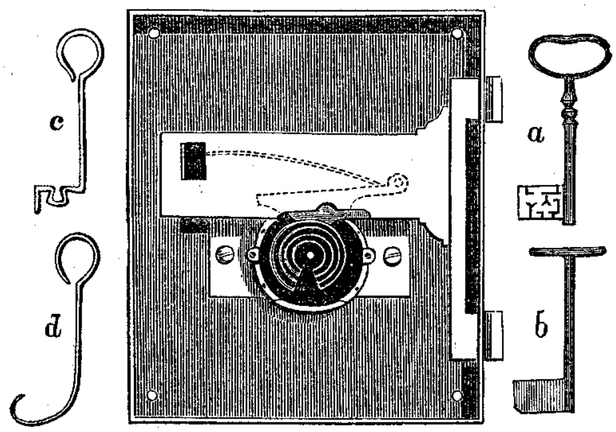

Figure 15 Examples of true and false keys.

The wards are here shown, surrounding the central key-pin; and from the appearance of the key, shown at **a**, it is evident that these wards must have been rather complex. But the uselessness of the wards was proved by the result. A burglar employed an instrument, shaped like that at **b** having on one of its faces, or sides, a layer of wax and yellow soap; this instrument, being introduced through the keyhole and turned a little way round, brought the soft composition in contact with the ends of the wards, and these ends thus left their impress on the composition.

A false key was then made, as at **c**, which, however clumsy it may appear, has a cavity, or vacuity, where there is a cavity in the true key; and by such a surreptitious instrument was the lock opened. Even so crude an instrument as **d**, by passing round the wards, might open such a lock. We are somewhat anticipating the full consideration of this subject; but it is desirable at once to explain how and why an improvement on the warded lock was sought for.

In connection with the fanciful eighteenth-century locks, lately adverted to, we may remark that no less a man than Louis XVI was an amateur workman in this department of mechanical art. or at least in smith's work, which in France is generally considered to include lock-making. Sir Archibald Alison says, in his *History of*

Europe: "He had an extraordinary fondness for athletic occupation and mechanical labor; insomuch that he frequently worked several hours a day with a blacksmith of the name of Gamin, who taught him the art of wielding the hammer and managing the forge."

"He took the greatest interest in this occupation, and loaded his preceptor in the art with kindness; who returned it by betraying to the Convention a secret iron recess which they had together worked out in the walls of the cabinet in the Tuileries, wherein to deposit his secret papers during the storms of the Revolution." There are not wanting indications that the unfortunate monarch wrought upon locks, as well as upon safes and strong rooms.

Besides wards, there have been numerous other contrivances far adding to the security of locks, including screws, escutcheons, spiral springs, wheel-and-pinion work, alarms, and multiple bolts. As these are not of sufficient importance to be treated in separate chapters, we shall here give just so much notice of them as will illustrate their general character. Some of them are found combined with the "tumbler" principle, presently to be described; but all of them, it is now well known, were employed in various ways when the tumbler lock was but little understood, and when the warded lock was held in esteem.

The Marquis of Worcester, whose curious *Century of Inventions,* written nearly two hundred years ago, contains so many suggestions which ingenuity has since developed into practical completeness, gives four of his inventions in the following words:

69. "A way how a little triangle-screwed key, not weighing a shilling, shall be capable and strong enough to bolt and unbolt, round about a great chest, a hundred bolts, through fifty staples, two in each, with a direct contrary motion; and as many more from both sides and ends; and, at the same time, shall fasten it to the place beyond a man's natural strength to take it away; and in one and the same turn both locketh and openeth it."

70. "A key with a rose-turning pipe and two roses pierced through endwise the bit thereof, with several handsomely contrived wards, which may likewise do the same effects."

71. "A key, perfectly square, with a screw turning within it, and more conceited than any of the rest, and no heavier than the triangle-screwed key, and cloth the same effects."

72. "An escutcheon, to be placed before any of these locks, with these properties: First, the owner, though a woman, may with her delicate hand vary the ways of causing to open the lock ten millions of times beyond the knowledge of the smith that made it, or of me that invented it.

Second, if a stranger open it, it setteth an alarm, which the stranger cannot stop from running out; and besides, though none shall be within hearing, yet it catcheth his hand as a trap cloth a fox; and though far from maiming him, yet it leaveth such a mark behind it as will discover him if suspected; the escutcheon or lock plainly showing what money he hath taken out of the box to a farthing, and how many times opened since the owner had been at it."

Mr. Partington, in his edition of the Marquis's singular work, makes a few comments on these lock-and-key contrivances. He says that the lock is evidently intended to operate on the principle of applying a *screw* for the purpose of moving the bolt, instead of using a key as a lever for this purpose. That such a plan might be applied to locks generally, he observes, there can be no doubt; and by a similar contrivance the large keys at present in use for outer doors, iron chests, etc, might be advantageously reduced by this means. By employing the escutcheon mentioned by the Marquis, much additional security would be obtained. It must be confessed, however, that many of the marquis's statements are difficult to credit.

The escutcheon has been a favorite resource with lock makers. Mr. Mordan's escutcheon, for instance, introduced before the Society of Arts in 1830, is a contrivance to be placed temporarily over the keyhole of a door, to prevent the picking of the lock during the owner's absence. The escutcheon, or "protector," has a short pipe which, after the door has been locked, is thrust into the keyhole.

Attached to the pipe is a small lock, on Bramah's or any other convenient principle, so contrived that, on turning its key, two lancet-shaped pieces fly out laterally and bury themselves in the wood. The escutcheon cannot be removed until the small key has reacted upon the small lock; and until this removal has taken place, the large key cannot reach the keyhole.

A curious application of the escutcheon principle attracted some attention among locksmiths about seventy years ago. One of the

first premiums awarded by the Society of Arts, after the commencement of their "Transactions," was to Mr. Marshall, for a “secret escutcheon," in 1784. In his description of his new invention, he adverts to the Marquis of Worcester's wonderful escutcheon, and to the many attempts which have since been made to produce an apparatus which should realize the Marquis's description.

He supposes that the letter padlock originated as one among many varieties of these imitative inventions; but this may be doubted. Mr. Marshall's contrivance, however, was in effect an endeavor to improve upon the letter-lock. He considered it an objection that, in ordinary locks of this kind, the letter-rings admit of no variation of place; and he sought to remedy this defect.

It is not so much a new lock, as an escutcheon for a lock which he produced. There is a studded bar passing through a barrel; there are five rings which work concentrically on this barrel; there are letters on the outer surfaces of the rings, and notches on the inner surface; but when, by the usual puzzle-action of the rings, the notches in them have been brought into a right line with the studs of the bar, the result is, not that the hasp of a padlock is raised, but that the escutcheon is removed from the keyhole of an ordinary lock. Mr. Marshall’s contrivance, therefore, is not so much a ring padlock, as a puzzle-ring security for the escutcheon of a fixed lock.

Some locks work by a screw and a spiral spring, instead of an ordinary key. Mr. W. Russell received a silver medal from the Society of Arts, about thirty years ago, for a new mode of locking the cocks of liquor-casks. Under ordinary circumstances, as is well known, the cock of a barrel or cask is in no way secure from the action of any one who can approach near enough to touch it; and different methods have been adopted of obtaining this security or secrecy.

One plan is to employ a perforated cap, soft-soldered to the barrel of the cock, immediately over the grooved plug, the top of which plug is formed to the shape of the perforation, and a socket-key of the same form is introduced to turn the plug or open the lock. Another plan is to employ an iron saddle or staple, passing over the plug and below the bottom of the cock, through which a bolt is put, and a pendent padlock attached.

The first method is very inefficient; the second is much superior, and has been largely adopted for locking the cocks of

coppers, stills, vats, and other large vessels. But Mr. Russell thought some further improvement was needed. He caused a hole to be bored through the barrel, and to some depth into the plug when the latter is in the position for closing the cock. A stud works into this hole in such a way, that when the stud is driven home, the plug cannot be turned or the lock opened.

The stud is attached at its other end to a spiral spring connected with a screw; a key is employed, the hollow pipe of which has an internal screw; and when this key is inserted in the cock-barrel and turned twice round, it draws back the stud, and allows the plug to be turned round in the proper way for opening the cock.

It is not often that wheel-and-pinion work is introduced into locks; the delicacy, the cost, the weakness, and the tendency to get out of order would all militate against the frequent adoption of such a course. It is, however, adopted occasionally. Mr. Friend's secret-lock, introduced to the notice of the Society of Arts in 1825, had a train of wheels which acted upon the bolt, driving it out whenever the circular arcs of three wheels moved against it, but allowing a spring to force it back again whenever a deep cleft in each of the wheels locked into a stud on the bolt.

There were certain numbers on a guide-plate, and a power of combining these numbers in great variety; and a provision that the bolt could be unlocked only by the same combination of numbers that had locked it. The guide-plate was a separate piece of apparatus, carried in the pocket of the user as a companion to the key. The key was of no use without the guide-plate, nor the guide-plate without the key.

The user 'set' the numbers on the guide-plate, then applied it to the face of the lock, then introduced the key into the keyhole, and turned the key partially round; the bolt was now shot, and the guide-plate removed. If the key were used without the guide-plate, the bolt might be locked, but it was always unlocked again by the time the key had made a complete circuit. There was considerable ingenuity in the idea of this lock; but we believe it never went further than a model. Indeed many of the locks elaborately described in books have never had an existence as acting working locks.

A very ingenious principle has been occasionally introduced in which clockwork regulates the interval of time that must elapse

before a lock can be opened, even with its **proper** key. The object is to ensure the safety of the lock during a journey, or until a particular person be present, or until the locked article is conveyed to a particular room. A patent was taken out in 1831 for a look on this principle by Mr. Rutherford, a bank agent at Jedburgh.

Against the end of the bolt of the lock is placed a circular stop-plate, so adjusted that the bolt cannot be withdrawn until a particular notch in the rim of the circular plate is opposite the end of the bolt. The plate is put in rotation by clockwork. As the notch can be set at pleasure to any required distance from the end of the bolt, the lock may be secured against being opened, either by its own or any other key, until any assigned number of minutes or hours after it has been locked; for the plate may be made to revolve either slowly or quickly, by varying the number of wheels in the clockwork.

When the lock is used for boxes or portable packages, the clockwork must be moved and regulated by a spring; but when it is applied to closets or safes, a descending weight and a pendulum may be employed. It is manifest that this system is susceptible of being greatly varied in its mode of application; and it has many points of interest about it. That a man cannot open his own lock with his own proper key until the lock gives permission by assuming a particular state or condition, certainly strikes one as being susceptible of many useful applications, where time is an element taken into the account.

A curious alarm lock was invented by Mr. Meighan, in 1836, in which the bell or alarm is not placed behind a door, as in many alarm contrivances, but within the **lock** itself. Two or more studs are placed on the bolt, which press against the lower end of a small tumbler. The movement of the tumbler elevates a hammer; but as soon as the point of the tumbler becomes released from the stud, a spring presses the hammer down forcibly, and causes it to strike against a small bell placed near it. This sounding of the bell will be repeated, during the shutting of the bolt, as many times as there are studs to act upon the point of the tumbler.

Much of the ingenuity that has been displayed in locks depends on the employment of multiple bolts, there being all the additional strength that results from the use of two or more bolts instead of simply one. Ordinary doors seldom afford us examples of these double bolts; but they may be frequently seen in cabinets and desks, where two staples fixed to the lid fall into two holes in

the lock, and are retained by two bolts.

The most remarkable and complicated varieties, however, are those in which the bolts, instead of shooting parallel and nearly together, shoot in wholly different ways; one up, one down, one to the right, one to the left, and so on. It is on safes, strong boxes, and the doors of strong rooms containing valuable treasures, that such locks are usually placed. The mechanism is such that the key acts upon all the bolts at once, through the intervention of levers and springs of various kinds.

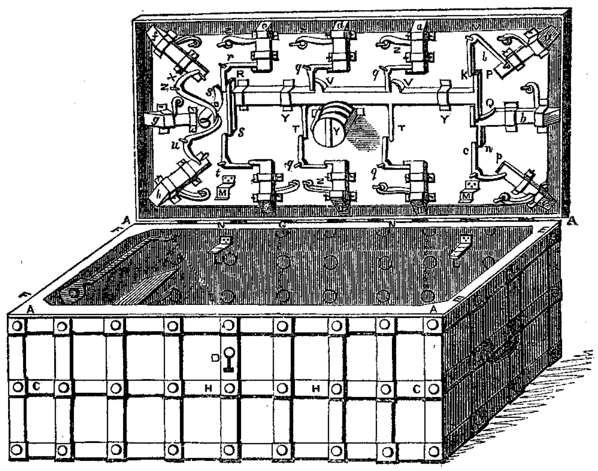

Figure 16 Multiple bolts of an old chest look.

The above woodcut represents a very curious specimen of these multiple-bolt locks. It is copied from the great French work; and the ponderous chest to which it is attached is, we are told by Reaumur, "known at Paris by the name of the strong German coffer." He further says, "nothing is wanting in these coffers on the score of solidity. They are made entirely of iron; or if of wood, they are banded both within and without with iron; and can only be broken open by very great violence." "Their locks are almost as large as the top of the coffer, and close with a great number of bolts. The one which we have engraved has twelve fastenings; they have been made with twenty-four, or more."

His next remark on the subject is a sensible one: "Notwithstanding the large size of these locks, and all the apparatus with which they are provided, they correspond but ill with the solidity of the rest of the coffer. If we have given a representation of one, it is chiefly to show how little confidence one could have in such a lock, and what are its defects, in order that we may avoid them."

It is not difficult, by tracing the action of the several levers, to see how one movement of the key, in the center of the lid, would act upon all the bolts. In the engraving (Figure 16) ***a,f,h,c*** are the four corner bolts; six others, ***ace, ace,*** are on the long sides, three on each; and two, ***bg,*** on the short sides.

Every bolt is provided with a spring, of which three or four are shown at **zzz**. There is no staple or box to receive each bolt; but all shoot or snap beneath the raised edge **E** running round the top of the box just within the exterior at **AA**. The keyhole in the front of the box at **D** is a deception or mask; the real keyhole is in the middle of the lid concealed by a secret door opened by a spring.

When the key has moved the great central bolt, this acts upon the other bolts **P Q R S T** etc.; **v v** are studs which act upon two of the bolts; **yy** are staples confining the great bolt; ***k,l, c,p,x,*** *are* small levers which transmit the action to the corner bolts; ***q,r,s,t,n,*** are the small levers which render a similar service to the side and end bolts; **LL** within the chest, and **MM** on the lid, are contrivances for limiting the movement of the latter; **CH, UC** are iron straps or bands by which the interior of the chest is strengthened. After all, this is not so much a lock as a series of spring latches.

If a lock can be picked, the picking is as effective whether the lock has one bolt or twelve bolts. This fact led Mr. Duce, in 1824, to construct, instead of a four-bolt lock, four distinct one-bolt locks, fixed in the same frame and opened by the same key; the bolts to be moved in succession instead of simultaneously. It would require four times as long to pick this as a four-bolt lock of similar action.

There have been many other varieties of the multiple bolt, but we need not stop to describe them.

CHAPTER FIVE: On Tumbler or Lever Locks

MASTER EXHIBIT LIST

SECURITY being the primary object in all locks, any considerations as to mechanical ingenuity and graceful decoration give place to those which relate to safety. A spring lock may be ingenious and even beautiful in its construction, but an imitative key will easily open it. Hence arose the invention of wheels or wards; and as wards failed in trustworthiness, they in their turn yielded to something better.

We have already explained how the insecurity of mere warded locks arises; and we shall have something more to say on the subject in a future chapter. It is sufficient here to remark, that wards, springs, screws, alarms, wheel-work, escutcheons, all, however useful for particular purposes, are wanting in the degree of surety which we require in a lock. Hence the invention of *tumblers, levers,* or *latches,* which fall into the bolt and prevent it from being shot until they have been raised or released by the action of the key.

We have been unable to ascertain at what time, or in what country, or by whom, tumbler-locks were invented. The invention has been claimed by or for persons subsequently to the year 1767, when the celebrated French treatise *(Art du Serrurier)* already referred to was published; and yet this treatise contains numerous examples of simple tumbler locks of ingenious construction, as will presently be shown.

One of the most elementary forms of tumbler-lock is shown in **figure 17**. In this case the bolt, instead of having two notches in the bottom edge, like those in the back-spring lock, **figure 6**, has two square notches or slots in the upper edge; and as the key acts upon the bolt, these notches must of course share in whatever movements the bolt is subjected to.

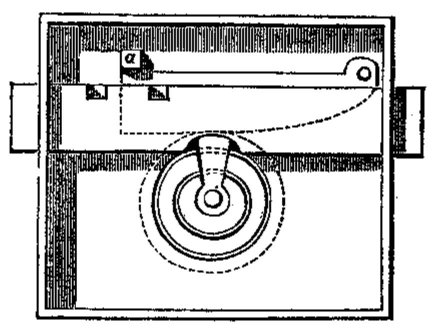

Figure 17 Simple tumbler lock.

Behind the bolt is a kind of latch or tumbler (the lower part of which is shown by dotted lines), with a stump or projecting piece of metal at **a**; the tumbler moves freely on a pivot at the other end, and is made to rise through a small arc whenever the key acts upon the bolt. When the bolt is wholly shot, the stump falls into one notch and prevents the motion of the bolt; when wholly withdrawn, the stump falls into the other notch, and equally prevents the motion of the bolt.

It is not, therefore, until the key, by elevating the tumbler, has raised the stump out of the notch, that the bolt has freedom of movement. If the shape of the key does not enable its web to effect this elevation to a sufficient degree, the bolt remains immovable; and to this extent a certain additional security is obtained by making the shape of the key significant as well as the wards.

The tumbler principle, as we have said, is difficult to trace to its origin on account of the various aspects that it presents; but the great French treatise proves that the locksmiths of France were familiar with tumbler locks a century ago. The plates of that work represent the details of numerous locks, on the upper edge of the bolts of which were notches called *encoches,* as at figure 18; into these notches sank a small iron stud or stump called the *arrest du pene,* or bolt-stop, shown in **figure 19**, attached to the upper portion of the *gachette* or tumbler, which, for the sake of economy of metal, is made in the form of a triangular spring in front of the bolt ***ki;*** and not until the key, by its circular action, had raised this stud out of one or other of the notches, could the bolt move to the right or left.

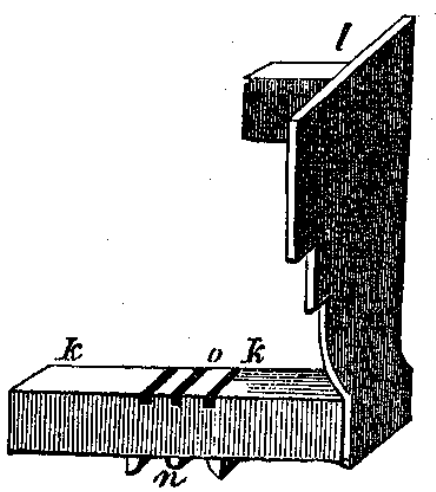

Figure 18 French pin tumbler lock.

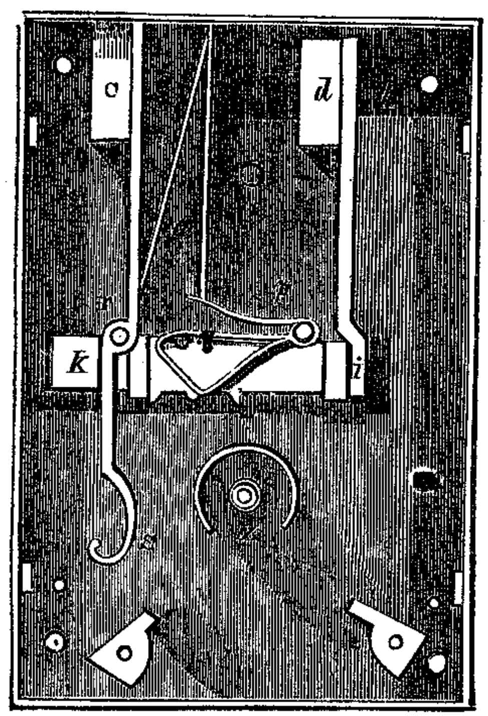

Figure 19 Old French lock.

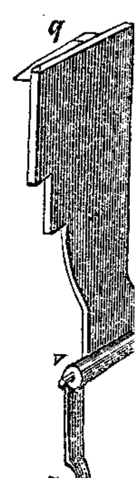
The stud was generally fixed to a spring that forced it down



again into the notch as soon as the action of the key had ceased. Sometimes, however, the stud was fixed to the bolt, and the notches were in a separate tumbler or *gachette* (see **E E**, **figure 21)***;* and in other instances, again, the stump was fixed to the case of the lock and caught into notches in the bolt.

It will be seen, when we come to treat of tumbler locks of later date, that there was much in these early locks to point out the way. **Figure 19**, copied from the French work, represents a lock of the box or casket kind. Two staples, fixed into the cover, fall into two cavities or receptacles at **cd***;* and a short bolt in each receptacle catches into each staple, one near **g** and one near ***h.***

The small bolt **q** is attached to the upper extremity of the lever ***qrs, F*****igure 19**, and shown separately in **Figure 20***;* and by the pressure of a spring **a** (**Figure 19**) upon this lever, the bolt ***q*** is kept locked in the staple. The vertical portion of this spring presses at its lower end on another spring **p** (**Figure 19**) of singular curvature*;* and attached to the horizontal part of this second spring is the stud, which falls into a notch in the top of the bolt.

The action of these parts, then, is as follows: when the key is placed upon the key-pin at **z**, and turned round in the direction in which the hands of a watch move, the bit presses against the tail **s** of the lever, moves it upon its center **z**, **Figure 19**, **v**, **Figure 20**, to the left, and consequently moves the upper part ***q*** to the right, ***Figure 20,*** drawing it out of the receptacle and liberating the staple within **c**.

Thus it will be seen that the lever **q r s**, held in one position by the spring **a**, forms in itself a simple kind of spring catch-lock, and was, in fact, formerly used as such, without any other appendages except the staple in the lever, into which the catch ***q*** fitted on shutting down the lid.

So also we may regard the other portion, **Figure 18**, or ***k i p h*** (**Figure 19**), as forming a separate lock*;* for the key after having passed **s** comes in contact with the triangular spring, which it raises thereby, lifting the stud out of the bolt, and exerting pressure against the barbs of the bolt **n Figure 18** shoots the bolt ***k,*** and also the short bolt **l**, which passes through the staple

also the short bolt I, which passes through the staple in the cavity **d, Figure 19.**

Figure 2

The lock represented in the four following figures is also from M de Reaumur's chapter on locks in the work referred to. In this lock, the tumbler principle is carried out in a very elaborate manner, for not only is the stump or stud **H** (**Figure 23**) attached to a very strong spring (best shown at **H, Figure 22**), which holds it with considerable force in one of the three notches of the principal bolt **r S** (**Figure 24**); but there is also a second set of notches EE in the *gachette* **GO** (**Figure 21**), and a pin attached to one of the plates of the lock fits into one of these notches, thereby preventing the bolt from being moved until the *gachette is* lowered by the revolution of the key; so that in attempting to pick this lock, not only must the spring **H** be raised so as to release the stud from the notches of the great bolt, but the *gachette* must be lowered to disengage the fixed pin from the notches.

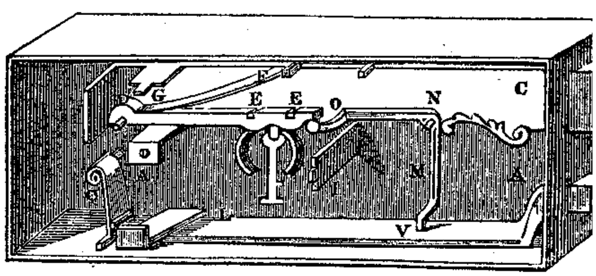


Figure 21 Details of an old French lock.

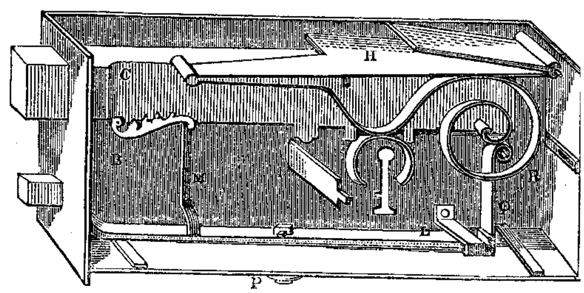

Figure 22 Another view of the same.

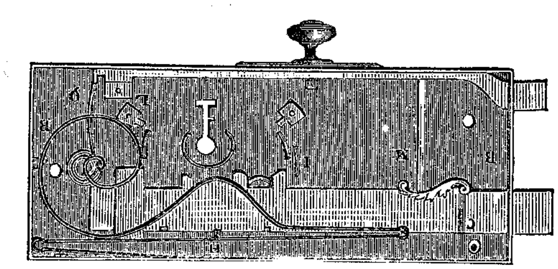

Figure 23 Another view of the same.

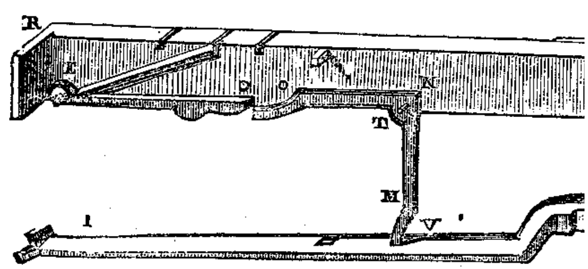

Figure 24 The two bolts detached.

There is yet a third source of security. Attached to the large bolt are short projecting pins **F** (**Figure 21**), against which an arm or detent, **GF**, of the *gachette* projects, thus preventing the bolt from being shot back by any pressure applied to its

extremity **s**.

There are a few details relating to this remarkable lock that may as well be introduced here in order to complete the description. The principal bolt can be shot twice, or be *double-locked;* hence it is furnished with three barbs for the key to act against, and with three notches for the spring-stud. The lower bolt **I E**: can be shot by the horizontal pressure of the button **P** (**figures 22, 23**), which is situated on the inner side of the door to which this lock is attached, so that a person inside the room can secure the door against any one on the outside who is not furnished with the proper key, for it must be remarked that the small bolt as well as the large one is acted upon by the key.

Suppose that the small bolt to be shot or locked is kept so by the pressure of the coiled spring **Q** (**figures 21, 22**). But this small bolt is connected with the large one by means of the bent lever **ONM** (**figures 21, 24**), which turns on a pin **N** attached to the main bolt. Now, when both bolts are either fully shot or upshot, the arm **ON** lies flat against and parallel with the main bolt; but when the large bolt is unshot and the small one not moved, the arms **ON**, **NM**, fall into an inclined position, and the arm **ON** passing a little below the main bolt comes within the range of the web of the key, which in its revolution causes the bent lever to move upon its center **N**, thereby restoring **ON** to its horizontal position, and at the same time causing the arm **N M** to move from right to left, or in the direction for unshooting the small bolt. The end of this arm thus catches into a mortise **v** (**figures 21, 24**) in the small bolt, and immediately unlocks it.

Let us return to the subject of tumbler-locks. About the year 1778, Mr. Barron introduced that species of double-action (as it may perhaps be termed) which so greatly increases the security of the simple tumbler, **Figure 17**. In the tumbler-locks previously made, if the tumbler was raised sufficiently high, the lock could be opened: there was no such possibility as raising it *too* high; but Mr. Barron, by his invention, patented 31st October, 1778, rendered it absolutely necessary that a limit should be put to the height to which the tumbler should be raised, by rendering the bolt equally immovable whether the tumbler were too much or too little raised.

Another important improvement was the introduction of two tumblers instead of one. The bolt has in its middle a slot or gating notched on both edges, the notches being fitted for the reception of studs fixed to the tumblers. If the studs or stumps

of the tumblers are at rest in the lower notches, they require to be elevated to the general level of the gating before the bolt can he moved. Whereas, if the tumblers were raised ever so little too high, the studs will enter the upper notches, and prevent the shooting of the bolt.

The lower edge, or belly, of each tumbler is acted upon by the steps of the key during its circular movement; the leverage of the key being so exactly adjusted as to raise the tumbler to the desired height and no further. The tumblers are made unequally wide, so that steps or inequalities in the bit of the key are requisite to lift them both to the proper height. There are thus two improvements introduced: there are two **tumblers** instead of one, and each tumbler has a double instead of a single action.

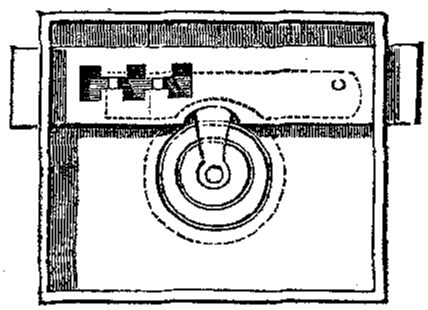

Figure 25 Action of Barron's tumbler-look.

This ingenious and very useful lock is represented, so far as regards its governing principle, in **Figure 25**. The bolt is here seen to have a peculiar slot or hole cut in it, consisting of a narrow horizontal passage or gating, with three notches above it and three below it. These double notches might be available even for one tumbler only; but Barron used two or more for the sake of additional security. In **Figure 25**, there are two tumblers shown, expressed by dotted lines. Both are hinged to one pivot, both are raised by the same action of the key, but the stump on the one tumbler does not coincide in position with that on the other.

It will be seen that if the studs of the tumblers were to rest in the lower notches, they would be required to be elevated to the level of the gating before the bolt could be moved; while, on the other hand, if lifted too high, the stumps would be caught in the upper notches, and would equally prevent the passage of the bolt. The tumblers are unequally wide; and the bit of the key is stepped or notched in a corresponding way, that there may be one step fitted to act upon each tumbler.

Mr. Barron also adopted the reverse arrangement of having the stump on the bolt, and the openings in the tumblers; so that the principle of his patent may be concisely expressed as being "an arrangement to allow a stump on the tumbler to pass through an opening in the bolt, or a stump on the bolt to pass through an opening in the tumbler."

A very elaborate tumbler-lock, patented 23thd February, 1790, by Mr. Rowntree, contrasts remarkably with the simplicity of Barron's lock. Mr. Rowntree's lock consisted of tumblers combined with revolving discs or wheels. Its mechanism may be understood from the following description and engravings. The same letters refer to the same parts in the several figures.
